The complement inhibitor that has achieved the widest attention as a therapeutic agent to stop complement activation is a monoclonal antibody that targets C5 and prevents its cleavage to C5a (potent anaphylatoxin) and C5b (initiator of the membrane attack complex) (see Fig. 37-5). The generation of the C3b and C4b still occurs, allowing opsonization of pathogens and formation of immune complexes. Because activation of early complement components is also important for the maintenance of tolerance to self-antigens, inhibition of C5 activation is less worrisome than inhibition of C3 activation. The one consequence of C5 deficiency in humans is an increased risk of *Neisseria* infections (Chapters 274 and 275) that can largely be mitigated through vaccination. The anti-C5 monoclonal antibody eculizumab has been approved for use in patients with paroxysmal nocturnal hemoglobinuria, atypical hemolytic uremic syndrome, neuromyelitis optica, and myasthenia gravis. Additional inhibitors targeting the C3 convertase, specific complement receptors, and early pathway-specific activation mechanisms are all under active development and clinical trials.

The complement system is undergoing a renaissance. There are several reasons but probably the foremost is the discovery of mutations in complement regulators leading to atypical hemolytic uremic syndrome and age-related macular degeneration. Second is the therapeutic success of a monoclonal antibody to C5 in the treatment of atypical hemolytic uremic syndrome and paroxysmal nocturnal hemoglobinuria. Third is the introduction of purified C1-INH, kallikrein inhibitors, and a bradykinin receptor antagonist to prevent and treat swelling attacks in hereditary angioedema. Last, intriguing recent data implicate the complement system in the pathophysiology of multiple disorders, including age-related macular degeneration, ischemia/reperfusion injury, organ regeneration, brain development (pruning of undesirable synapses), intracellular metabolomics and polarization processes, obesity, asthma, T-cell activation phenomena associated with allergic and rheumatic diseases,[15,16] and more.

38 TRANSPLANTATION IMMUNOLOGY

MEGAN SYKES

DEFINITION

Clinical transplantation encompasses transplantation of organs and islets of Langerhans containing insulin-producing β cells, in which it is necessary to overcome the host-versus-graft (HVG) immune response to avoid rejection, as well as hematopoietic cell transplantation (Chapter 163), in which it is necessary to contend with not only the HVG but also the graft-versus-host (GVH) immune response. Because preparations of bone marrow or mobilized peripheral blood stem cells contain mature T cells, their administration to conditioned and consequently immunoincompetent recipients is associated with the risk for GVH disease (GVHD). Transplanted organs and tissues include corneas, kidneys, livers, hearts, lungs, small intestines, pancreases, hands, and faces. Uterine, penile, and laryngeal transplantation are composite tissue transplants that have only recently become possible, and the numbers performed are consequently quite low.

Transplants originating from a member of the same species are referred to as *allotransplants*. However, transplants from other species, termed *xenografts*, provide a promising solution to the severely inadequate supply of allogeneic organs and tissues, and may be used in the future. Transplants of tissues or cells originating from the recipient, either by processing of cells from the recipient's own organ (e.g., islets of Langerhans following pancreatectomy for chronic pancreatitis) or cell populations (e.g., $CD34^+$ hematopoietic progenitor and stem cells collected from leukapheresis products following mobilization from the bone marrow before high-dose radiation or chemotherapy to treat cancer) are referred to as *autologous*. In the future, these transplants may include stem cell–derived autologous cells used for therapeutic purposes.

ANTIGENS IN TRANSPLANTATION

The major antigens recognized during graft rejection and the cell types targeting them are summarized in Table 38-1.

MAJOR HISTOCOMPATIBILITY ANTIGENS

The major histocompatibility complex (MHC; human leukocyte antigens [HLAs] in the human) controls adaptive and some innate immune responses and is of central importance in many immune-mediated diseases. The MHC also presents the strongest immunologic obstacle to all types of allografts. The HLA molecules include two major isoforms, termed class I and class II, and are all encoded in the MHC complex of chromosome 6. Although all HLA molecules have a similar general structure, class I and class II molecules show different expression patterns, with class I MHC expressed on most cells of the body, whereas class II antigens are expressed mainly on antigen-presenting cell populations, such as dendritic cells, macrophages, and B cells, as well as thymic epithelial cells involved in T-cell selection. Class II MHC can also be expressed on human vascular endothelial cells and activated T cells.

The function of both classes of MHC molecules is to present peptide antigens to T-cell receptors, allowing adaptive immune responses to occur (Chapter 35). Class I molecules typically present eight- to nine-amino acid peptides derived from cytosolic proteins (e.g., viral proteins) that are transported into the endoplasmic reticulum, where they are processed and loaded onto class I molecules. CD8 molecules interact with the α_3 domain of the class I heavy chain, thereby strengthening the interaction of $CD8^+$ T cells that recognize class I–peptide complexes. Peptides presented by class II MHC molecules, on the other hand, are mostly 10- to 20-mers derived from exogenous proteins (e.g., phagocytosed bacteria) that are processed through the endosomal processing pathway, and these are recognized by receptors of T cells whose CD4 molecules strengthen the overall T cell–antigen-presenting cell interaction. The class I presentation pathway is of particular importance in allowing destruction of virally infected cells, consistent with the expression of class I MHC on almost all cell types in the body. An exception occurs when class I molecules present peptides from exogenous antigens, thereby resulting in cross-presentation and cross-priming of T cells. Class II MHC presentation of exogenous antigens takes place primarily on professional antigen-presenting cells and B cells, consistent with the role of $CD4^+$ T cells in initiating immune responses by activating antigen-presenting cells, providing direct and indirect

Other concerns about complement inhibition include whether it is short or long term and whether it is systemic or local. Long-term inhibition of complement, particularly at one of the early steps, is likely to predispose to infection and possibly autoimmunity. Short-term (hours to days) inhibition at any step is unlikely to cause problems. Given that inflammation is usually a local phenomenon, several mechanisms are being tested to target complement inhibitors to these sites. In this way, higher levels of inhibition can be achieved when needed and with lower doses of inhibitor.

NATURAL COMPLEMENT INHIBITORS

Naturally occurring compounds that control complement activation include products or extracts of plants, fungi, insects, bacteria, viruses, and venoms. The mechanism of complement inhibition by some of these natural products is known and is of clinical and experimental importance. In particular, to protect themselves from the host's complement system, poxviruses, herpesviruses, and flaviviruses produce either mimics of the human regulators that they at one time hijacked from their hosts or proteins that bind the hosts' regulators such as the plasma protein factor H. Bacteria also express a wide variety of inhibitors of the human complement system. *Staphylococcus aureus,* for example, synthesizes up to 10 distinct proteins that inhibit at almost every key step of the complement cascade. Cobra venom factor (CVF) is a modified form of cobra C3b secreted by venom glands in the oral cavity. It is a 144,000-dalton glycoprotein that forms an alternative pathway convertase in association with host factor B. Upon injection, CVF leads to massive activation of the alternative pathway, resulting in shock and pulmonary microvascular injury in experimental animals. It is resistant to the host's inhibitors because the site for that interaction is altered on CVF. Perhaps the most widely used natural inhibitor of complement activation is heparin. It decreases activation of the classical pathway and alternative pathway. In clinical practice, the anticomplementary effect of heparin has been used to prevent complement activation during cardiopulmonary bypass. Measurement of complement activation products such as C3a or soluble C5b-9 after bypass showed decreases of 35 to 70% for adult and pediatric patients when heparin-coated extracorporeal circuits were used. Although numerous studies have looked at the decrease in complement activation by heparin-coated bypass circuits, there have been few attempts to correlate this with clinical outcome.

ANTI-C5

The complement inhibitor that has achieved the widest attention as a therapeutic agent to stop complement activation is a monoclonal antibody that targets C5 and prevents its cleavage to C5a (potent anaphylatoxin) and C5b (initiator of the membrane attack complex) (see Fig. 37-5). The generation of the C3b and C4b still occurs, allowing opsonization of pathogens and formation of immune complexes. Because activation of early complement components is also important for the maintenance of tolerance to self-antigens, inhibition of C5 activation is less worrisome than inhibition of C3 activation. The one consequence of C5 deficiency in humans is an increased risk of *Neisseria* infections (Chapters 274 and 275) that can largely be mitigated through vaccination. The anti-C5 monoclonal antibody eculizumab has been approved for use in patients with paroxysmal nocturnal hemoglobinuria, atypical hemolytic uremic syndrome, neuromyelitis optica, and myasthenia gravis. Additional inhibitors targeting the C3 convertase, specific complement receptors, and early pathway-specific activation mechanisms are all under active development and clinical trials.

The complement system is undergoing a renaissance. There are several reasons but probably the foremost is the discovery of mutations in complement regulators leading to atypical hemolytic uremic syndrome and age-related macular degeneration. Second is the therapeutic success of a monoclonal antibody to C5 in the treatment of atypical hemolytic uremic syndrome and paroxysmal nocturnal hemoglobinuria. Third is the introduction of purified C1-INH, kallikrein inhibitors, and a bradykinin receptor antagonist to prevent and treat swelling attacks in hereditary angioedema. ABSTRACT

Clinical transplantation encompasses allogeneic organs such as kidneys, livers, intestines, hearts, and lungs; composite tissues such as limbs; tissues such as islets of Langerhans; and cells such as bone marrow or mobilized peripheral blood hematopoietic cells. Allograft rejection due to host-versus-graft immune responses is driven largely by T cells and may also involve humoral responses. When hematopoietic cells are transplanted, rejection in the opposite direction may cause graft-versus-host disease. The most potent allograft responses in both directions are mediated by recognition of allogeneic human leukocyte antigen (HLA) molecules, which are highly polymorphic. When HLA is identical between the donor and recipient, responses to multiple minor histocompatibility antigens still pose significant barriers in both directions. New approaches to preventing graft-versus-host disease have recently permitted extension of hematopoietic cell transplantation to include alternative, HLA-mismatched donors. The mainstay of successful organ and tissue transplantation has been chronic nonspecific immunosuppressive therapy. Despite its overall success in advancing transplantation, this approach is associated with significant toxicity and has made little progress in preventing chronic rejection. Induction of allograft tolerance, which would obviate the need for lifelong immunosuppression while preventing both early and late rejection, is a major goal in the transplantation field. Several advances have recently been made toward this goal, and small trials of combined hematopoietic cell and kidney transplantation have successfully induced allograft tolerance. The inadequate supply of human organs for transplantation presents a major hurdle, resulting in exploration of xenotransplantation as a promising alternative for the future.

TABLE 38-1 LYMPHOCYTES INVOLVED IN GRAFT REJECTION

CELL TYPE	ANTIGENS RECOGNIZED	FUNCTION	RELEVANCE
$CD4^+$ T cells	Allogeneic class II MHC (+ peptide) Self class II MHC + donor peptide	Antigen-presenting cell activation Help (cytokines and costimulation) Proinflammatory cytokine production Cytotoxicity Regulatory function	Organ allografts Cellular allografts Xenografts GVHD
$CD8^+$ T cells	Allogeneic class I MHC (+ peptide) Self class I MHC + donor peptide	Cytotoxicity Cytokine production Regulatory function	Organ allografts Cellular allografts Xenografts GVHD
NK cells	Class I MHC (activates or inhibits NK cell function) Other activating ligands	Cytotoxicity Cytokine production	Organ allografts Cellular allografts Xenografts
B cells	Class I and class II MHC Blood group antigens Xenogeneic carbohydrates	Antibody-mediated rejection (hyperacute, acute humoral, and chronic rejection)	Organ and hematopoietic cell allografts Cellular allografts Xenografts GVHD

CTL = cytotoxic T lymphocyte; GVHD = graft-versus-host disease; MHC = major histocompatibility complex; NK = natural killer.

(through activated antigen-presenting cells that also present peptides on class I molecules) "help" for $CD8^+$ cytotoxic T lymphocytes, and providing help for antibody-producing B cells. B cells are able to focus the antigens recognized by their specific surface immunoglobulin receptors by binding and internalizing these antigens, which enter the endosomal antigen-processing pathway and become presented by class II molecules on that B cell. This ability of B cells preferentially to present peptides derived from their cognate antigens to CD4 T cells recognizing those alloantigens is very important in driving alloantibody production.

A number of MHC molecules have been crystallized, both alone and with T-cell receptors that recognize them. The structure of class I and II MHC molecules is similar overall and includes both the peptide-binding cleft formed by a β-pleated sheet and two α-helices forming the sides of the cleft (E-Fig. 38-1). However, class I and II MHC molecules also have significant structural differences, as summarized in E-Table 38-1. T-cell receptors interact physically with both the α-helices of the MHC molecules and side chains of the peptide that is bound in the groove, thereby representing a trimolecular MHC-peptide–T-cell receptor interaction (see E-Fig. 38-1). The most variable ("hypervariable") portion of the T-cell receptor, which is produced by V-D (for TCRβ)-J somatic rearrangements and N insertions in the T-cell receptor α and β chains, known as complementarity-determining region 3 (CDR3), recognizes specific MHC-peptide complexes.

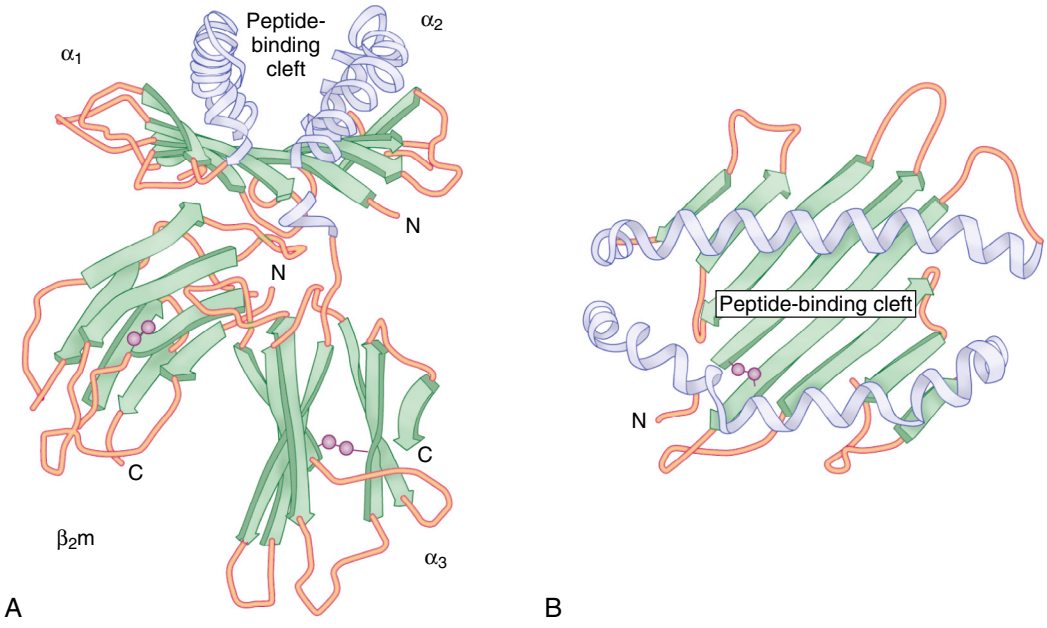
The HLA molecules are all encoded within a 3.6-million base-pair region that encodes more than 200 genes, including complement and tumor necrosis factor (TNF) genes and many others in addition to MHC that have immunologic functions. The organization of the HLA region is illustrated in E-Figure 38-2. The class II region contains two α- and β-chain genes, only one of which is functional, for each of HLA-DQ and DP. However, the DR locus contains different numbers of β-chains for different HLA alleles. Some of these DR β-chains are pseudogenes, but various HLA-DR alleles contain either one or two functional β-chain genes.

One of the striking features of HLA molecules (and the MHC of most mammalian species) is their extensive polymorphism.[1] The class I and class II regions contain thousands of defined HLA alleles. Because the primary function of antigen presentation to T cells is to permit responsiveness to and clearance of pathogenic microorganisms, this polymorphism may have evolved to maintain the diversity of immune responsiveness to various pathogens within a population, thereby avoiding annihilation of that population by a single microorganism that might not be presented well by a particular MHC. According to the most recently accepted nomenclature, HLA alleles are identified by the locus (e.g., HLA-A), followed by an asterisk, and then a unique number with up to four sets of digits separated by colons.[2] The first set describes the allele group (e.g., HLA-A*02), which usually corresponds to a serologically defined antigen, and the second set indicates the specific allele (e.g., HLA-A*02:101). The third and fourth sets of digits are of less practical importance because they identify silent nucleotide substitutions in different alleles and variations in the nontranslated regions of the gene, respectively.

Within certain populations, however, the level of diversity within allele groups may be quite limited because of the common genetic origin of the allele. For example, for the originally serologically defined HLA-DR3 allele group, there is little diversity among Northern Europeans, such that most carry the DRB1*0301 allele. Thus, for this population, it is reasonable to refer to the serologic HLA-DR3 type as defining this allele. Certain alleles predominate within racial groups. For example, as few as five DRB1 alleles predominate among Northern Europeans, with each allele represented in 10 to 30% of this population (E-Table 38-2).

Most organ transplantations are performed across HLA disparities, and the strong immunosuppressive regimens used in transplant recipients are designed to prevent rejection by this exceptionally strong immune response. In contrast to T-cell responses to peptide antigens derived from foreign proteins, which are recognized by a very small fraction of naïve T cells (in the range of 1 in 10^5), a very high proportion, estimated at 1 to 10% of the T-cell repertoire, recognizes MHC alloantigens. The application of high-throughput sequencing of the hypervariable regions of T-cell receptors of those T cells that proliferate to allogeneic MHC has directly demonstrated the large number of T-cell clones contributing to this response.[3] The strong immunogenicity of allogeneic MHC molecules relates to the manner in which T cells are selected in the thymus; developing thymocytes do not survive unless they can weakly recognize a self MHC/peptide complex on a thymic stromal cell. This process is termed *positive selection*. Thymocytes whose receptors have high affinity for self/MHC complexes are deleted, however, so strongly autoreactive T cells rarely make it into the peripheral T-cell pool. Allogeneic antigens are not part of this *negative selection* process. The net result of these two selection steps and the inherent cross-reactivity of T-cell receptors is that the T-cell "repertoire" recognizes allogeneic MHC molecules, providing a barrier to organ and hematopoietic cell transplantation. In the case of organ transplantation, in which long-term pharmacotherapy with powerful immunosuppressive drugs is used in an effort to prevent graft rejection, this can translate into improved results with HLA-matched organs. Despite the disadvantage of prolonged cold ischemia associated with transportation of a deceased donor graft, a pediatric kidney transplant study has shown superior outcomes with well-matched deceased donor kidneys compared with poorly matched living donor transplants.[4] Because of the high rates of late graft loss associated with de novo anti-HLA antibody formation, efforts have aimed to reduce this outcome by identifying HLA mismatches that are less likely to induce these alloantibodies.

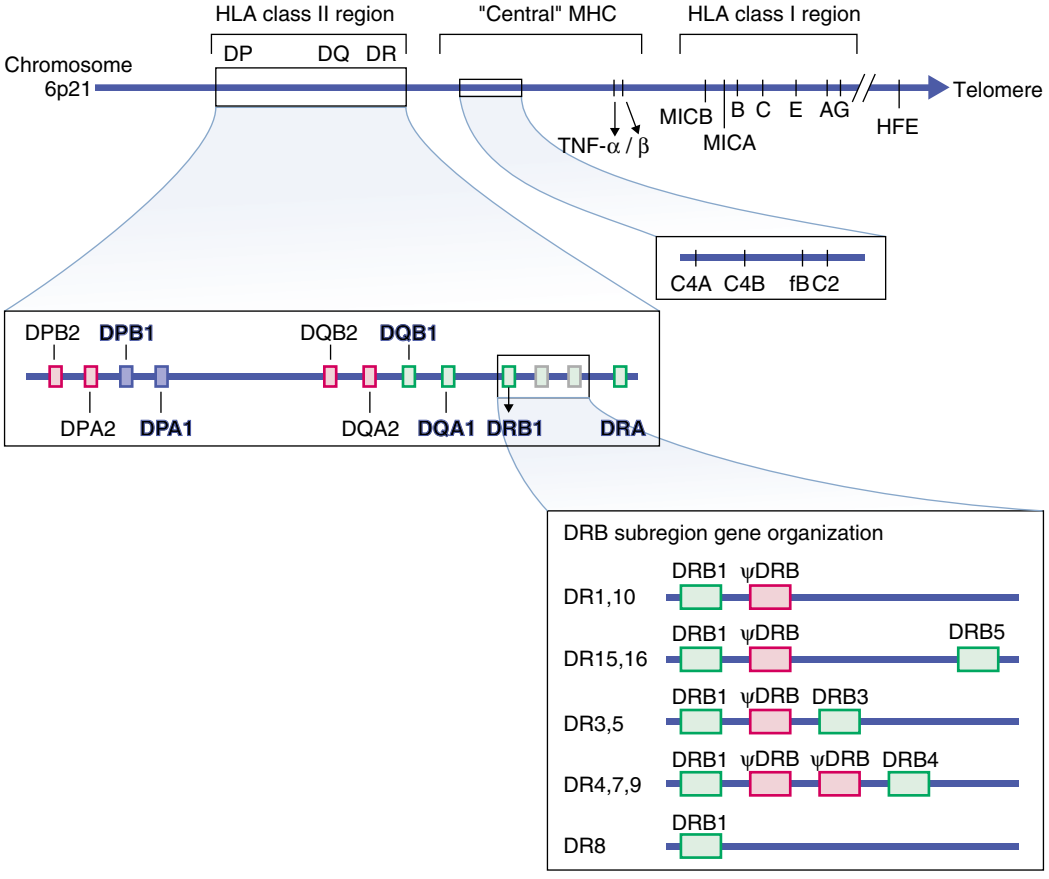
For hematopoietic cell transplantation (Chapter 163), the risks for GVHD and marrow graft failure are so greatly amplified in the presence of extensive HLA mismatches that such transplantations have been largely avoided in the past. Disparities in the highly polymorphic class I and class II molecules predispose to GVHD. The risk of GVHD is increased by HLA-DPB1 mismatching, despite its lower polymorphism, especially when the regulatory region variant rs9277534 is a high-expression allele in recipients but low-expression in donors. If a sufficiently matched, related donor is unavailable, a search has typically been conducted through large registries containing millions of volunteer unrelated donors. Because of its extensive polymorphism, truly MHC-identical, unrelated donors can be difficult to find in the human population at large. For individuals with common HLA genotypes, the likelihood of finding a matched unrelated donor is markedly greater than that for individuals with



E-FIGURE 38-1. Two views of an HLA class I molecule. A, Ribbon diagram showing the x-ray crystallographic structure of an HLA class I molecule (side view). The β-strand structures are indicated by *thick green arrows* (oriented in an amino to carboxy direction), whereas connecting loops are indicated as *thin lines*. The α-helices are shown flanking a peptide-binding cleft at the top (membrane distal portion) of the molecule. The base (membrane proximal portion) of the molecule is formed by the noncovalent association between the α_3 domain of the class I α-chain and β_2-microglobulin (β_2m). **B,** View from the top of the molecule emphasizing that the base of the peptide-binding cleft consists of β-pleated sheets flanked by α-helical structures. C = C terminal; N = N terminal. (Adapted from Bjorkman PJ, Saper MA, Samraoi B, et al. Structure of the class I histocompatibility antigen HLA-A2. *Nature*. 1987;329:506-512.)

E-TABLE 38-1 COMPARISON OF STRUCTURAL AND FUNCTIONAL FEATURES OF HLA CLASS I AND CLASS II ISOTYPES

FEATURE	HLA CLASS I	HLA CLASS II
Chain structure of heterodimer	45-kD α-chain 12-kD β_2-microglobulin	34-kD α-chain 28-kD β-chain
Tissue distribution	All nucleated cells	Antigen-presenting cells (monocytes, B cells, dendritic cells, Langerhans cells), thymic epithelium, and some T cells; inducible on other cell types by interferon-γ
Size of bound peptides	8-9 amino acids	10-20 amino acids
Source peptides	Cytosolic	Endosomal
Functions	Presentation of antigenic peptides to $CD8^+$ T cells; ligands for natural killer cell receptors	Presentation of antigenic peptides to $CD4^+$ T cells



E-FIGURE 38-2. Map of the human major histocompatibility complex (MHC) spanning approximately 3.5 million base pairs on the short arm of chromosome 6. The HLA class I and class II molecules are encoded in distinct regions of the MHC. The HLA class II region contains three subregions: DR, DQ, and DP. Each of these subregions contains a variable number of α- and β-chain genes. HLA class II loci with known functional protein products are labeled in bold. In the case of DR, different numbers of DRB genes are present in different haplotypes, some of which are nonfunctional pseudogenes (ψ). A summary of the most common of these is shown in the *box*. The DQ and DP subregions each contain one pair of functional α- and β-chain genes. The HLA class I region contains the three "classic" class I genes—HLA-A, HLA-B, and HLA-C—as well as other related "nonclassic" class I molecules such as MICA, MICB, HLA-E, and HLA-G. The gene for familial hemochromatosis (HFE) is found just telomeric to the HLA class I region, about 3 million base pairs distant from HLA-A. The "central" MHC also contains a number of genes related to immune function, including the complement components (C4A, C4B, C2, and factor B), as well as tumor necrosis factor (TNF)-α and -β. Not shown in the figure are more than 100 additional genes, many of which are located in the central MHC. (A complete listing of MHC-encoded genes can be found in Horton R, Wilming L, Rand V, et al. Gene map of the extended human MHC. *Nat Rev Genet*. 2004;5:889-899.)

E-TABLE 38-2 SUMMARY OF MAJOR ALLELIC GROUPS AT THE DRB1 LOCUS AND THEIR RELATIONSHIP TO COMMON DRB1 ALLELES DEFINED AT THE SEQUENCE LEVEL

ALLELIC GROUPS (SEROLOGIC TYPING)		EXAMPLES OF COMMON ALLELES (NORTHERN EUROPEAN WHITE INDIVIDUALS) DEFINED BY SEQUENCE*
MAJOR GROUPS	**SEROLOGIC "SPLITS"**	
DR1		DRB1* **0101**, 0102, 0103
DR2	DR15 DR16	DRB1* **1501**, 1502 DRB1*1601
DR3		DRB1* **0301**
DR4		DRB1* **0401**, 0402, 0403, 0404, 0405, 0406, 0407, 0408
DR5	DR11 DR12	DRB1*1101, 1102, 1103, 1104 DRB1*1201
DR6	DR13 DR14	DRB1*1301, 1302, 1303 DRB1*1401
DR7		DRB1* **0701**
DR8		DRB1*0801, 0802, 0803, 0804, 0806
DR9		DRB1*0901
DR10		DRB1*1001

*Alleles in bold are found in at least 10% of individuals in the population.

From Williams F, Meenagh A, Single R, et al. High resolution HLA-DRB1 identification of a Caucasian population. *Hum Immunol*. 2004;65:66-77.

rare genotypes. This situation relates in part to the phenomenon of *linkage disequilibrium*, wherein alleles at nearby loci are found together on the same chromosomal segment, or *haplotype*, more frequently than would be predicted by chance. The pattern of linkage disequilibrium is different in different racial groups, so the chance of finding a truly genotypically identical haplotype is greatest within the same population.

Advances in the ability to perform transplants from alternative donors have increased the availability of hematopoietic cell transplantation in individuals who lack an HLA-identical related donor (Chapter 163). Advances in avoiding GVHD in haploidentical related donor hematopoietic cell transplantation have increased the safety of HLA-mismatched hematopoietic cell transplantation, thereby yielding outcomes that may be superior to those using matched unrelated donors in some cases and comparable to results using matched sibling donors.

MINOR HISTOCOMPATIBILITY ANTIGENS

"Minor" histocompatibility antigens are peptides derived from polymorphic proteins presented by an MHC molecule. Even genotypically HLA-identical siblings have many different minor histocompatibility antigens that are sufficient to induce graft rejection if immunosuppressive pharmacotherapy is not used. Additionally, significant GVHD frequently (about 30 to 50% of the time) complicates hematopoietic cell transplantation between HLA-identical siblings, even with the use of pharmacologic immunoprophylaxis. Minor histocompatibility antigens, which can result from genetic polymorphisms in protein-coding regions or from homozygous loss-of-function variants in hematopoietic cell transplant donors or organ transplant recipients, render recipient and donor organs more susceptible to GVHD and rejection, respectively. An example of the latter is the *LIMS1* locus, which encodes a cell surface protein for which a homozygous loss-of-function variant is associated with anti-LIMS1 IgG2 and IgG3 antibodies and an increased risk of kidney allograft rejection. Another example is Y chromosome-encoded genes, which result in significantly increased graft rejection rates and GVHD in male-to-female and female-to-male organ and hematopoietic cell transplants, respectively.

OTHER ANTIGENS

The major blood group (ABO) antigens can be the targets of a dramatic "hyperacute" rejection process that occurs when mismatched vascularized grafts are transplanted. Recognition of blood group antigens on the endothelial surface of the graft vessels by recipient "natural" antibodies (antibodies that are present without known sensitization to the antigens) activates the complement and coagulation cascades, resulting in rapid graft thrombosis and ischemia. A similar outcome can occur after transplantation to an individual with preformed antidonor HLA antibodies resulting from presensitization by prior transplantations, transfusions, or pregnancies. Antibodies against other polymorphic antigens, such as MHC class I–related chain A (MICA), have been associated with graft rejection. In the past, transplantation could not be successfully performed in the presence of a positive antidonor crossmatch. However, considerable success has been achieved in the transplantation of ABO-mismatched kidneys, livers, and hearts (the latter in the neonatal period only) and in transplantation of kidneys to highly presensitized patients. In the case of kidney and liver transplantation, initial removal of the antibody and sometimes depletion of B cells, as well as the infusion of intravenous immunoglobulin (IVIG), has led to these successes.[5] Additional agents under investigation include proteosome inhibitors, interleukin-6 blockers, complement inhibitors, and IgG-degrading enzymes.[6] ABO-mismatched neonatal heart transplantation has succeeded because the transplantations are performed before the recipient has developed high levels of anti–blood group antigen antibodies, and the B cells seem to be rendered tolerant to the donor blood group antigen by the grafting process. Recognition of blood group antigens can also be of significance in hematopoietic cell transplantation, in which ABO barriers are routinely crossed in both directions. This can cause hemolysis of recipient erythrocytes if the mismatch is in the GVH direction, but this complication can be avoided by washing the cellular product before infusion. Mismatches in the HVG direction can cause more persistent problems due to ongoing destruction of donor erythropoietic cells, resulting in pure red cell aplasia. More often, however, donor erythropoiesis is successfully established, and antidonor isohemagglutinins disappear from the circulation. With the increasing application of HLA-mismatched donor hematopoietic cell transplantation, the importance of HLA alloantibodies in causing graft failure has recently been recognized and may require similar desensitization procedures to those used in sensitized organ allograft recipients.[7]

A and B blood group antigens are the consequence of the presence or absence of specific glycosylation enzymes in different individuals. Likewise, an antigenic specificity of the utmost importance in xenotransplantation is a carbohydrate epitope, Galα1–3Galβ1–4GlcNAc (αGal), which is produced by a specific galactosyl transferase. Humans and Old World monkeys lack a functional αGal transferase and produce high levels of natural antibodies against the ubiquitous αGal epitope. Because animals of interest as xenograft sources (e.g., pigs) express αGal at high levels on their vascular endothelium, transplantation of vascularized organs from pigs results in hyperacute rejection. The development of αGal-knockout pigs, therefore, was an important milestone that advanced the field of xenotransplantation. The more recent recognition of non-Gal carbohydrate natural antibody targets on cells of αGal-knockout pigs has led to further genetic modifications of these potential source animals, a procedure that has been greatly facilitated by current gene editing techniques.

In another type of transplant reaction, recognition as foreign results not from the presence of an antigen, but paradoxically from the absence of a self MHC molecule. Natural killer (NK) cells express a series of surface inhibitory and activating receptors that, collectively, determine whether the NK cell does or does not kill a potential target cell. The ligands for the inhibitory receptors are MHC class I molecules, and the receptors recognize specific groups of alleles. An NK cell may kill an allogeneic target that lacks a self MHC inhibitory ligand. This phenomenon can result in rapid bone marrow rejection in animal models and may be of significance in HLA-mismatched hematopoietic cell transplantation. The possible role of NK cells in organ allograft rejection is controversial, but they are thought to be of importance in organ xenotransplantation. NK cells clearly play a strong role in the rejection of xenogeneic hematopoietic cells, an observation that is relevant in one approach to inducing tolerance (see later discussion).

MECHANISMS OF REJECTION AND GRAFT-VERSUS-HOST DISEASE

CELLULAR MEDIATORS

Many different cell types participate in rejection responses, and considerable redundancy exists. T cells are key players in most forms of rejection, with the exception of rejection induced by antibodies in the absence of T-cell help, such as hyperacute and acute vascular rejection induced by natural antibodies. Several studies have suggested a dominant role for memory T cells in causing rejection, but it is difficult to distinguish whether "memory" T cells detected after a transplant converted from naïve T cells before or after the transplant.

DIRECT, SEMIDIRECT, AND INDIRECT ALLORECOGNITION

T-cell responses are induced by antigen-presenting cells that present alloantigens. Alloantigen recognition may be categorized as *direct*, *semidirect*, and *indirect* (Fig. 38-1). Direct allorecognition denotes recognition of donor antigens on donor antigen-presenting cells provided by the graft. The extraordinarily high frequency of T cells with alloreactivity is caused by direct recognition of allogeneic MHC. However, T cells with these specificities may also detect their ligands on recipient antigen-presenting cells, as these may pick up intact donor MHC-peptide complexes transferred in exosomes. This "semidirect" pathway may be important in maintaining strong direct alloresponses long after donor antigen-presenting cells in a grafted organ have been replaced by those of the recipient. Indirect recognition is the recognition of donor antigens

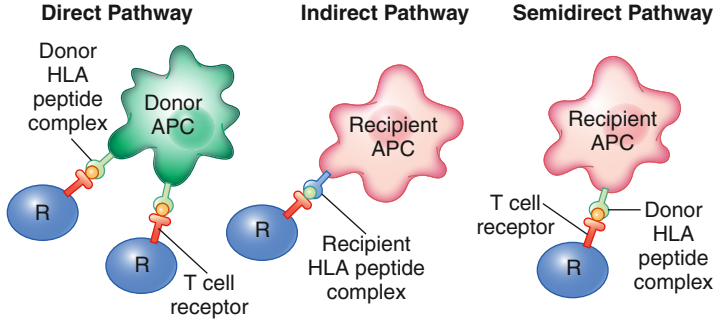


FIGURE 38-1. Direct and indirect allorecognition. Direct allorecognition involves the recognition by a T-cell receptor of major histocompatibility complex (MHC) molecules (with or without a peptide) on a donor antigen-presenting cell. Indirect allorecognition involves recognition by the T-cell receptor of a donor peptide presented on a recipient antigen-presenting cell that has picked up and processed donor antigens.

that are picked up, processed, and presented on recipient MHC molecules on recipient antigen-presenting cells. The indirect response is more similar to "normal" T-cell responses, in which professional antigen-presenting cells present peptide antigens to T cells that are present at relatively low frequency in the naïve repertoire. The indirect response, like the semidirect response, can be maintained by the constantly renewed pool of recipient antigen-presenting cells. The indirect response is of particular importance in inducing antibody responses.

EFFECTOR MECHANISMS OF REJECTION

T cells can promote graft rejection through several effector mechanisms. One is the antibody-dependent processes that have already been discussed. CD4 T cells provide cognate help to B cells when their T-cell receptors (TCRs) recognize complexes of self MHC with donor MHC–derived peptide antigens produced by B cells whose surface Ig receptors recognize and pick up the donor MHC antigen. Antidonor antibody can lead to the pathologic picture of acute humoral rejection and may also participate in a slower process of chronic rejection. Chronic rejection of kidney and heart allografts is characterized by unique vascular lesions with intimal thickening and loss of the vessel space. Chronic rejection of lung allografts is termed obliterative bronchiolitis. The mechanisms underlying these chronic rejection lesions are not well understood, and several different immune processes may in fact lead to similar lesions. Induced responses to autoantigens exposed by injured graft tissue have been implicated in several forms of chronic rejection.

Another major effector pathway leading to graft rejection involves cytotoxic T lymphocytes, which are predominantly $CD8^+$ but also include $CD4^+$ T cells. Several effector mechanisms lead to killing of target cells by cytotoxic T lymphocytes, including granzyme/perforin-mediated and Fas/Fas ligand (FasL) pathways and other members of the TNF/TNF-receptor families. Because $CD8^+$ cells recognize class I MHC molecules, which are widely expressed, it is not difficult to envision graft destruction by $CD8^+$ cytotoxic T lymphocytes. $CD8^+$ cytotoxic T lymphocytes may be activated through an antigen-presenting cell that is stimulated initially through contact with an alloreactive $CD4^+$ cell. This is one form of CD4 "help" for $CD8^+$ cells. In addition, $CD8^+$ cells may be dependent on cytokines such as interleukin-2 (IL-2) produced by $CD4^+$ cells for their expansion and cytotoxic differentiation. However, there are also many examples of $CD8^+$ cell–mediated rejection that is independent of "help" from $CD4^+$ cells. Class II MHC, which is recognized by $CD4^+$ T cells, is less widely expressed on graft tissues than is class I MHC, although it may be induced on endothelial cells and graft parenchymal cells in the presence of inflammatory cytokines such as interferon-γ (IFN-γ).

In addition to cytotoxic mechanisms resulting from direct allorecognition, $CD4^+$ and $CD8^+$ T cells with indirect specificity seem also to be capable of causing graft destruction under some circumstances. Cytokines such as IFN-γ and TNF-α, as well as innate cellular mediators, have been implicated in some instances, but in general, the pathways of indirect graft destruction are not well understood.

THE ROLE OF T-CELL TRAFFICKING

Rejection processes require trafficking of T cells into the graft, which occurs after the initial activation of naïve T cells in the lymphoid tissues. Naïve T cells can migrate into lymph nodes because of their expression of the CCR7 chemokine receptor and the adhesion molecule L-selectin. These T cells are activated by migratory graft antigen-presenting cells that also enter the lymph nodes. T-cell activation is associated with loss of CCR7 and L-selectin expression and acquisition of a new set of chemokine receptors and adhesion molecules that allow rolling and adhesion on the graft endothelium and entry into the graft parenchyma. Inflammation in the graft, such as that induced by ischemia-reperfusion injury and the transplantation procedure, as well as that induced by initially responding T cells, is associated with upregulation of chemokines and adhesion ligands that promote entry of lymphocytes into the graft. Nevertheless, well-healed-in grafts can be slowly rejected by adoptively transferred memory T cells, demonstrating that acute graft injury and inflammation are not essential for rejection in the presence of an established memory T-cell response. Rejection of hematopoietic cell grafts may involve many of the same mechanisms as those discussed for solid organs, although less detailed work has been done in this area.

MECHANISMS OF GRAFT-VERSUS-HOST DISEASE

Initiation of GVHD (Chapter 163) requires that donor T cells recognize host alloantigens. Donor T cells infiltrate a variety of recipient epithelial tissues, namely skin, the intestine, and liver. Animal models have demonstrated clear roles for both $CD4^+$ and $CD8^+$ cells in initiating GVHD, and each subset is able to do so independently of the other. The mechanisms of GVHD include activation of alloreactive donor T cells by recipient antigen-presenting cells within the recipient lymphoid tissues, leading to the differentiation of effector cells with direct cytotoxic activity and cytokine production in response to host antigens. A prominent role is played by TNF-α, whose production is induced in part by the translocation of bacteria across the intestinal wall, promoting innate immune system activation through toll-like receptors (Chapter 35). An intensely pro-inflammatory environment is produced by the combination of conditioning-induced tissue injury and disruption of mucosal barriers, bacterial activation of the innate immune system, and the GVH alloresponse. An important role is now appreciated for the inflamed microenvironment in target tissues in promoting the trafficking of GVH-reactive T cells into these tissues.

STRATEGIES TO PREVENT GRAFT-VERSUS-HOST DISEASE

In view of the critical role of donor T cells in inducing GVHD, an obvious strategy for preventing this complication is to remove mature T cells from the marrow graft. This approach has indeed been shown in both animal models and clinical studies to prevent GVHD effectively. However, there are several disadvantages to this approach. One is that adult humans, particularly those who have undergone prior chemotherapy and radiotherapy, have little remaining thymic tissue and therefore demonstrate sluggish T-cell recovery, leading to serious opportunistic infections. For example, the inclusion of antihuman T-lymphocyte immune globulin in a myeloablative conditioning regimen for patients with acute leukemia significantly lowers the rate of chronic GVHD but does not significantly improve survival.[A1]

T-cell depletion of hematopoietic cell grafts used to treat hematologic malignancies may be associated with an increased relapse rate due to loss of a graft-versus-tumor (GVT) effect, which is in large part mediated by GVH alloreactivity. Separation of GVHD from GVT effects is a major goal of research in hematopoietic cell transplantation, and some promising strategies are being explored (E-Table 38-3).[8] For example, Janus kinase inhibitors show promise for prevention of GVHD[9] and for the treatment of steroid-refractory GVHD after hematopoietic cell transplantation (Chapter 163).[A2,A3] Trials of low-dose IL-2 have shown efficacy in preventing chronic GVHD, apparently by expanding regulatory T cells. Infusion of expanded regulatory T cells has also entered clinical trials,[10] and infusion of mesenchymal stromal cells has shown benefit in treating refractory GVHD.[11] Preventing T-cell trafficking into epithelial target tissues of GVHD is a particularly promising approach because of the theoretical preservation of graft-versus-tumor effects in lymphohematopoietic tissues. Chemokine receptor blockade is a promising approach to achieving this goal.

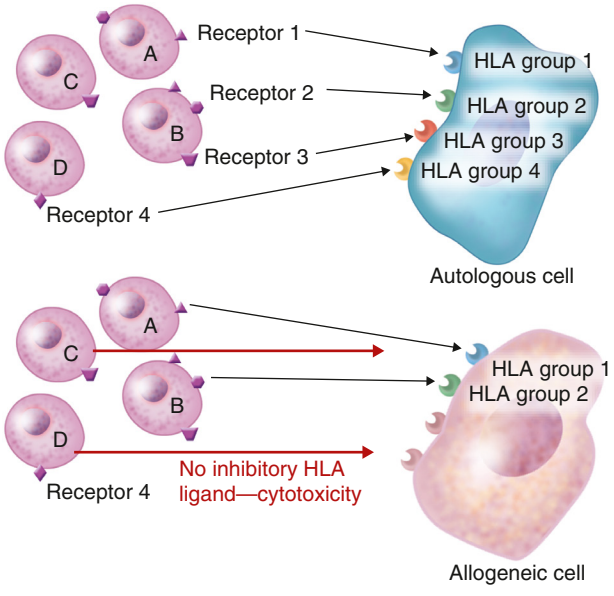
A third disadvantage of T-cell depletion is that it eliminates the engraftment-promoting effect conferred by alloreactive T cells, resulting in increased rates of allograft failure, especially in the setting of HLA-mismatched transplantation. NK-cell recognition in the GVH direction resulting from the absence in the recipient of a class I MHC ligand (E-Fig. 38-3) that can trigger a donor NK-cell inhibitory receptor (KIR) may promote donor hematopoietic cell engraftment and antitumor effects against acute myeloid leukemias in the setting of T-cell–depleted, HLA-mismatched hematopoietic cell transplantation. The role of donor-recipient KIR mismatch and of polymorphisms in KIR genotype and expression in antitumor effects, GVHD, and infectious immunity in hematopoietic cell transplantation is complex and may vary with different diseases and types of transplant conditioning, in addition to different types of donor-recipient mismatch.

Clinically, pharmacologic immunosuppressive prophylaxis is usually used in at least the first 6 months after hematopoietic cell transplantation to minimize the complication of GVHD. Posttransplant cyclophosphamide significantly reduces the risk of GVHD although it does not increase overall survival.[A4] Additionally, HLA-matched or closely matched donors are chosen whenever possible because GVHD increases in frequency and severity as increased HLA barriers are transgressed. These measures, nevertheless, are insufficient, and GVHD remains a major complication of hematopoietic cell transplantation. Therefore, many of the new strategies being explored in organ transplantation and other fields are also being examined for the prevention of GVHD in experimental models. It should be borne in mind, however, that tolerance of donor T cells to recipient alloantigens (see later discussion) might not be entirely beneficial in the hematopoietic cell transplantation setting for the treatment of malignant

E-TABLE 38-3 EXPERIMENTAL STRATEGIES TO PREVENT GRAFT-VERSUS-HOST DISEASE

STRATEGY	ADVANTAGES	LIMITATIONS
Donor T-cell T_H2 polarization (e.g., conditioning with ATG and TLI; in vitro stimulation with cytokine exposure)	May preserve GVL	May limit GVL; T_H2 can contribute to acute and chronic GVHD
Tolerance induction of donor T cells (e.g., costimulatory blockade; activation pathway inhibitors)	Some strategies may selectively tolerize GVH-reactive T cells (e.g., in vitro antigen exposure with costimulatory blockade)	Global immunosuppression may limit GVL and anti-infectious immunity; tolerance (i.e., GVH protection) may be incomplete
Regulatory cell infusion or induction (e.g., low-dose IL-2)	GVL and infectious immunity may be preserved Does not compromise engraftment	GVL might be compromised by reduced alloreactivity
Depletion of naïve donor T cells	May preserve GVL and memory responses to infection	Incomplete protection from GVHD
Donor T-cell depletion plus NK-cell infusion with class I mismatched transplantation	NK cells do not cause GVHD but may mediate antitumor effects; donor NK cells may eliminate host APCs that trigger GVHD	Antitumor effect against only certain types of malignancies; requires appropriate MHC disparity and expression of polymorphic NK-cell receptors; insufficient T-cell immunity to infection
Donor T-cell depletion followed by delayed donor lymphocyte infusion (DLI)	Preserves high level of GVL due to GVH reactivity. GVHD does not occur if host inflammation from conditioning has subsided and initial HCT was devoid of donor T cells	Antitumor effect delayed until time of DLI; most applicable for indolent lymphohematopoietic tumors. GVHD more difficult to control in humans than animal models, probably owing to occult or overt infection resulting from T-cell deficiency before DLI
Depletion of donor T cells recognizing host alloantigens by in vitro or in vivo activation/depletion (i.e., "allodepletion")	Preserves anti-infectious immunity and tumor antigen–specific responses while limiting GVHD	Loss of GVH reactivity will limit GVL and engraftment; highly efficient allodepletion methods not yet available. Residual T cells may cause GVHD
Donor T-cell depletion with infusion of expanded infection-specific T cells (e.g., CMV or EBV specific)	Reduces GVHD potential while protecting against significant infectious organisms	Lack of GVL effect; lack of broad anti-infectious immunity; expense and inefficiency of in vitro T-cell expansion; loss of survival/homing potential of cultured T cells
Donor T-cell depletion with infusion of expanded tumor antigen-specific T cells (expanded from natural repertoire or transduced with a T-cell receptor or chimeric antigen receptor)	GVL without GVHD	Lack of anti-infectious immunity; expense and inefficiency of in vitro expansion of tumor-specific T cells; loss of survival/homing potential of cultured T cells
Insertion of suicide gene (e.g., thymidine kinase) into donor T cells	Drug targeting inserted gene (e.g., ganciclovir) kills donor T cells to treat GVHD after GVL initiated	Expense and inefficiency of in vitro transduction of T cells; loss of function/survival/homing potential of cultured T cells; risk for GVHD if transduction incomplete; curtailment of GVL when donor T cells killed in vivo
Block T-cell trafficking to epithelial GVHD target tissues (e.g., blockade of adhesion molecules or chemokines, sphingosine 1 phosphate agonists)	Permits lymphohematopoietic GVH reactions to occur, with associated GVL effects. Preserves infectious immunity	Redundancy of trafficking pathways in inflammatory environment may limit efficacy; tumors outside of lymphohematopoietic system not targeted
Block injury/promote repair in epithelial target tissues (e.g., keratinocyte growth factor)	Permits lymphohematopoietic GVH reactions to occur, with associated GVL effects. Preserves infectious immunity	Efficacy may be limited

APC = antigen-presenting cell; ATG = antithymocyte globulin; CMV = cytomegalovirus; DLI = donor lymphocyte infusion; EBV = Epstein-Barr virus; GVHD = graft-versus-host disease; GVL = graft-versus-leukemia effects; HCT = hematopoietic cell transplantation; MHC = major histocompatibility complex; NK = natural killer; T_H2 = helper T lymphocytes type 2; TLI = total lymphoid irradiation.



E-FIGURE 38-3. Killing of allogeneic targets by natural killer (NK) cells due to "missing self." NK cells express clonally distributed inhibitory receptors (KIRs) with specificity for different groups of major histocompatibility complex (MHC) class I alleles, referred to in the figure as human leukocyte antigen (HLA) groups 1, 2, 3, and 4. Four different NK cells (A, B, C, and D) are shown, each with a different set of KIRs (referred to as receptors 1, 2, 3, and 4). Examples of HLA allele groups in the human are the HLA-Cw4, HLA-Cw3, and HLA-Bw4 groups; examples of KIRs are the ligands for these allele groups—namely, KIR2DL1, KIR2DL2/3, and KIR3DL1, respectively. Each functional NK cell has one or more inhibitory receptors that recognize a "self" (autologous) HLA molecule. Although some of the NK cells (e.g., cells A and B in the figure) will also find an HLA ligand to which their receptors bind on allogeneic cells, others (e.g., cells C and D) will not. The latter cells therefore will not receive inhibitory signals from the allogeneic cells and will kill them due to recognition by other (activating) receptors.

disease because loss of GVH alloreactivity is likely to come with loss of antitumor effects.

STRATEGIES TO PREVENT ALLOGRAFT REJECTION

NONSPECIFIC IMMUNOSUPPRESSION

Immunosuppressive drugs are the mainstay of clinical organ transplantation, and improvements in these drugs following the discovery of cyclosporine have extended organ transplantation to include hearts, lungs, pancreases, livers, and other organs and tissues in the past 40 years. The mechanisms of action of these agents, which typically include a calcineurin inhibitor, an anti-proliferative drug, and corticosteroids, are discussed in Chapter 28. However, it is noteworthy that, despite these improvements and their enormous impact on early graft survival, pharmacologic agents have been less effective in attenuating late graft loss. Because chronic immunologic rejection processes and side effects of the immunosuppressive drugs themselves are responsible for much of this late graft loss, improved immunosuppressive agents and induction of immune tolerance (see later discussion) are major research goals in transplantation.

COSTIMULATORY BLOCKADE

As understanding of immune responses has increased, recent years have seen the exploration of numerous biologic agents, including antibodies and small molecules targeting receptors of the immune system, as well as cell-based therapies,[12] in efforts to improve allograft survival. Because of the central role played by T cells in the immune response, considerable attention has been focused on blockers of T-cell costimulation. When a naïve T cell recognizes antigen through its unique TCR, additional "costimulatory" signals are required to allow full activation, expansion, and differentiation to occur. These signals are provided by antigen-presenting cells in the form of ligands (e.g., B7-1, B7-2) for costimulatory receptors (e.g., CD28) on the T cell. Cross-talk between the T cell and the antigen-presenting cell (e.g., due to CD40 activation by CD154 upregulation on the activated T cell) further amplifies the costimulatory activity of the antigen-presenting cell, allowing it to effectively activate other T cells as well. The CD154 (T cell)–CD40 (B cell) interaction also promotes Ig class switching and functioning of B cells as antigen-presenting cells. Blockade of these processes (e.g., by CTLA4Ig and anti-CD154 or CD40 monoclonal antibodies [mAbs]) has led to marked prolongation of allograft survival in stringent rodent and large-animal models. Robust, systemic tolerance to donor antigens has been achieved in rodents receiving bone marrow transplantation with costimulatory blockade and little or no additional conditioning. Some of these agents have joined the armamentarium of immunosuppressive agents in clinical trials in transplantation and autoimmune diseases. Although the optimal protocol for its use is still in development, CTLA4Ig has permitted sparing of nephrotoxic calcineurin inhibitors, with improved long-term patient and renal allograft survival.[13] Although anti-CD154 antibodies have been associated with thromboembolic complications, precluding further evaluation in transplantation trials, recently developed nonthrombogenic anti-CD154 and anti-CD40 antibodies have shown promise in preclinical studies and have entered clinical trials.[14] Numerous additional costimulatory and inhibitory pathways that affect T-cell responses have been described, and these all are potential targets for further manipulation of the alloresponse.

IMMUNE TOLERANCE

Immune tolerance denotes a state in which the immune system is specifically unreactive to the donor graft (or recipient in the case of GVH reactivity) while remaining normally responsive to other antigens.[15] Tolerance is distinct from the state produced by nonspecific immunosuppressive agents, which increase risks for infection and malignancy. Numerous approaches to tolerance induction have been described in rodent models, largely owing to the strong tolerogenicity of primarily vascularized heart, liver, and kidney grafts in these animals. Such grafts are less tolerogenic in humans, and few of these strategies have been effectively applied clinically to date. Since the test for tolerance is graft acceptance without continuous immunosuppressive therapy (i.e., without the standard of care), tolerance protocols being evaluated clinically should first demonstrate efficacy in stringent animal models, including highly immunogenic grafts such as MHC-mismatched skin in rodents and vascularized organ graft models in large animals.

The three major mechanisms of T-cell tolerance are deletion, anergy, and suppression (often referred to as "regulation"). *Deletion* denotes the destruction of T cells with receptors that recognize donor antigens; it can be achieved during T-cell development in the thymus, for example, by induction of mixed chimerism in T-cell–depleted hosts. Deletion can also be applied to mature T cells in the periphery, for example, by transplantation of a tolerogenic organ or marrow graft in combination with blockade of costimulatory molecules. *Anergy* denotes the inability of T cells to respond fully to antigens they recognize, and it can be induced by antigen presentation without costimulation. *Suppression* has attracted considerable interest since the discovery that constitutively $CD25^+$ T cells of the $CD4^+$ subset have suppressive activity that is dependent on expression of the transcription factor Forkhead Box Protein 3 (FoxP3). These and other types of suppressive T cells (e.g., NKT cells, regulatory $CD8^+$ cells and B cells, myeloid-derived suppressor cells, regulatory monocytes, and dendritic cells) have been implicated in rodent transplantation tolerance models and in prevention of autoimmunity. The use of expanded regulatory cells has recently entered clinical trials in both transplantation and autoimmune disease, including both antigen-specific and nonspecific ("polyclonal") regulatory cell therapy,[16] as well as chimeric antigen receptor (CAR) Tregs.[17] Other regulatory cell types, including tolerogenic monocytes and dendritic cells, have demonstrated safety in early clinical trials.[18] However, in the absence of large animal studies demonstrating the efficacy of these cellular therapies in achieving tolerance and without validated biomarkers for tolerance, rapid immunosuppression withdrawal to test tolerance induction is not the goal of these studies. There is also interest in strategies for activating or expanding regulatory T cells in vivo, thereby favoring the suppressive immune response over destructive alloimmunity.

The developments in animal models and understanding of immune mechanisms described here have provided impetus for efforts to achieve immune tolerance in clinical transplantation. Every transplantation center has anecdotal cases of patients who have removed themselves from chronic immunosuppression without experiencing graft rejection. However, for every such patient, there are dozens more who have experienced rejection on dose reduction or removal of immunosuppressive drugs. Trials of slow withdrawal of nonspecific immunosuppressive therapy have had very little success in renal allograft recipients and higher success rates in a very highly selected group of liver allograft recipients, especially children with long-term rejection-free graft survival.[A5,19] Application of this approach to a larger subset of patients will depend on future advances in the ability to identify biomarkers that are predictive of success. "Tolerance signatures" with sufficient predictive value to allow such withdrawal to be safely undertaken have not yet been identified.

One approach developed in animal models has been successfully applied to the induction of immune tolerance in a small group of patients receiving renal allografts. This approach, involving bone marrow transplantation after nonmyeloablative conditioning, which is less toxic than standard hematopoietic cell transplantation conditioning, was shown to be effective in the most stringent rodent and large-animal models before being evaluated clinically. Initial success using combined kidney and bone marrow transplantation in patients with renal failure due to multiple myeloma led to pilot studies in patients with renal failure without malignant disease, with encouraging results. This protocol involved induction of transient chimerism in combination with a kidney allograft from HLA-mismatched related donors and was free of the complication of GVHD. Mechanistic studies, including a high-throughput sequencing-based approach to identifying and tracking donor-reactive T-cell clones, implicated an early role for regulatory T cells followed by gradual clonal deletion in the long-term tolerance.[20] Another nonmyeloablative approach has succeeded in achieving more durable chimerism and tolerance, but only in the HLA-identical sibling transplant setting,[21] and a third approach has led to full donor chimerism across extensive HLA barriers, but with significant toxicity, including GVHD.[22] With further refinements of this approach and proof of efficacy in large animal models, it is hoped that transplantation of all organ types might ultimately be routinely performed without the need for chronic immunosuppressive therapy, with its attendant complications and limited ability to control chronic rejection. Because autoimmune diseases are major contributors to end-stage renal disease, β-cell loss in type 1 diabetes, and other types of organ failure, the potential for tolerance strategies to reverse autoimmunity while inducing allograft tolerance is also a source of hope. All these approaches must, however, be undertaken with the caution that successful regimens could also lead to immune tolerance to active infectious organisms.

39 APPROACH TO THE PATIENT WITH POSSIBLE CARDIOVASCULAR DISEASE

LEE GOLDMAN

Patients with cardiovascular disease may present with a wide range of symptoms and signs, each of which may be caused by noncardiovascular conditions. Conversely, patients with substantial cardiovascular disease may be asymptomatic. Because cardiovascular disease is a leading cause of death in the United States and other developed countries, it is crucial that patients be evaluated carefully to detect early cardiovascular disease, that symptoms or signs of cardiovascular disease be evaluated in detail, and that appropriate therapy be instituted.

In evaluating a patient with known or suspected heart disease, the physician must determine quickly whether a potentially life-threatening condition exists. In these situations, the evaluation must focus on the specific issue at hand and be accompanied by the rapid performance of appropriately directed additional tests. Examples of potentially life-threatening conditions include acute myocardial infarction (MI) (Chapter 58), unstable angina (Chapter 57), suspected aortic dissection (Chapter 63), pulmonary edema (Chapter 46), and pulmonary embolism (Chapter 68).

USING THE HISTORY TO DETECT CARDIOVASCULAR SYMPTOMS

Patients may complain spontaneously of a variety of cardiovascular symptoms (Table 39-1), but sometimes these symptoms are elicited only by obtaining a careful, complete medical history. In patients with known or suspected cardiovascular disease, questions about cardiovascular symptoms are key components of the history of present illness; in other patients, these issues are a fundamental part of the review of systems.

CHEST PAIN

Chest discomfort or pain is the cardinal manifestation of myocardial ischemia resulting from coronary artery disease or any condition that causes myocardial ischemia by an imbalance of myocardial oxygen demand compared with myocardial oxygen supply (Chapter 56). Women[1] and older individuals may be less likely to complain of classic anginal pain despite equivalent or even more advanced coronary disease.

New, acute, often ongoing pain may indicate an acute myocardial infarction, unstable angina, or aortic dissection; a pulmonary cause, such as acute pulmonary embolism or pleural irritation; a musculoskeletal condition of the chest wall, thorax, or shoulder; or a gastrointestinal abnormality, such as esophageal reflux or spasm, peptic ulcer disease, or cholecystitis (Table 39-2). The chest discomfort of an acute coronary syndrome (Chapter 57) or a myocardial infarction commonly occurs without an immediate or obvious precipitating clinical cause and builds in intensity for at least several minutes; the sensation can range from annoying discomfort to severe pain (Chapter 58).[2,3] Although a variety of adjectives may be used by patients to describe the sensation, physicians must be suspicious of any discomfort, especially if it radiates to the neck, shoulder, or arms.

The chest discomfort of unstable angina is clinically indistinguishable from that of an acute myocardial infarction except that the former may be precipitated more clearly by activity and may be more rapidly responsive to antianginal therapy (Chapter 57). Aortic dissection (Chapter 63) classically presents with the sudden onset of severe pain in the chest and radiating to the back; the location of the pain often provides clues to the location of the dissection. Ascending aortic dissections commonly present with chest discomfort radiating to the back, whereas dissections of the descending aorta commonly present with back pain radiating to the abdomen. The presence of back pain or a history of hypertension or other predisposing factors, such as Marfan syndrome, should prompt a careful assessment of peripheral pulses to determine whether the great vessels are affected by the dissection and of the chest radiograph to evaluate the size of the aorta. If this initial evaluation is suggestive, further testing with transesophageal echocardiography, computed tomography (CT), or magnetic resonance imaging (MRI) is indicated. The pain of pericarditis (Chapter 62) may simulate the pain of an acute myocardial infarction, may be primarily pleuritic, or may be continuous; a key physical finding is a pericardial rub. The pain of pulmonary embolism (Chapter 68) is commonly pleuritic in nature and is associated with dyspnea; hemoptysis also may be present. Pulmonary hypertension (Chapter 69) of any cause may be associated with chest discomfort with exertion; it commonly is associated with severe dyspnea and often is associated with cyanosis.

Recurrent, episodic chest discomfort may be noted with angina pectoris and with many cardiac and noncardiac causes (Chapter 56). A variety of stress tests (Table 39-3) can be used to provoke reversible myocardial ischemia in susceptible individuals and to help determine whether ischemia is the pathophysiologic explanation for the chest discomfort (Chapter 56).

TABLE 39-1 CARDINAL SYMPTOMS OF CARDIOVASCULAR DISEASE

Chest pain or discomfort
Dyspnea, orthopnea, paroxysmal nocturnal dyspnea, wheezing
Palpitations, dizziness, syncope
Cough, hemoptysis
Fatigue, weakness
Pain in extremities with exertion (claudication)

DYSPNEA

Dyspnea, which is an uncomfortable awareness of breathing, is commonly caused by cardiovascular or pulmonary disease. A systematic approach (see Fig. 71-2) with selected tests nearly always reveals the cause.[4] Acute dyspnea can be caused by myocardial ischemia, heart failure, severe hypertension, pericardial tamponade, pulmonary embolism, pneumothorax, upper airway obstruction, acute bronchitis or pneumonia, or some drug overdoses (e.g., salicylates). Subacute or chronic dyspnea is also a common presenting or accompanying symptom in patients with pulmonary disease (Chapter 71). Dyspnea also can be caused by severe anemia (Chapter 144) and can be confused with the fatigue that often is noted in patients with systemic and neurologic diseases (Chapters 236 and 366).

In heart failure, dyspnea typically is noted as a hunger for air and a need or an urge to breathe. The feeling that breathing requires increased work or effort is more typical of airway obstruction or neuromuscular disease. A feeling of chest tightness or constriction during breathing is typical of bronchoconstriction, which is commonly caused by obstructive airway disease (Chapters 75 and 76) but also may be seen in pulmonary edema. A feeling of heavy breathing, a feeling of rapid breathing, or a need to breathe more is classically associated with deconditioning.

In cardiovascular conditions, chronic dyspnea usually is caused by increases in pulmonary venous pressure as a result of left ventricular failure (Chapters 45 and 46) or valvular heart disease (Chapter 60). Orthopnea, which is an exacerbation of dyspnea when the patient is recumbent, is caused by increased work of breathing because of either increased venous return to the pulmonary vasculature or loss of gravitational assistance in diaphragmatic effort. Paroxysmal nocturnal dyspnea is severe dyspnea that awakens a patient at night and forces the assumption of a sitting or standing position to achieve gravitational redistribution of fluid. Of note is that acute diuresis relieves the dyspnea of severe heart failure, but the degree of relief is not always directly related to the amount of diuresis.

PALPITATIONS

Palpitations (Chapter 49) describe a subjective sensation of an irregular or abnormal heartbeat. Palpitations may be caused by any arrhythmia (Chapters 52 and 53) with or without important underlying structural heart disease. Palpitations should be defined in terms of the duration and frequency of the episodes; the precipitating and related factors; and any associated symptoms of chest pain, dyspnea, lightheadedness, or syncope. The history can determine whether the palpitations are caused by an irregular or a regular heartbeat. The feeling associated with a premature atrial or ventricular contraction, often described as a "skipped beat" or a "flip-flopping of the heart," must be distinguished from the irregularly irregular rhythm of atrial fibrillation or the rapid but regular rhythm of supraventricular tachycardia. Associated symptoms of chest pain, dyspnea, lightheadedness, dizziness, or diaphoresis suggest an important effect on cardiac output and mandate further evaluation. In general, evaluation begins with ambulatory electrocardiography (ECG; Table 39-4), which is always indicated in patients who have palpitations in

ABSTRACT

The approach to the patient with possible cardiovascular disease begins with a careful history. Chest pain may be of cardiac origin (e.g., ischemic heart disease, pericarditis, aortic dissection, pulmonary embolism, or pulmonary hypertension) or from noncardiac causes, ranging from pulmonary diseases (e.g., pneumonia with pleurisy, spontaneous pneumothorax), musculoskeletal diseases, gastrointestinal conditions (e.g., esophageal reflux, peptic ulcer, gall bladder disease), or anxiety states. Acute dyspnea may be a symptom of myocardial ischemia, heart failure, pericardial tamponade, pulmonary embolism, pneumothorax, a variety of pulmonary diseases, or even severe anemia. Palpitations can be caused by arrhythmias, with or without important underlying structural heart disease. Light-headedness or syncope can be caused by arrhythmias but also can be the result of other conditions that decrease cardiac output (e.g., left ventricular/right ventricular failure or inflow or outflow obstruction, cardiac tamponade, aortic dissection), reflex-mediated vasomotor instability (e.g., vasovagal, situational, or carotid sinus syncope), or hypostatic hypotension. Cough can be an early manifestation of heart failure. Fatigue and weakness are common in advanced cardiac disease. Claudication suggests possible peripheral arterial disease. Careful physical examination includes assessment of the jugular venous pressure and carotid pulse, as well as cardiac auscultation. The timing, quality, and duration of a heart murmur provide clues to its cause. Evaluation of the abdomen, extremities, and skin may demonstrate evidence of hypoperfusion, heart failure, or infective endocarditis. Careful laboratory testing, noninvasive imaging, and cardiac catheterization may help determine the cause of cardiovascular symptoms and signs, as well as how best to treat them.

TABLE 39-2 CAUSES OF CHEST PAIN

CONDITION	LOCATION	QUALITY	DURATION	AGGRAVATING OR RELIEVING FACTORS	ASSOCIATED SYMPTOMS OR SIGNS
CARDIOVASCULAR CAUSES					
Angina	Retrosternal region; radiates to or occasionally isolated to neck, jaw, epigastrium, shoulder, or arms (left common)	Pressure, burning, squeezing, heaviness, indigestion	<2-10 min	Precipitated by exercise, cold weather, or emotional stress; relieved by rest or nitroglycerin; atypical (Prinzmetal) angina may be unrelated to activity, often early morning	S_3 or murmur of papillary muscle dysfunction during pain
Rest or unstable angina	Same as angina	Same as angina but may be more severe	Usually <20 min	Same as angina, with decreasing tolerance for exertion or at rest	Similar to stable angina but may be pronounced; transient heart failure can occur
Myocardial infarction	Substernal and may radiate like angina	Heaviness, pressure, burning, constriction	≥30 min but variable	Unrelieved by rest or nitroglycerin	Shortness of breath, sweating, weakness, nausea, vomiting
Pericarditis	Usually begins over sternum or toward cardiac apex and may radiate to neck or left shoulder; often more localized than the pain of myocardial ischemia	Sharp, stabbing, knifelike	Lasts many hours to days; may wax and wane	Aggravated by deep breathing, rotating chest, or supine position; relieved by sitting up and leaning forward	Pericardial friction rub
Aortic dissection	Anterior chest; may radiate to back	Excruciating, tearing, knifelike	Sudden onset, unrelenting	Usually occurs in setting of hypertension or predisposition, such as Marfan syndrome	Murmur of aortic insufficiency, pulse or blood pressure asymmetry; neurologic deficit
Pulmonary embolism (chest pain often not present)	Substernal or over region of pulmonary infarction	Pleuritic (with pulmonary infarction) or angina-like	Sudden onset; minutes to <1 hr	May be aggravated by breathing	Dyspnea, tachypnea, tachycardia; hypotension, signs of acute right ventricular failure, and pulmonary hypertension with large emboli; rales, pleural friction rub, hemoptysis with pulmonary infarction
Pulmonary hypertension	Substernal	Pressure; oppressive	Similar to angina	Aggravated by effort	Pain usually associated with dyspnea; signs of pulmonary hypertension
NONCARDIAC CAUSES					
Pneumonia with pleurisy	Localized over involved area	Pleuritic, localized	Brief or prolonged	Painful breathing	Dyspnea, cough, fever, dull to percussion, bronchial breath sounds, rales, occasional pleural friction rub
Spontaneous pneumothorax	Unilateral	Sharp, well localized	Sudden onset, lasts many hours	Painful breathing	Dyspnea; hyperresonance and decreased breath and voice sounds over involved lung
Musculoskeletal disorders	Variable	Aching	Short or long duration	Aggravated by movement; history of muscle exertion or injury	Tender to pressure or movement
Herpes zoster	Dermatomal in distribution	Burning, itching	Prolonged	None	Vesicular rash appears in area of discomfort
Esophageal reflux	Substernal, epigastric	Burning, visceral discomfort	10-60 min	Aggravated by large meal, postprandial recumbency; relief with antacid	Water brash
Peptic ulcer	Epigastric, substernal	Visceral burning, aching	Prolonged	Relief with food, antacid	
Gallbladder disease	Epigastric, right upper quadrant	Visceral	Prolonged	May be unprovoked or follow meals	Right upper quadrant tenderness may be present
Anxiety states	Often localized over precordium	Variable; location often moves from place to place	Varies; often fleeting	Situational	Sighing respirations, often chest wall tenderness

the presence of coronary artery disease, structural heart disease, or substantial accompanying symptoms.[§] In such patients, more detailed evaluation is also warranted (see Fig. 49-3).

Lightheadedness or *syncope* (Chapter 49) can be caused by any condition that decreases cardiac output (e.g., bradyarrhythmia, tachyarrhythmia, obstruction of the left ventricular or right ventricular inflow or outflow, cardiac tamponade, aortic dissection, or severe pump failure), by reflex-mediated vasomotor instability (e.g., vasovagal, situational, or carotid sinus syncope), or by orthostatic hypotension (see Table 49-1). Neurologic diseases (e.g., migraine headaches, transient ischemic attacks, or seizures) also can cause transient loss of consciousness. The history, physical examination, and ECG can often diagnose the cause of syncope (see Table 49-2). Syncope caused by a cardiac arrhythmia usually occurs with little warning. Syncope with exertion or just after conclusion of exertion is typical of aortic stenosis and hypertrophic obstructive cardiomyopathy. In many patients, additional testing is required to document central nervous system disease, the cause of reduced cardiac output, or carotid sinus syncope. When the history, physical examination, and ECG do not provide helpful diagnostic information that points toward a specific cause of syncope, it is imperative that patients with heart disease or an abnormal ECG be tested with continuous ambulatory ECG monitoring to diagnose a

TABLE 39-3 COMMON EXERCISE TEST PROTOCOLS*

TABLE 39-4 INDICATIONS FOR AMBULATORY ELECTROCARDIOGRAPHIC MONITORING

History, physical examination, or 12-lead electrocardiogram suggests a possible arrhythmia
Known coronary or structural heart disease or a family history of genetic arrhythmia or sudden cardiac death
Symptoms warrant targeted therapy that depends on diagnosing the specific arrhythmia
Patient requires reassurance or a specific diagnosis because of anxiety or other concerns

possible arrhythmia; in selected patients, formal electrophysiologic testing may be indicated (Chapter 49). In patients with no evident heart disease, tilt testing (Chapter 49) can help detect reflex-mediated vasomotor instability.

OTHER SYMPTOMS

Nonproductive *cough* (Chapter 71), especially a persistent cough (see Fig. 71-1), can be an early manifestation of elevated pulmonary venous pressure and otherwise unsuspected heart failure. *Fatigue* and *weakness* are common accompaniments of advanced cardiac disease and reflect an inability to perform normal activities. A variety of approaches have been used to classify the severity of cardiac limitations, ranging from class I (little or no limitation) to class IV (severe limitation) (Table 39-5). *Hemoptysis* (Chapter 71) is a classic presenting finding in patients with pulmonary embolism, but it is also common in patients who have mitral stenosis, pulmonary edema, pulmonary infections, and malignant neoplasms (see Table 71-6). *Claudication*, which is pain in the extremities with exertion, should alert the physician to possible peripheral arterial disease (Chapters 65 and 66).

COMPLETE MEDICAL HISTORY

The complete medical history should include a thorough review of systems, family history, social history, and past medical history (Chapter 12). The review of systems may reveal other symptoms that suggest a systemic disease as the cause of any cardiovascular problems. The family history should focus on premature atherosclerosis or evidence of familial abnormalities, such as may be found with various causes of the long QT syndrome (Chapter 53) or hypertrophic cardiomyopathy (Chapter 47).

The social history should include specific questioning about cigarette smoking, alcohol intake, and use of illicit drugs. The past medical history may reveal prior conditions or medications that suggest systemic diseases, ranging from chronic obstructive pulmonary disease, which may explain a complaint of dyspnea, to hemochromatosis, which may be a cause of restrictive cardiomyopathy. A careful history to inquire about recent dental work or other procedures is crucial if bacterial endocarditis is part of the differential diagnosis.

PHYSICAL EXAMINATION FOR DETECTION OF SIGNS OF CARDIOVASCULAR DISEASE

The cardiovascular physical examination, which is a subset of the complete physical examination (Chapter 6), provides important clues to the diagnosis of asymptomatic and symptomatic cardiac disease and may reveal cardiovascular manifestations of noncardiovascular diseases. The cardiovascular physical examination begins with careful measurement of the pulse and blood pressure (Chapter 7). If aortic dissection (Chapter 63) is a consideration, blood pressure should be measured in both arms and, preferably, in at least one leg. When coarctation of the aorta is suspected (Chapter 55), blood pressure must be measured in at least one leg and in the arms. Discrepancies in blood pressure between the two arms also can be caused by atherosclerotic disease of the great vessels. Pulsus paradoxus, which is more than the usual 10-mm Hg drop in systolic blood pressure during inspiration, is typical of pericardial tamponade (Chapter 62).

GENERAL APPEARANCE

The respiratory rate may be increased in patients with heart failure. Patients with pulmonary edema are usually markedly tachypneic and may have labored breathing. Patients with advanced heart failure may have Cheyne-Stokes respirations.

Systemic diseases, such as hyperthyroidism (Chapter 207), hypothyroidism (Chapter 207), rheumatoid arthritis (Chapter 243), scleroderma (Chapter 246), and hemochromatosis (Chapter 196), may be suspected from the patient's general appearance. Marfan syndrome (Chapter 239), Turner syndrome (Chapter 217), Down syndrome (Chapter 32), and a variety of congenital anomalies also may be readily apparent.

OPHTHALMOLOGIC EXAMINATION

Examination of the fundi may show diabetic (see Fig. 391-22) or hypertensive retinopathy (see Fig. 391-24) or Roth spots (see Fig. 391-26) typical of infectious endocarditis. Beading of the retinal arteries is typical of severe hypercholesterolemia. Osteogenesis imperfecta, which is associated with blue sclerae, also is associated with aortic dilation and mitral valve prolapse. Retinal artery occlusion (see Fig. 391-27) may be caused by an embolus from clot in the left atrium or left ventricle, a left atrial myxoma, or atherosclerotic debris from the great vessels. Hyperthyroidism may present with exophthalmos and typical stare (see Fig. 391-5), whereas myotonic dystrophy, which is associated with atrioventricular block and arrhythmia, often is associated with ptosis and an expressionless face (see Fig. 389-2).

JUGULAR VEINS

The external jugular veins help in assessment of mean right atrial pressure, which normally varies between 5 and 10 cm H_2O; the height (in centimeters) of the central venous pressure is measured by adding 5 cm to the height of the observed jugular venous distention above the sternal angle of Louis (Fig. 39-1). The normal jugular venous pulse, best seen in the internal jugular vein (and not seen in the external jugular vein unless insufficiency of the jugular venous valves is present), includes an *a* wave, caused by right atrial contraction; a *c* wave, reflecting carotid artery pulsation; an *x* descent; a *v* wave, which corresponds to isovolumetric right ventricular contraction and is more marked in the presence of tricuspid insufficiency; and a *y* descent, which occurs as the tricuspid valve opens and ventricular filling begins (Fig. 39-2). Abnormalities of the jugular venous pressure (Fig. 39-3) as detected on physical examination or point-of-care ultrasonography[6] are useful in detecting heart failure, and they

TABLE 39-5 A COMPARISON OF THREE METHODS OF ASSESSING CARDIOVASCULAR DISABILITY

CLASS	NEW YORK HEART ASSOCIATION FUNCTIONAL CLASSIFICATION	CANADIAN CARDIOVASCULAR SOCIETY FUNCTIONAL CLASSIFICATION	SPECIFIC ACTIVITY SCALE
I	Patients with cardiac disease but without resulting limitations of physical activity Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea, or anginal pain	Ordinary physical activity, such as walking and climbing stairs, does not cause angina Angina with strenuous or rapid or prolonged exertion at work or recreation	Patients can perform to completion any activity requiring ≥7 metabolic equivalents, for example, can carry 24 lb up 8 steps; carry objects that weigh 80 lb; do outdoor work (shovel snow, spade soil); do recreational activities (skiing, basketball, squash, handball, jog or walk 5 mph)
II	Patients with cardiac disease resulting in slight limitation of physical activity They are comfortable at rest Ordinary physical activity results in fatigue, palpitations, dyspnea, or anginal pain	Slight limitation of ordinary activity Walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, in cold, in wind, or when under emotional stress, or only during the few hours after awakening Walking >2 blocks on the level and climbing >1 flight of ordinary stairs at a normal pace and in normal conditions	Patient can perform to completion any activity requiring ≥5 metabolic equivalents but cannot and does not perform to completion activities requiring ≥7 metabolic equivalents, e.g., have sexual intercourse without stopping, garden, rake, weed, roller skate, dance foxtrot, walk at 4 mph on level ground
III	Patients with cardiac disease resulting in marked limitation of physical activity They are comfortable at rest Less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain	Marked limitation of ordinary physical activity Walking 1 or 2 blocks on the level and climbing >1 flight in normal conditions	Patient can perform to completion any activity requiring ≥2 metabolic equivalents but cannot and does not perform to completion any activities requiring ≥5 metabolic equivalents, for example, shower without stopping, strip and make bed, clean windows, walk 2.5 mph, bowl, play golf, dress without stopping
IV	Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort Symptoms of cardiac insufficiency or of the anginal syndrome may be present even at rest If any physical activity is undertaken, discomfort is increased	Inability to carry on any physical activity without discomfort—anginal syndrome may be present at rest	Patient cannot or does not perform to completion activities requiring ≥2 metabolic equivalents; cannot carry out activities listed above (Specific Activity Scale, class III)

From Goldman L, Hashimoto B, Cook EF, et al. Comparative reproducibility and validity of systems for assessing cardiovascular functional class: advantages of a new specific activity scale. *Circulation*. 1981;64:1227-1234. Reproduced by permission of the American Heart Association.

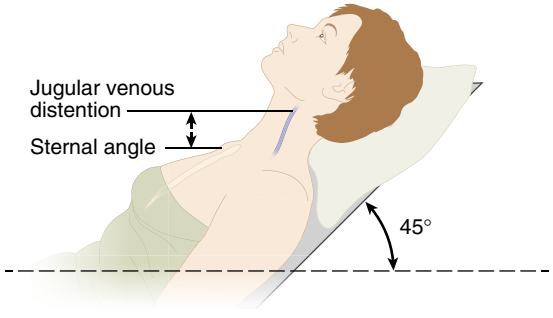

FIGURE 39-1. Jugular venous distention is defined by engorgement of the internal jugular vein more than 5 cm above the sternal angle at 45 degrees. The central venous pressure is the observed venous distention above the sternal angle plus 5 cm.

correlate well with brain natriuretic peptide levels (Chapter 45) and echocardiographic evidence of an elevated pulmonary artery pressure (Chapter 43). The jugular venous pressure also helps in the diagnosis of pericardial disease, tricuspid valve disease, and pulmonary hypertension (Table 39-6).

CAROTID PULSE

The carotid pulse should be examined in terms of its volume and contour. The carotid pulse (Fig. 39-4) may be increased in frequency and may be more intense than normal in patients with a higher stroke volume secondary to aortic regurgitation, arteriovenous fistula, hyperthyroidism, fever, or anemia. In aortic regurgitation or arteriovenous fistula, the pulse may have a bisferious quality. The carotid upstroke is delayed in patients with valvular aortic stenosis (Chapter 60) and has a normal contour but diminished amplitude in any cause of reduced stroke volume.

CARDIAC INSPECTION AND PALPATION

Inspection of the precordium may reveal the hyperinflation of obstructive lung disease or unilateral asymmetry of the left side of the chest because of right ventricular hypertrophy before puberty. Palpation may be performed with the patient either supine or in the left lateral decubitus position; the

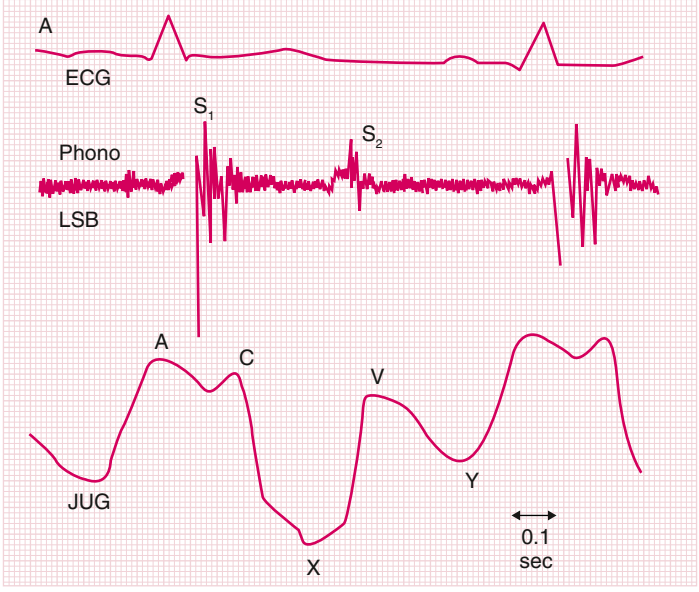

FIGURE 39-2. Normal jugular venous pulse. ECG = electrocardiogram; JUG = jugular vein; LSB = left sternal border; phono = phonocardiogram; S_1 = first heart sound; S_2 = second heart sound.

latter position moves the left ventricular apex closer to the chest wall and increases the ability to palpate the point of maximal impulse and other phenomena. Low-frequency phenomena, such as systolic heaves or lifts from the left ventricle (at the cardiac apex) or right ventricle (parasternal in the third or fourth intercostal space), are felt best with the heel of the palm. With the patient in the left lateral decubitus position, this technique also may allow palpation of an S_3 gallop in cases of advanced heart failure or an S_4 gallop in cases of poor left ventricular distensibility during diastole. The left ventricular apex is more diffuse and sometimes may be frankly dyskinetic in patients

FIGURE 39-3. Typical distention of the internal jugular vein. (From http://courses.cvcc.vccs.edu/WisemanD/jugular_vein_distention.htm.)

TABLE 39-6 ABNORMALITIES OF VENOUS PRESSURE AND PULSE AND THEIR CLINICAL SIGNIFICANCE

Positive hepatojugular reflux	Suspect heart failure, particularly left ventricular systolic dysfunction (echocardiography recommended)
Elevated systemic venous pressure without obvious *x* or *y* descent, quiet precordium, and pulsus paradoxus	Suspect cardiac tamponade (echocardiography recommended)
Elevated systemic venous pressure with sharp *y* descent, Kussmaul sign, and quiet precordium	Suspect constrictive pericarditis (cardiac catheterization and MRI or CT recommended)
Elevated systemic venous pressure with a sharp brief *y* descent, Kussmaul sign, and evidence of pulmonary hypertension and tricuspid regurgitation	Suspect restrictive cardiomyopathy (cardiac catheterization and MRI or CT recommended)
A prominent *a* wave with or without elevation of mean systemic venous pressure	Exclude tricuspid stenosis, right ventricular hypertrophy caused by pulmonary stenosis, and pulmonary hypertension (echo-Doppler study recommended)
A prominent *v* wave with a sharp *y* descent	Suspect tricuspid regurgitation (echo-Doppler or cardiac catheterization to determine etiology)

CT = computed tomography; MRI = magnetic resonance imaging.
From Braunwald E, ed. *Heart Disease: A Textbook of Cardiovascular Medicine*. 5th ed. Philadelphia: WB Saunders; 1997.

with advanced heart disease. The distal palm is best for feeling thrills, which are the tactile equivalent of cardiac murmurs. By definition, a thrill denotes a murmur of grade 4/6 or louder. Higher-frequency events may be felt best with the fingertips; examples include the opening snap of mitral stenosis or the loud pulmonic second sound of pulmonary hypertension.

AUSCULTATION

The first heart sound (Fig. 39-5), which is largely produced by closure of the mitral and—to a lesser extent—the tricuspid valves, may be louder in patients with mitral valve stenosis and intact valve leaflet movement and less audible in patients with poor closure caused by mitral regurgitation (Chapter 60). The second heart sound is caused primarily by closure of the aortic valve, but closure of the pulmonic valve is also commonly audible. In normal individuals, the louder aortic closure sound occurs first, followed by pulmonic closure. With expiration, the two sounds are virtually superimposed. With inspiration, by comparison, the increased stroke volume of the right ventricle commonly leads to a discernible splitting of the second sound. This splitting may be fixed in patients with an atrial septal defect (Chapter 55) or a right bundle branch block. The split may be paradoxical in patients with left bundle branch block or other causes of delayed left ventricular emptying. The aortic component of the second sound is increased in intensity in the presence of systemic hypertension and decreased in intensity in patients with aortic stenosis. The pulmonic second sound is increased in the presence of pulmonary hypertension.

Early systolic ejection sounds are related to forceful opening of the aortic or pulmonic valve. These sounds are common in congenital aortic stenosis, with a mobile valve; in hypertension, with forceful opening of the aortic valve; and in healthy young individuals, especially when cardiac output is increased. Midsystolic or late systolic clicks are caused most commonly by mitral valve prolapse (Chapter 60). Clicks are relatively high-frequency sounds that are heard best with the diaphragm of the stethoscope.

An S_3 corresponds to rapid ventricular filling during early diastole. It may occur in normal children and young adults, especially if stroke volume is increased. After about 40 years of age, however, an S_3 should be considered abnormal; it is caused by conditions that increase the volume of ventricular filling during early diastole (e.g., mitral regurgitation) or that increase pressure in early diastole (e.g., advanced heart failure).[7] A left ventricular S_3 gallop is heard best at the apex, whereas the right ventricular S_3 gallop is heard best at the fourth intercostal space at the left parasternal border; both are heard best with the bell of the stethoscope. An S_4 is heard rarely in young individuals but is common in adults older than 40 or 50 years because of reduced ventricular compliance during atrial contraction; it is a nearly ubiquitous finding in patients with hypertension, heart failure, or ischemic heart disease.

The opening snap of mitral and, less commonly, tricuspid stenosis (Chapter 60) occurs at the beginning of mechanical diastole, before the onset of the rapid phase of ventricular filling. An opening snap is high pitched and is heard best with the diaphragm; this differential frequency should help distinguish an opening snap from an S_3 on physical examination. An opening snap commonly can be distinguished from a loud pulmonic component of the second heart sound by the differential location (mitral opening snap at the apex, tricuspid opening snap at the left third or fourth intercostal space, pulmonic second sound at the left second intercostal space) and by the longer interval between S_2 and the opening snap.

Heart murmurs may be classified as systolic, diastolic, or continuous (Table 39-7).[8] Murmurs are graded by intensity on a scale of 1 to 6. Grade 1 is faint and appreciated only by careful auscultation; grade 2, readily audible; grade 3, moderately loud; grade 4, loud and associated with a palpable thrill; grade 5, loud and audible with the stethoscope only partially placed on the chest; and grade 6, loud enough to be heard without the stethoscope on the chest. Systolic ejection murmurs usually peak in early to mid-systole when left ventricular ejection is maximal; examples include fixed valvular, supravalvular, or infravalvular aortic stenosis and pulmonic stenosis. The murmur of hypertrophic obstructive cardiomyopathy has a similar ejection quality, although its peak may be later in systole when dynamic obstruction is maximal (Chapter 47). Pansystolic murmurs are characteristic of mitral or tricuspid regurgitation or with a left-to-right shunt from conditions such as a ventricular septal defect (left ventricle to right ventricle). A late systolic murmur is characteristic of mitral valve prolapse (Chapter 60) or ischemic papillary muscle dysfunction. Ejection quality murmurs also may be heard in patients with normal valves but increased flow, such as occurs with marked anemia, fever, or bradycardia secondary to congenital complete heart block; they also may be heard across a valve that is downstream from increased flow because of an intracardiac shunt. Maneuvers such as inspiration, expiration, standing, squatting, and hand gripping can be especially useful in the differential diagnosis of a murmur; however, echocardiography commonly is required to make a definitive diagnosis of cause and severity (Table 39-8).

High-frequency, early diastolic murmurs are typical of aortic regurgitation and pulmonic regurgitation from a variety of causes. The murmurs of mitral and tricuspid stenosis begin in early to mid-diastole and tend to diminish in intensity later in diastole in the absence of effective atrial contraction, but they tend to increase in intensity in later diastole if effective atrial contraction is present.

Continuous murmurs may be caused by any abnormality that is associated with a pressure gradient in systole and diastole. Examples include a patent ductus arteriosus, ruptured sinus of Valsalva aneurysm, arteriovenous fistula (of the coronary artery, pulmonary artery, or thoracic artery), and a mammary souffle. In some situations, murmurs of two coexistent conditions (e.g., aortic stenosis and regurgitation, atrial septal defect with a large shunt and resulting flow murmurs of relative mitral and pulmonic stenosis) may mimic a continuous murmur.

Although experienced examiners may still be able to diagnose meaningful valvular heart disease accurately by auscultation, most general physicians are not nearly so accurate, even after training. As a result, echocardiography (Chapter 43) is critical to the evaluation of patients with suspected structural heart disease.

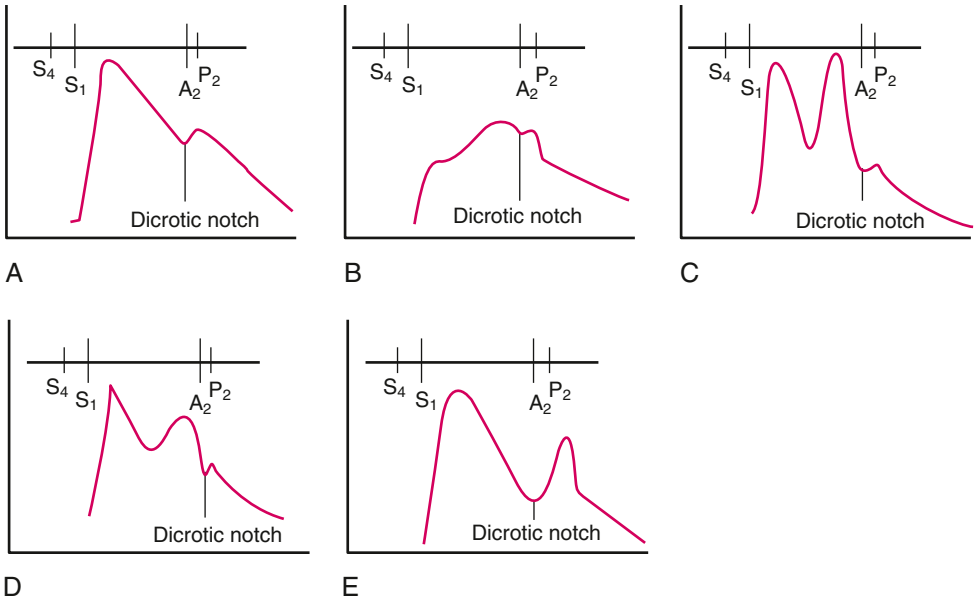

FIGURE 39-4. Schematic diagrams of the configurational changes in the carotid pulse and their differential diagnosis. Heart sounds also are illustrated. **A**, Normal. **B**, Anacrotic pulse with slow initial upstroke. The peak is close to the second heart sound. These features suggest fixed left ventricular outflow obstruction, such as valvular aortic stenosis. **C**, Pulsus bisferiens, with percussion and tidal waves occurring during systole. This type of carotid pulse contour is observed most frequently in patients with hemodynamically significant aortic regurgitation or combined aortic stenosis and regurgitation with dominant regurgitation. It rarely is observed in patients with mitral valve prolapse or in normal individuals. **D**, Pulsus bisferiens in hypertrophic obstructive cardiomyopathy. This finding rarely is appreciated at the bedside by palpation. **E**, Dicrotic pulse results from an accentuated dicrotic wave and tends to occur in sepsis, severe heart failure, hypovolemic shock, and cardiac tamponade and after aortic valve replacement. A_2 = aortic component of the second heart sound; P_2 = pulmonary component of the second heart sound); S_1 = first heart sound; S_4 = atrial sounds. (From Chatterjee K. Bedside evaluation of the heart: the physical examination. In: Chatterjee K, Chetlin MD, Karliner J, et al, eds. *Cardiology: An Illustrated Text/Reference*. Philadelphia: JB Lippincott; 1991:3.11-3.51.)

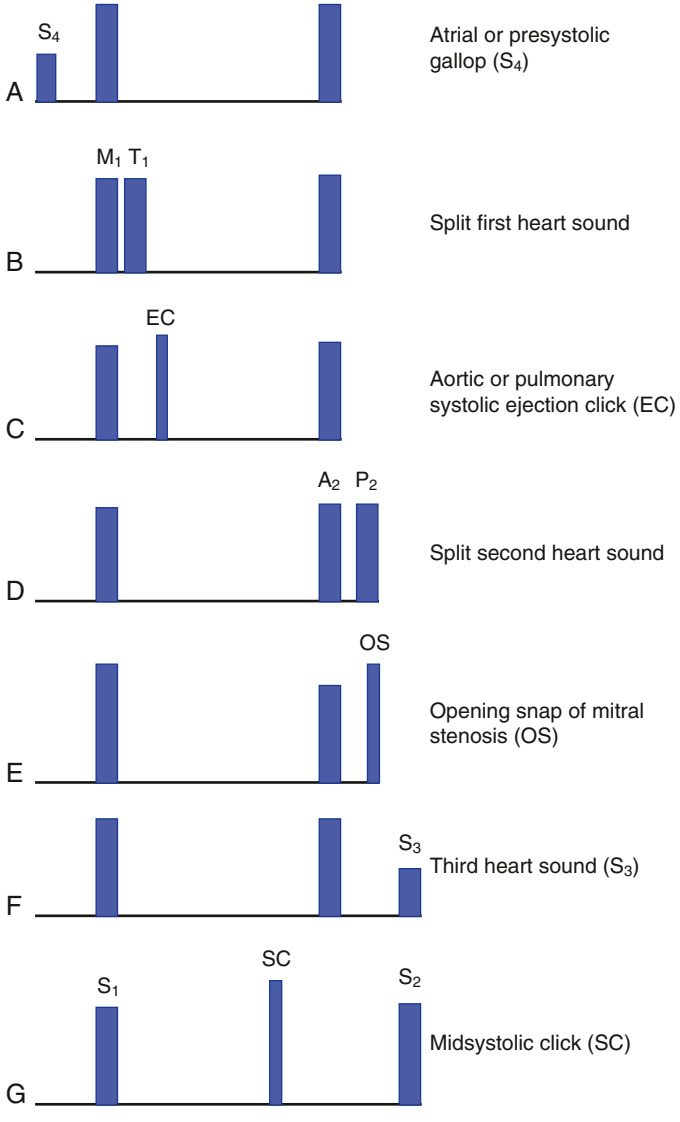

FIGURE 39-5. Timing of the different heart sounds and added sounds. (Modified from Wood P. *Diseases of the Heart and Circulation*. 3rd ed. Philadelphia: JB Lippincott; 1968.)

ABDOMEN

The most common cause of hepatomegaly in patients with heart disease is hepatic engorgement from elevated right-sided pressures associated with right ventricular failure of any cause. Hepatojugular reflux is elicited by pressing on the liver and showing an increase in the jugular venous pressure; it indicates advanced right ventricular failure or obstruction to right ventricular filling. Evaluation of the abdomen also may reveal an enlarged liver caused by a systemic disease, such as hemochromatosis (Chapter 196) or sarcoidosis (Chapter 83), which also may affect the heart. In more severe cases, splenomegaly and ascites also may be noted. Large, palpable, polycystic kidneys (Chapter 112) commonly are associated with hypertension. A systolic bruit suggestive of renal artery stenosis (Chapter 110) or an enlarged abdominal aorta (Chapter 63) is a clue of atherosclerosis.

EXTREMITIES

Extremities should be evaluated for peripheral pulses, edema, cyanosis, and clubbing. Diminished peripheral pulses suggest peripheral arterial disease (Chapters 65 and 66). Delayed pulses in the legs are consistent with coarctation of the aorta and are seen after aortic dissection.

Edema (Fig. 39-6) is a cardinal manifestation of right-sided heart failure. When it is caused by heart failure, pericardial disease, or pulmonary hypertension, the edema is usually symmetrical and progresses upward from the ankles; each of these causes of cardiac edema commonly is associated with jugular venous distention and often with hepatic congestion.[9] Unilateral edema suggests thrombophlebitis or proximal venous or lymphatic obstruction (Fig. 39-7).[10] Edema in the absence of evidence of right-sided or left-sided heart failure suggests renal disease, hypoalbuminemia, myxedema, or other noncardiac causes. Among unselected patients with bilateral edema, about 40% have an underlying cardiac disease, about 40% have an elevated pulmonary blood pressure, about 20% have bilateral venous disease, about 20% have renal disease, and about 25% have idiopathic edema. In patients who have chronic leg edema with recurrent cellulitis, leg compression therapy can reduce the risk of subsequent cellulitis.[A1]

Cyanosis (Fig. 39-8) is a bluish discoloration caused by reduced hemoglobin exceeding about 5 g/dL in the capillary bed. Central cyanosis is seen in patients with poor oxygen saturation resulting from a reduced inspired oxygen concentration or inability to oxygenate the blood in the lungs (e.g., as a result of advanced pulmonary disease, pulmonary edema, pulmonary arteriovenous fistula, or right-to-left shunting); it also may be seen in patients with marked erythrocytosis. Methemoglobinemia (Chapter 144) also can present with cyanosis. Peripheral cyanosis may be caused by reduced blood flow to the extremities secondary to vasoconstriction, heart failure, or shock.

TABLE 39-7 SOME COMMON CAUSES OF HEART MURMURS*

	USUAL LOCATION	COMMON ASSOCIATED FINDINGS
SYSTOLIC		
Holosystolic		
Mitral regurgitation	Apex → axilla	↑ with handgrip; S_3 if marked mitral regurgitation; left ventricular dilation common
Tricuspid regurgitation	LLSB	↑ with inspiration; right ventricular dilation common
Ventricular septal defect	LLSB → RLSB	Often with thrill
Early to midsystolic		
Aortic valvular stenosis	RUSB	Ejection click if mobile valve; soft or absent A_2 if valve immobile; later peak associated with more severe stenosis
Fixed supravalvular or subvalvular	RUSB	
Dynamic infravalvular	LLSB → apex + axilla	Hypertrophic obstructive cardiomyopathy; murmur louder if left ventricular volume lower or contractility increased, softer if left ventricular volume increased†; can be later in systole if obstruction delayed
Pulmonic valvular stenosis	LUSB	↑ with inspiration
Infravalvular (infundibular)	LUSB	↑ with inspiration
Supravalvular	LUSB	↑ with inspiration
"Flow murmurs"	LUSB	Anemia, fever, increased flow of any cause‡
Mid to late systolic		
Mitral valve prolapse	LLSB or apex → axilla	Preceded by click; murmur lengthens with maneuvers that decrease left ventricular volume†
Papillary muscle dysfunction	Apex → axilla	Ischemic heart disease
DIASTOLIC		
Early diastolic		
Aortic regurgitation	RUSB, LUSB	High-pitched, blowing quality; endocarditis, diseases of the aorta, associated aortic valvular stenosis; signs of low peripheral vascular resistance
Pulmonic valve regurgitation	LUSB	Pulmonary hypertension as a causative factor
Mid to late diastolic		
Mitral stenosis, tricuspid stenosis	Apex, LLSB	Low pitched; in rheumatic heart disease, opening snap commonly precedes murmur; can be caused by increased flow across normal valve‡
Atrial myxomas	Apex (L), LLSB (R)	"Tumor plop"
Continuous		
Venous hum	Over jugular or hepatic vein or breast	
Patent ductus arteriosus	LUSB	
Arteriovenous fistula		
Coronary	LUSB	
Pulmonary, bronchial, chest wall	Over fistula	
Ruptured sinus of Valsalva aneurysm	RUSB	Sudden onset

*See also Chapters 55 and 60.

†Left ventricular volume is decreased by standing or during prolonged, forced expiration against a closed glottis (Valsalva maneuver); it is increased by squatting or by elevation of the legs; contractility is increased by adrenergic stimulation or in the beat after an extrasystolic beat.

‡Including a left-to-right shunt through an atrial septal defect for tricuspid or pulmonic flow murmurs and a ventricular septal defect for pulmonic or mitral flow murmurs.

LLSB = left lower sternal border (fourth intercostal space); LUSB = left upper sternal border (second and third intercostal spaces); RLSB = right lower sternal border (fourth intercostal space); RUSB = right upper sternal border (second and third intercostal spaces).

TABLE 39-8 SENSITIVITY AND SPECIFICITY OF BEDSIDE MANEUVERS IN THE IDENTIFICATION OF SYSTOLIC MURMURS

MANEUVER	RESPONSE	MURMUR	SENSITIVITY (%)	SPECIFICITY (%)
Inspiration	↑	RS	100	88
Expiration	↓	RS	100	88
Valsalva maneuver	↑	HC	65	96
Squat to stand	↑	HC	95	84
Stand to squat	↓	HC	95	85
Leg elevation	↓	HC	85	91
Handgrip	↓	HC	85	75
Handgrip	↑	MR and VSD	68	92
Transient arterial occlusion	↑	MR and VSD	78	100

HC = hypertrophic cardiomyopathy; MR = mitral regurgitation; RS = right sided; VSD = ventricular septal defect.

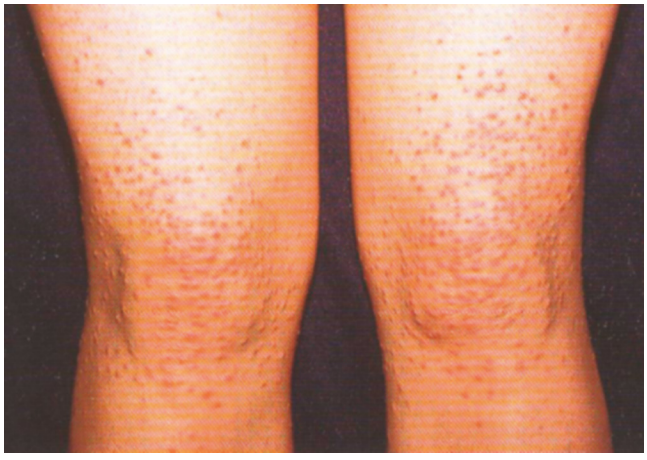
Clubbing (Fig. 39-9), which is loss of the normal concave configuration of the nail as it emerges from the distal phalanx, is seen in patients with cyanotic congenital heart disease (Chapter 55), but in adults it is usually related to pulmonary abnormalities such as lung cancer (Chapter 177).[11]

EXAMINATION OF THE SKIN

Examination of the skin may reveal bronze pigmentation typical of hemochromatosis (Chapter 196); jaundice (see Fig. 132-1) characteristic of severe right-sided heart failure or hemochromatosis; or capillary hemangiomas typical of hereditary hemorrhagic telangiectasia (see Fig. 159-3), which also is associated with pulmonary arteriovenous fistulas and cyanosis. Infectious endocarditis may be associated with splinter hemorrhages (Fig. 39-10),[12] Osler nodes (see Fig. 61-2), or Janeway lesions (Chapter 61). Xanthomas (E-Fig. 39-1) are subcutaneous deposits of cholesterol seen on the extensor surfaces of the extremities or on the palms and digital creases; they are found in patients with severe hypercholesterolemia.

LABORATORY STUDIES

All patients with known or suspected cardiac disease should have an ECG. The ECG (Chapter 42) helps identify rate, rhythm, conduction abnormalities, and possible myocardial ischemia or myocardial infarction. Blood testing in patients with known or suspected cardiac disease should be targeted to the conditions in question. In general, a complete blood cell count, thyroid indices, and lipid levels are part of the standard evaluation. Genetic screening



E-FIGURE 39-1. Eruptive xanthomas of the extensor surfaces of the lower extremities. This patient had marked hypertriglyceridemia. (From Massengale WT, Nesbitt LT Jr. Xanthomas. In: Bolognia JL, Jorizzo JL, Rapini RP, eds. *Dermatology*. Philadelphia: Mosby; 2003:1449.)

has become increasingly useful in individuals who have a family history of cardiomyopathy, arrhythmias, or sudden death.[13]

The chest radiograph (Chapter 44) yields important information on chamber enlargement, pulmonary vasculature, and the great vessels. Point-of-care ultrasonography is increasingly being used in acute care settings to distinguish heart failure from pulmonary causes of dyspnea,[14] to diagnose severe valvular heart disease, and to evaluate suspected pericardial tamponade.[15]

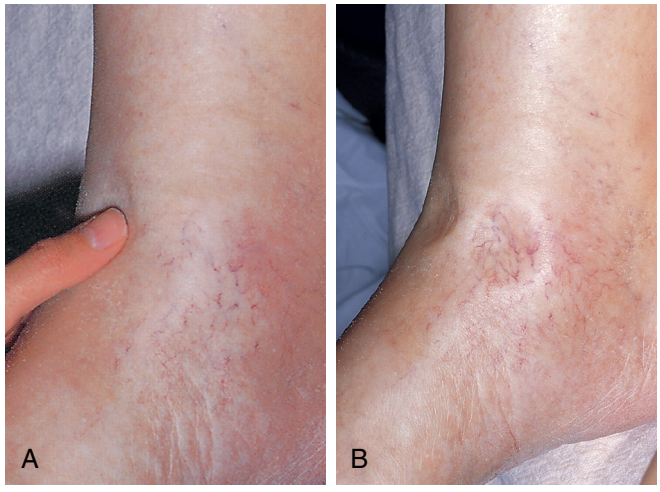


FIGURE 39-6. **A and B, Pitting edema in a patient with cardiac failure.** A depression ("pit") remains in the edema for some minutes after firm fingertip pressure is applied. (From Forbes CD, Jackson WD. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)

For patients who have acute chest pain or other symptoms that suggest acute myocardial ischemia, the probability of an acute myocardial infarction can be estimated by integrating information from the history, physical examination, and ECG. If the ECG shows evidence of ST-segment or T-wave changes that are consistent with myocardial ischemia and that are not known to be old, admission is mandatory, and acute interventions are often required (Chapters 57 and 58). In other patients who have suggestive symptoms but a nondiagnostic ECG, rapid testing with a high-sensitivity troponin assay is very helpful for guiding triage decisions (Chapter 57). An undetectable high-sensitivity troponin level at presentation reduces the probability of acute MI or an acute coronary event to less than 1%.[16] A protocol in which the ECG and troponin level are repeated in 2 hours is as good as longer observation periods for evaluating patients with acute chest pain and suspected myocardial infarction. However, the advent of high-sensitivity troponin assays has also greatly increased the risk for a false-positive diagnosis of myocardial infarction, especially because of chronic troponin elevations in many cardiac conditions and in some elderly patients (Chapter 57). In this acute setting, early CT angiography does not improve clinical outcomes compared with invasive coronary angiography (Chapter 57).[A2]

In patients who have dyspnea or other symptoms or signs of potential heart failure, a pro–B-type natriuretic peptide level (Chapter 45) is very useful for their emergency evaluation. A level <300 pg/mL nearly excludes the diagnosis of heart failure.[17]

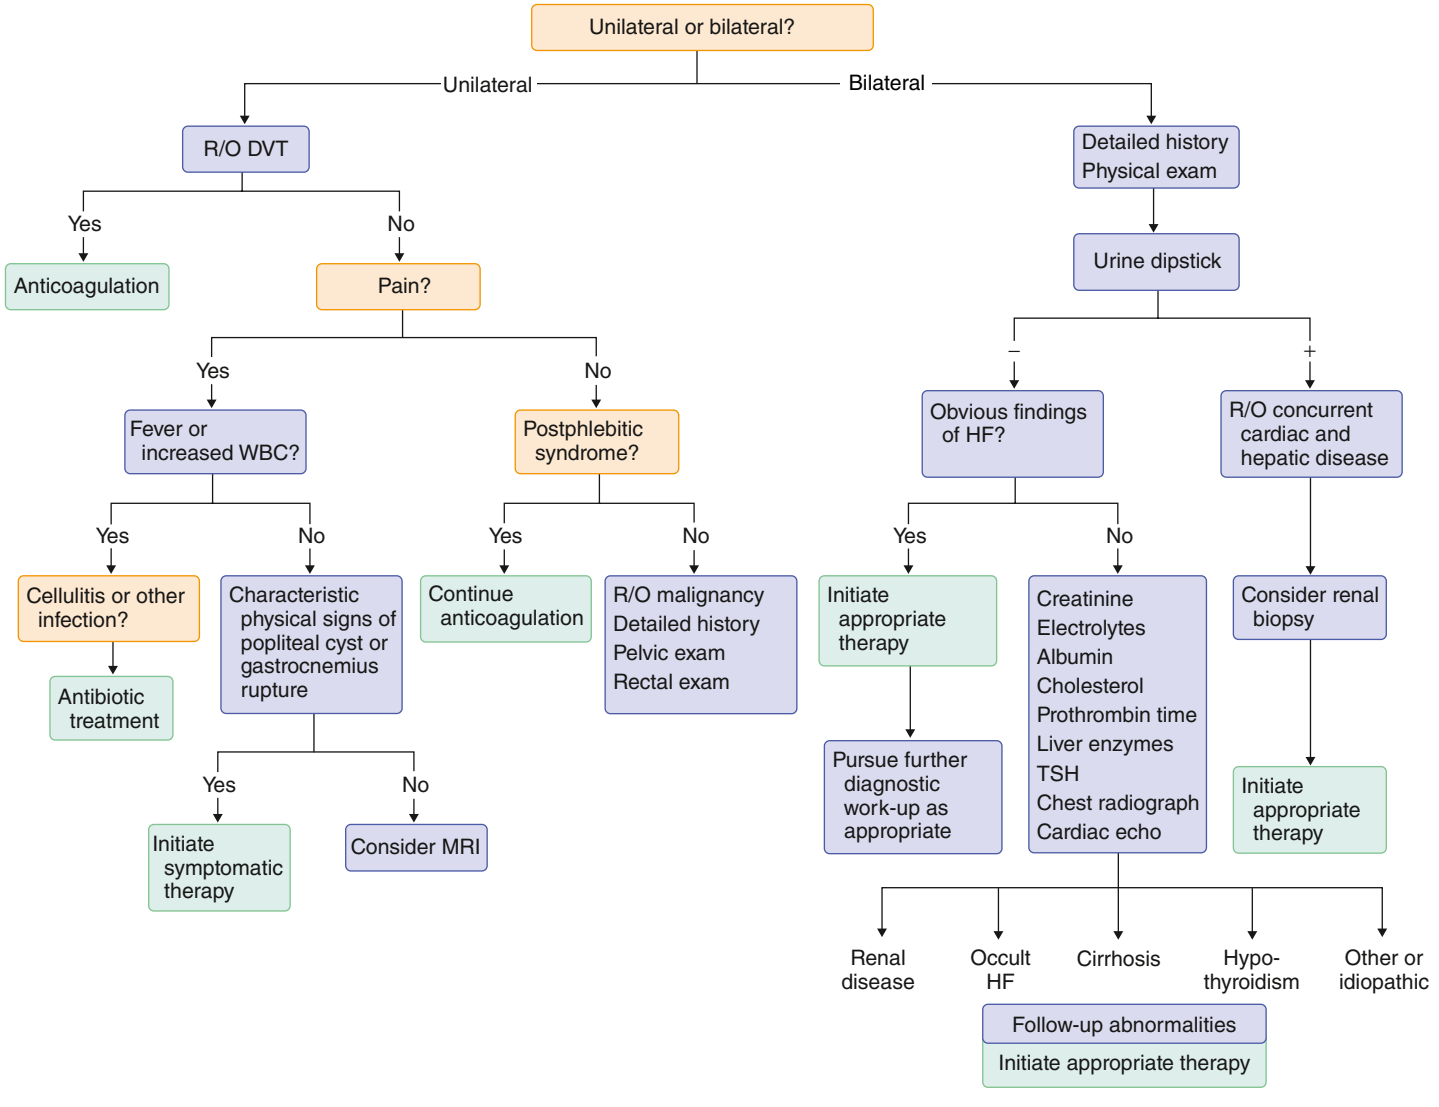

FIGURE 39-7. **Diagnostic approach to patients with edema.** DVT = deep vein thrombosis; HF = heart failure; MRI = magnetic resonance imaging; R/O = rule out; TSH = thyroid-stimulating hormone; WBC = white blood cell count. (From Chertow G. Approach to the patient with edema. In: Braunwald E, Goldman L, eds. *Primary Cardiology*. 2nd ed. Philadelphia: WB Saunders; 2003.)

Echocardiography (Chapter 43) is the most useful test to analyze valvular and ventricular function. By use of Doppler flow methods, stenotic and regurgitant lesions can be quantified. Handheld ultrasonography performed by generalists can improve the assessment of left ventricular function, cardiomegaly, and pericardial effusion. Transesophageal echocardiography is the preferred method to evaluate possible aortic dissection and to identify clots in the cardiac chambers. Radionuclide studies (Chapter 44) can measure left ventricular function, assess myocardial ischemia, and determine whether ischemic myocardium is viable. CT can detect coronary calcium, which is a risk factor for symptomatic coronary disease (Chapter 44).[18]

Multislice CT scanning can diagnose coronary disease. In a randomized trial of emergency department patients at low to intermediate risk for a possible acute coronary syndrome, coronary CT angiography resulted in a higher rate of discharge from the emergency department (50% vs. 23%), a shorter length of stay (median, 18 vs. 24.8 hours), and a higher rate of detection of coronary disease (9% vs. 3.5%) without any change in the rate of serious adverse events. However, in a subsequent randomized trial of emergency department patients with symptoms suggestive of acute coronary syndromes but without ischemic ECG changes or an initially positive troponin test, incorporating coronary CT angiography into the triage strategy did not decrease overall costs of care.

Stress testing by exercise or pharmacologic stress is useful to precipitate myocardial ischemia that may be detected by ECG abnormalities, perfusion abnormalities on radionuclide studies, or transient wall motion abnormalities on echocardiography. These tests are often crucial for the diagnosis of possible myocardial ischemia (see Figs. 56-1, 56-2, and 56-3) and for understanding the prognosis in patients with known ischemic heart disease.

In symptomatic patients with suspected coronary disease, the strategies of initial coronary CT angiography and functional testing using exercise electrocardiography, nuclear stress testing, or stress echocardiography provide equivalent clinical outcomes over a median follow-up of 2 years,[A3] but CT angiography may be preferable when follow-up is extended to 5 years.[A4] In patients whose chest pain portends an intermediate risk for stable underlying coronary artery disease, CT coronary angiography is as good as invasive coronary angiography in terms of guiding therapy over at least 3.5 years.[A5] However, none of these tests are currently recommended in asymptomatic individuals, either routinely or prior to participation in sports or other physical activities.

Cardiac catheterization (Chapter 59) can measure precise gradients across stenotic cardiac valves, judge the severity of intracardiac shunts, and determine intracardiac pressures. Coronary angiography provides a definitive diagnosis of coronary disease and is a necessary prelude to coronary revascularization with a percutaneous coronary intervention or coronary artery bypass graft surgery (Chapter 59).

Continuous ambulatory ECG monitoring can help diagnose arrhythmias. A variety of newer technologies allow longer-term monitoring in patients with important but infrequently occurring symptoms (Chapter 49). Formal invasive electrophysiologic testing can be useful in the diagnosis of ventricular or supraventricular wide-complex tachycardia, and it is crucial for guiding a wide array of new invasive electrophysiologic therapies (Chapter 54).

APPROACH TO THERAPY

The history, physical examination, and laboratory evaluation should help the physician establish the cause of any cardiovascular problem; identify and quantify any anatomic abnormalities; determine the physiologic status of the valves, myocardium, and conduction system; determine functional capacity; estimate prognosis; and provide primary or secondary prevention. Improvements in diagnosis, therapy, and prevention have contributed to a 70% or so decline in age-adjusted cardiovascular death rates in the United States since the 1960s. Key preventive strategies that should be part of the approach to every patient, with or without heart disease, include dietary modification (Chapter 13), recognition and treatment of hypertension (Chapter 64) and hyperlipidemia (Chapter 190), cessation of cigarette smoking (Chapter 363), and adequate physical exercise (Chapter 14).

40 EPIDEMIOLOGY OF CARDIOVASCULAR DISEASE

DONALD M. LLOYD-JONES

Cardiovascular diseases remain the leading causes of death, disability, and medical costs in the world, and they are expected to remain so for the foreseeable future. Cardiovascular disease manifests in a number of different ways, including: congenital heart and vascular malformations (Chapter 55); coronary heart disease (Chapters 56, 57, 58, and 59); heart failure (Chapter 46); cardiomyopathies (Chapter 47); valvular heart disease (Chapter 60); dysrhythmias (Chapters 49, 50, 51, 52, and 53); pericardial diseases (Chapter 62); aortic (Chapter 63), peripheral (Chapter 65), and cerebrovascular diseases (Chapter 375); systemic hypertension (Chapter 64); vasculitides (Chapter 249); venous thromboembolic disease (Chapter 68); and pulmonary vascular hypertension (Chapter 69). Of these, coronary heart disease, stroke, and heart failure, which share many common underlying risk factors, have by far the largest impact on the population in terms of incidence, prevalence, quality of life, and medical costs.

BURDEN IN THE UNITED STATES

Cardiovascular diseases have been the leading cause of death in the United States in every year of the 20th and 21st centuries except for 1918, when the influenza epidemic surpassed them. Even during the severe acute respiratory disease coronavirus 2 (SARS-CoV-2) pandemic (Chapter 336), cardiovascular disease remained the leading cause of death. Cardiovascular diseases account for 1 in 3 deaths in the United States annually, or more than 850,000 deaths, including about 420,000 women and slightly more men. The overall age-adjusted annual rate of death due to cardiovascular disease in the United States is about 219 per 100,000 persons, with higher rates in men than in women and in Black than in White, Hispanic, or Asian Americans.[1] Because of secular trends in risk factors and the development of effective treatments over the last 50 years, cardiovascular disease mortality rates declined by approximately 70% from their peak in the 1960s, but rates have been constant since 2011.[2]

Cardiovascular diseases also are the leading cause of hospitalizations and medical costs in the United States. Each year about 5 million Americans are hospitalized for cardiovascular disease, over 1 million of which are due to coronary heart disease and approximately 1 million more each are due to heart failure and stroke. The United States currently spends approximately $360 billion annually on direct costs for cardiovascular diseases, and total costs are projected to exceed $800 billion annually by 2030.

In the United States, about 20.1 million adults (7.2%) have coronary heart disease, 45% of whom have had a myocardial infarction. Each year, Americans suffer over 1 million new and recurrent myocardial infarctions, with about 365,000 deaths due to coronary heart disease, a large percentage of which are sudden cardiac deaths. There are 7.6 million stroke survivors (2.7%) in the United States, with the proportion twice as high in Black than in White Americans, and 795,000 new or recurrent strokes occur every year. Stroke rates are especially high in the so-called "stroke belt" in the southeastern United States. At present, 6 million Americans (2.1%) have chronic heart failure, with prevalence 50% higher in men than women and in individuals who identify as Black. With aging, the risks for stroke and heart failure tend to increase at younger ages in women and Black Americans than in White men, whose coronary risk increases earlier.

GLOBAL BURDEN

Cardiovascular diseases, including coronary heart disease and stroke, became the leading cause of death and disability globally in the early 21st century (E-Fig. 40-1). About 80% of cardiovascular deaths and events now occur in low- and middle-income countries, and the onset of cardiovascular disease tends to be at an earlier age in these countries.[3] For example, about 50% of coronary deaths occur before age 70 years in India, whereas only 25% occur by that age in high-income countries.[4] Unfavorable global trends in eating patterns, high rates of smoking, and increasing burdens of obesity, diabetes, and hypertension are driving the burden of cardiovascular disease. Although stroke was the dominant cause of death and disability in East Asian countries for decades owing to high sodium intake and resulting hypertension, recent changes in diet, activity levels, and smoking have made coronary heart disease an equivalent or greater health burden in this area of the world.

RISK FACTORS FOR CARDIOVASCULAR DISEASE

ESTABLISHED RISK FACTORS

A number of causal factors have been established for cardiovascular disease based on their strength and consistency of associations, specificity, temporality, and biologic plausibility. Furthermore, these established risk factors explain the vast majority of risk for incident myocardial infarction. Longitudinal cohort studies demonstrate that 90% of individuals who suffer a myocardial infarction have at least one established clinical risk factor prior to their first event, and adverse levels of nine risk factors and behaviors collectively account for 90% or more of the risk for myocardial infarction in men and women, in older and younger individuals, and in all regions of the world. These nine risk factors and behaviors include smoking (Chapter 363), elevated apolipoprotein B/apolipoprotein A1 ratio (Chapter 190), hypertension (Chapter 64), diabetes (Chapter 210), abdominal obesity (Chapter 201), psychosocial factors, lower consumption of fruits and vegetables (Chapter 13), alcohol intake (Chapter 364), and physical inactivity (Chapter 14). Many of the established risk factors tend to cluster in a *metabolic syndrome*, which is characterized by abdominal adiposity, insulin resistance, hyperglycemia, elevated blood pressure, elevated triglyceride levels, and lower high-density lipoprotein (HDL)-cholesterol levels. This clustering of cardiovascular risk factors can lead to synergistic increases in the risk for events.

Age is the most powerful risk factor for the development of most cardiovascular diseases, especially stroke (Chapter 376), heart failure (Chapters 45 and 46), and atrial fibrillation (Chapter 52). Chronologic age integrates a person's aggregate exposure to multiple physiologic and environmental factors on the cardiovascular system. The incidence of cardiovascular disease at least doubles with each additional decade of age in adulthood until the oldest ages, when the heavy burden of competing causes of mortality (Chapter 22) limits further progression. Newer methods of assessing biologic age, as compared with chronologic age, may lead to improved assessment of cardiovascular risk.[5]

The impact of a person's *sex* on cardiovascular disease is important. Women tend to develop risk factors later in life than do men, and women's cardiovascular disease incidence rates lag men's by approximately 10 years. The precise contributions of sex hormones to these age trends are uncertain, but many women develop worsening risk factor levels, particularly with regard to lipids, blood pressure, weight, and insulin resistance, during and after the menopausal transition (Chapter 222). Pregnancy is a cardiovascular stress test, and adverse outcomes of pregnancy are markers of risk for future cardiometabolic disease.[6]

Large disparities in cardiovascular disease are noted by *self-identified race* or ethnicity, but the established causal risk factors have broadly similar effects in all racial and ethnic groups. Hypertension tends to be more prevalent in individuals of African ancestry, especially in environments with higher sodium intake, and to have a somewhat stronger association with cardiovascular events, especially heart failure and stroke. Compared with Whites, individuals of East Asian and South Asian descent have a greater risk for developing metabolic syndrome, insulin resistance, and diabetes at a lower overall body mass index. A substantial proportion of the differences in cardiovascular risks and outcomes observed across race and ethnic groups can be attributed to differences in social determinants of health (education, socioeconomic position, health care access; Chapter 4),[7] but racial differences still exist after considering these factors.[8]

Blood lipid levels (Chapter 190), including the total serum cholesterol level and its subfractions, particularly low-density lipoprotein (LDL) cholesterol, have significant, continuous, and graded associations with the risk of coronary heart disease. Cumulative exposure is more predictive than any single measurement, elevated levels earlier in life are associated with greater risk,[9] and earlier reduction in lipid levels will have greater absolute benefit.[10] By comparison, independent, direct associations of blood lipids with stroke and heart failure events are much weaker. Apolipoprotein B–containing particles comprise the subpopulation of circulating cholesterol-containing particles that represent the atherogenic lipoprotein fractions. These particles are considered to be the central actors in the initiation and promotion of atherogenesis on the basis of a substantial body of epidemiologic, clinical, and basic science evidence. Among U.S. adults aged 20 years and older, 38.1% (or about 94 million) have total cholesterol levels above the desirable range of less than 200 mg/dL, and 11.5% (28 million) have elevated levels at or over 240 mg/dL. Mean total cholesterol levels have been falling sharply in recent decades, because of changes in dietary composition but also because of more widespread use of lipid-lowering medications. In the 1970s, mean total cholesterol concentrations

ABSTRACT

Despite decades of progress in prevention and treatment, cardiovascular disease remains the leading cause of mortality, morbidity, and health care costs in high-income countries, and it has emerged as the leading cause in low- and middle-income countries. A number of modifiable, causal risk factors for cardiovascular disease have been identified, including blood lipid levels, blood pressure, tobacco, dysglycemia, excess body weight, adverse diet, and physical inactivity; collectively they account for the vast majority of excess risk in populations. Individuals who avoid the development of risk factors have very favorable long-term health outcomes and longevity, whereas it is difficult to restore low risk once risk factors have developed. The causal risk factors also tend to cluster and interact additively or synergistically to increase risk. Together, these factors are used to estimate short- and long-term risks for cardiovascular events in individuals and in populations in order to predict the burden of disease and scale the intensity of prevention efforts. Numerous novel blood-based risk markers have been proposed to refine risk assessment, but they have proven less useful than noninvasive imaging modalities (especially measurement of the coronary artery calcium score using computed tomographic imaging) that directly assess the presence and extent of subclinical atherosclerosis disease burden. The advent of genomic and systems biology approaches to studying health and disease in populations, as well as the availability of "big data" phenotypes from electronic health records, are revolutionizing our ability to perform cardiovascular epidemiology on a large scale and with greater precision.

E-FIGURE 40-1. Global burden of cardiovascular disease deaths in 2019 in terms of total deaths (A) and death rates per 100,000 population (B). (Data and visualization from the Global Burden of Disease Study, https://vizhub.healthdata.org/gbd-compare/.)

were approximately 220 mg/dL, whereas currently they are just under 200 mg/dL. These improvements have been a major contributor to the decline in coronary death rates over the same time period. Randomized clinical trials have unequivocally established LDL cholesterol (and the particles that carry it) as a causal agent for coronary heart disease, and LDL cholesterol-lowering therapies (Chapter 190) are effective at reducing rates of both coronary heart disease and stroke significantly and substantially.[A1,11]

Blood pressure (Chapter 64) has a strong, continuous, and independent association with incident coronary heart disease, stroke, and heart failure events. In worldwide studies of nearly one million individuals, the risk at every age for all types of cardiovascular disease death doubled with each 20 mm Hg higher systolic blood pressure and each 10 mm Hg higher diastolic blood pressure, beginning at a blood pressure of 115/75 mm Hg. In 2017, U.S. blood pressure guidelines lowered the definition of hypertension to 130 mm Hg systolic or higher or 80 mm Hg diastolic or higher; under this definition nearly half of U.S. adults have hypertension, and its prevalence has been increasing owing to the obesity epidemic. In the United States, rates of treatment and control were gradually increasing prior to the SARS-CoV-2 pandemic, which caused a significant decline.[12] Hypertension has stronger relative associations with stroke and heart failure than with coronary heart disease, in part because of its effects on myocardial and cerebrovascular remodeling. The effective treatment of hypertension reduces the risk of stroke, heart failure, and coronary heart disease events. Current data suggest that a treatment goal of lower than 120 mm Hg systolic (with an average achieved systolic pressure of 120 to 124 mm Hg) reduces cardiovascular events and all-cause mortality compared with a goal of lower than 140 mm Hg systolic in patients without preexisting heart failure or diabetes.[13] For patients with diabetes, a goal of lower than 130 mm Hg is reasonable.[14]

Cigarette smoking (Chapter 363) is one of the strongest risk factors for cardiovascular disease events. After adjustment for other risk factors, smoking confers two- to three-fold higher risk for all manifestations of cardiovascular disease, especially coronary heart disease and peripheral arterial disease. Fortunately, consistent public health efforts have reduced the prevalence of smoking in the United States from about 45% in the 1960s to just under 15% currently. The prevalence of smoking remains higher in many European and Asian countries, and its continued increase in some parts of the world drives unfavorable trends in cardiovascular morbidity and mortality. A large body of evidence indicates that environmental exposure to tobacco smoke in nonsmokers ("second hand" or "passive" smoking) also increases risk for cardiovascular events substantially (Chapter 363) and contributes to the population burden of disease. Substantial data also support the benefits of smoking cessation for reducing the risks of a subsequent coronary event and death.[15,16]

Overweight and obesity have been increasing in the United States and worldwide. Prior to 1985, fewer than 10% of Americans were obese, defined as having a body mass index of 30 kg/m^2 or higher. Now, however, approximately 70% (170 million) of U.S. adults are overweight or obese, with 40% being obese (Chapter 201). Thirty-five percent (26 million) of U.S. children ages 2 to 19 years are overweight or obese (Chapter 201), with roughly half in each stratum. Major societal changes in the availability of food and in dietary content, coupled with reductions in physical activity, have produced this unprecedented epidemic. Although overweight and obesity themselves tend to be weak independent predictors of cardiovascular events in the short term, they are major drivers of elevated blood pressure, elevated blood glucose levels, and adverse lipid profiles that are themselves major contributors to the incidence of cardiovascular disease in the short and long term. The existence of an "obesity paradox," in which individuals diagnosed with cardiovascular disease who are overweight or obese appear to live longer than normal weight individuals, appears to represent earlier onset of cardiovascular disease owing to overweight, with shorter total longevity and more time spent with cardiovascular disease.[17]

Blood glucose (Chapter 210) and its surrogate marker for chronic levels, hemoglobin A_{1c}, have a continuous and independent association with cardiovascular events.[18] People with diabetes, whether diagnosed or undiagnosed, have two- to three-fold higher adjusted risk for cardiovascular events compared with persons without diabetes, and they also have substantially higher risks for developing chronic kidney disease (Chapter 116). Whereas diabetes was relatively uncommon before the 1980s, the obesity epidemic has led to a dramatic increase in the prevalence of type 2 diabetes and of impaired fasting glucose levels, termed *prediabetes*, with worsening of glycemic control in the United States over the past 20 or so years.[19] At present in the United States, 26 million people, representing 9.8% of all adults, have diagnosed diabetes, and another 9.4 million (about 3.7% of adults) have undiagnosed diabetes. Fully 92 million more adults, or about 38% of adults, currently have prediabetes. Diabetes disproportionately affects non-White racial and ethnic groups, such as American Indians, Black Americans, South Asians, East Asians, and Latinos, who appear to have greater probability of insulin resistance at lower body mass index, in much greater proportions than Whites. Unfortunately, tight control of glucose levels in persons with diabetes has not been associated consistently with significant reductions in risk for macrovascular cardiovascular disease (Chapter 210). However, treatment of type 2 diabetes with sodium-glucose cotransporter-2 inhibitors or glucagon-like peptide-1 receptor agonists can reduce the risk of cardiovascular events (Chapter 210).[A2,20]

Adverse diet (Chapter 13) is a major contributor to obesity, diabetes, hypertension, and dyslipidemia. Healthy eating patterns emphasize a lower caloric intake and focus on fruits and vegetables, healthy fats from nuts and olive oil, lean sources of protein such as fish, whole grains, a reduced sodium intake, and limiting the intake of processed foods, unhealthy fats, and simple sugars.[21] This eating pattern is typical of the Mediterranean diet (Fig. 13-1), which has been shown to be associated with lower cardiovascular disease incidence,[A3,A4] and the similar DASH (Dietary Approaches to Stop Hypertension) eating pattern (Table 13-4). The consumption of more sodium and less potassium is associated with a higher risk of cardiovascular disease,[22] and using a salt substitute (75% sodium chloride, 25% potassium chloride) in patients who have a history of stroke or who are over age 60 years and have hypertension can reduce cardiovascular events and all-cause death.[A5] By comparison, supplemental vitamins, minerals, and n-3 fatty acids, independent of eating pattern, have not been shown conclusively to reduce cardiovascular risk,[A6,A7] even in patients with diabetes or preexisting heart disease.[A8-A10]

Alcohol (Chapter 364) has a complex association with cardiovascular events. Moderate intake of one serving of alcohol per day is associated with a modestly lower risk for cardiovascular disease, but it is unlikely that this association is causal.[23] At higher levels of intake, however, risks for total mortality, hypertension, stroke, and heart failure clearly increase. Whereas heavy alcohol use and patterns of binge use are associated with heart failure and atrial fibrillation, alcohol's association with atherosclerotic cardiovascular disease is less clear.

Physical inactivity (Chapter 14) *and a sedentary lifestyle* are significant risk factors for cardiovascular disease.[24] Individuals who participate in no physical activity are at highest risk for events. The risk is significantly lower for people who participate in even minimal physical activity, and risks decrease further with greater activity levels, particularly to the extent they contribute to higher objective physical fitness. The biology and risks of sedentary time may be more than just the absence of physical activity, since sedentary lifestyle, as measured best by the hours of time spent in front of a television or computer screen, seems to have an adverse effect independent of time spent doing physical activity.

Family history is clearly an important cardiovascular risk factor, independent of other measurable risk factors. Genetic variants that influence cardiovascular risk factors over the lifespan, such as blood pressure and lipid levels, affect lifetime risk even more than would be estimated by adult epidemiologic or intervention studies. However, ideal levels of cardiovascular health do not appear to be genetically programmed. The heritability of ideal cardiovascular health is less than 20%, thereby suggesting strong environmental and behavioral influences on the development of cardiovascular disease.

NOVEL RISK MARKERS

Blood markers of inflammation and *target organ damage* such as C-reactive protein, high-sensitivity troponin, or natriuretic peptide levels have demonstrated significant associations with incident and recurrent cardiovascular events, independent of established risk factors. However, inflammatory markers have contributed very little additional utility for the identification of patients at risk for cardiovascular disease. Measures of myocardial damage in apparently healthy individuals appear to have more potential clinical utility.

Noninvasive cardiac testing and imaging have demonstrated ability to detect preclinical disease and guide appropriate preventive pharmacotherapeutic decisions for higher risk individuals, or avoidance of drug therapy in individuals who are thought to be at risk but do not have evidence of preclinical disease. For example, electrocardiographic evidence of left ventricular hypertrophy confers significant excess risk for coronary heart disease over and above the presence of hypertension and other risk factors. Higher levels of coronary calcification on computed tomographic (CT) imaging of the heart (Chapter 44) or greater carotid intima-media thickness measured by B-mode ultrasound of the carotid arteries portend a higher risk of future cardiovascular events. Because these imaging markers detect evidence of the actual underlying diseases of interest (i.e., left ventricular hypertrophy or atherosclerosis), rather than nonspecific

risk factors, they are more effective at identifying individuals at high risk for incident clinical events, such as heart failure, stroke, and myocardial infarction. Of the available modalities, CT screening for coronary artery calcification is the preferred and widely available means for detecting individuals at near-term risk. For example, asymptomatic individuals with coronary artery calcium scores of more than 100 Agatston units have relative hazards for a coronary event that are 7- to 10-fold higher than in individuals without any coronary calcification, even after adjustment for major established risk factors. Coronary calcium scoring is the most effective and reliable means for reclassifying risk after a quantitative risk assessment using established risk factors,[25] with the ability to more correctly classify lower-risk individuals who nonetheless will have a cardiovascular event as well as higher-risk individuals who will not.

Polygenic risk scores, which can quantify genetic variation across the entire genome, have been examined for their ability to predict risk above and beyond the traditional, routinely measured clinical risk factors. To date, such scores have demonstrated statistically significant but clinically modest ability to add value to cardiovascular risk stratification in middle-aged and older individuals.[26,27]

ASSESSMENT OF RISK FOR CARDIOVASCULAR DISEASE

Estimation of Short-Term Risk

Adverse levels of any single risk factor or risk marker are associated with elevated risk for incident cardiovascular events. However, combinations of adverse risk factors are additive and sometimes synergistic for increasing risk. To improve the prediction of cardiovascular events and provide quantitative risk assessment, a number of multivariable risk equations or scores, such as the Pooled Cohort Equations,[28] have been developed. The vast majority of risk scores available have focused on predicting 10-year absolute risk, and essentially all include age, sex, smoking status, cholesterol, and blood pressure, with some also including diabetes, family history, body mass index, socioeconomic status, or novel biomarkers. The end points of interest for diverse risk equations have varied widely, from the prediction of cardiovascular death alone to the prediction of fatal and nonfatal major coronary events, major atherosclerotic events (coronary disease and stroke), or a broader range of cardiovascular events (including heart failure, coronary revascularization, angina, or claudication). As an example, the 10-year risk for incident atherosclerotic cardiovascular disease can be predicted in 50-year-old men and women according to sex, race, and different levels of risk factors (E-Fig. 40-2), and the risks are dramatically higher with a greater risk factor burden.

Lifetime Risk Estimation

Despite the widespread use of 10-year risk estimates to guide prevention strategies, this approach has important limitations. For example, one consequence of the substantial weighting of age in 10-year risk equations is that younger men and women, even those with substantial risk factor burden, do not tend to have a high short-term risk. When treatment thresholds are applied to quantitative risk estimates for clinical guidelines, men younger than 50 years of age and women under 60 years of age will infrequently exceed those thresholds. Therefore, recent guidelines have considered longer risk horizons, such as 30 years or the remaining lifespan. The established risk factors are all associated with lifetime risks for cardiovascular disease, but the nature of the relationships sometimes differs from short-term associations because of competing risks. For example, smoking is a strong risk factor for near-term cardiovascular events but a weaker discriminator of lifetime risk for cardiovascular events because of the simultaneous and substantial risk for cancer death, which limits the lifetime risk for cardiovascular disease among smokers. As a result, lifetime risk estimates may enhance communication for individual patients, but how they should be used in decision making regarding the institution of preventive drug therapy in younger individuals is less certain.

PREVENTION OF CARDIOVASCULAR DISEASE

Because patients with prevalent cardiovascular disease are at the highest risk, preventive interventions such as lifestyle modifications and drug therapy to reduce risk are most effective and cost-effective when used as therapy for secondary prevention of recurrent events, or complications such as heart failure. Examples of intensive lifestyle modification and of proven therapies include cardiac rehabilitation, antiplatelet therapy, LDL cholesterol–lowering therapy, antihypertensive medications, mineralocorticoid receptor antagonists, and certain classes of diabetes medications, as well as implantable devices that may prevent complications such as fatal ventricular dysrhythmias (Chapter 54).

For primary prevention, asymptomatic individuals may be at risk because of a heritable family history of premature cardiovascular disease, one or more markedly elevated risk factors, or multiple modestly elevated risk factors. Aspirin has no net benefit over placebo in healthy elderly individuals, in whom it actually reduces disability-free survival and overall survival,[A11,A12,29] without significantly reducing the risk of cardiovascular disease.[A13] Even in patients with diabetes or patients at moderate risk of cardiovascular disease, any benefits for preventing future cardiovascular events are offset by aspirin's side effects.[A14-A16]

The current primary prevention paradigm is to match the intensity of prevention efforts to the absolute risk of the patient.[A17] Appropriate lifestyle interventions (e.g., smoking cessation, weight loss, dietary modification) are recommended for all individuals, whereas drug therapy is recommended only for individuals in whom the absolute benefits can be expected to outweigh any potential adverse drug effects and to be cost-effective in doing so. In underserved or resource-limited settings, polypill formulations containing a statin plus several blood pressure–lowering medications in one pill, with or without aspirin, have been effective in reducing lipid levels, blood pressure,[A18] and even major cardiovascular events[A19-A21] compared with placebo or usual care. Treatment that restores optimal risk factor levels, however, does not imply that the treated individual will now have the very low incidence rates observed in people who have maintained optimal risk factor levels throughout young adulthood and into middle age. As a result, a concept gaining in importance is *primordial prevention*, which is the prevention of the development of risk factors in the first place. Primordial prevention requires a focus on health behaviors that may prevent the development of dyslipidemia, diabetes, and hypertension, as well as population-level strategies that attempt to create an environment conducive to favorable health behaviors. Mobile applications may help with the self-management that is likely critical for such efforts.[29]

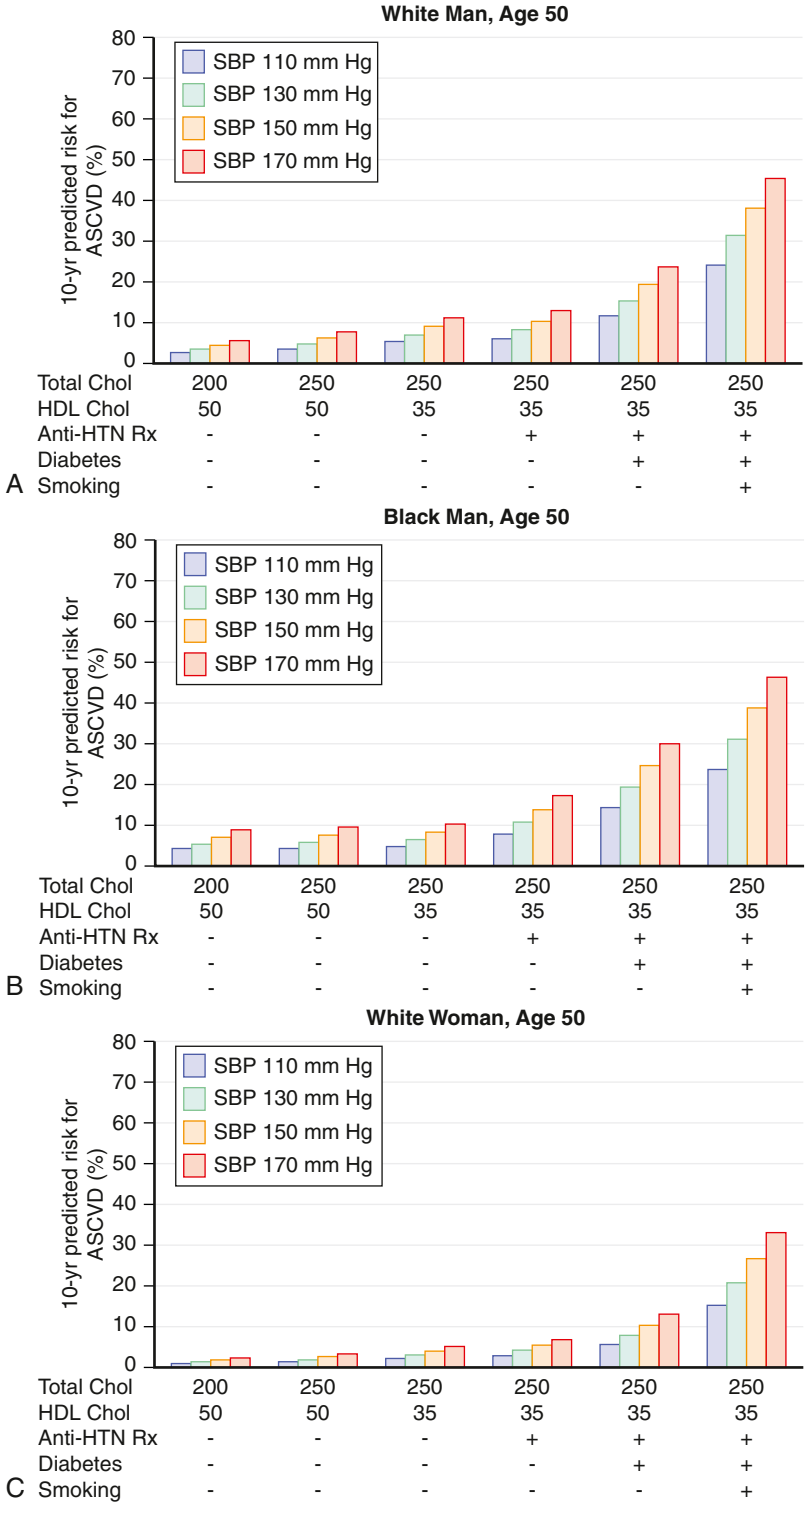
CARDIOVASCULAR HEALTH: A NEW PARADIGM

In addition to resuming declines in mortality rates from cardiovascular diseases and stroke in the United States, a newer goal is to promote cardiovascular health in individuals and the population, monitor it over time, and improve it by concerted action. Central to the concept of cardiovascular health is the observation that optimal levels of seven health behaviors and health factors (Table 40-1) are associated with ideal cardiovascular health. Although about 40% of American adults believe they are in ideal cardiovascular health, fewer than 1% have all seven metrics at ideal levels, principally because of a poor-quality diet. Persons who maintain high levels of cardiovascular health from young age to middle age have extremely favorable outcomes from middle to older ages,[30] including: a markedly increased longevity; a better quality of life; a substantially lower incidence of fatal and nonfatal cardiovascular disease events; a lower incidence of other chronic diseases of aging, including cancer, dementia, and venous thromboembolism; a lower burden of subclinical atherosclerosis (e.g., carotid intima-media thickness, coronary artery calcification); higher levels of cognitive function in middle and older ages; and reduced medical care costs. These outcomes are observed in all segments of the population, as well as across all ages and both sexes.

People who pursue healthy lifestyles from young adulthood to middle age are far more likely to preserve ideal cardiovascular health than those who pursue none: 60% of the former group compared with only 3% of the latter group maintained ideal cardiovascular health factors into middle age. Cardiovascular health promotion thus represents a major paradigm shift and opportunity in public health efforts. If even 50% of U.S. adults could preserve ideal cardiovascular health into mid-life, an estimated 900,000 events would be prevented annually.[31]

FUTURE OF CARDIOVASCULAR EPIDEMIOLOGY

Decades of success in observational epidemiology research continue to provide novel insights into trends and risk markers for cardiovascular disease, as well as the influence of in utero and early life exposures on the life course of cardiovascular diseases. New techniques to characterize environmental and behavioral exposures, physiology, health status, and precursors of disease include epigenetics, proteomics, metabolomics, and high-resolution imaging. With these tools, epidemiologic research has advanced to improve the characterization of the life course of cardiovascular diseases in living individuals and populations and to understand the complex interplay of genes and environment. For example, studies of the genotypes of individuals at the extremes of the distribution of LDL cholesterol levels led to the discovery of polymorphisms in the proprotein convertase subtilisin/kexin type 9 (*PCSK9*) gene. Although such polymorphisms are uncommon, specific missense and nonsense mutations in White and Black men and women are associated with significantly lower lifelong levels of LDL cholesterol and substantially lower lifetime risks for coronary heart disease. *PCSK9* has since become an established therapeutic target for reducing atherosclerotic cardiovascular risk. Other genes discovered



E-FIGURE 40-2. **Predicted 10-year risks for atherosclerotic cardiovascular disease, including fatal coronary heart disease, nonfatal myocardial infarction, and fatal or nonfatal stroke, as a function of selected risk factor levels in a 50-year-old White man (A), Black man (B), White woman (C) or Black woman (D).** (Predicted risks are derived from the Pooled Cohort Equations used in Arnett DK, Blumenthal RS, Albert MA, et al. 2019 ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease. *Circulation*. 2019;140:e596-e646.)

TABLE 40-1 DEFINITIONS OF POOR, INTERMEDIATE, AND IDEAL CARDIOVASCULAR HEALTH FOR EACH OF SEVEN METRICS IN ADULTS AND CHILDREN

METRIC	POOR	INTERMEDIATE	IDEAL
CURRENT SMOKING			
Adults	Yes	Former, ≤12 mo	Never or quit >12 mo
Children	Tried in last 30 days	—	Never tried; never smoked whole cigarette
BODY MASS INDEX			
Adults	30 kg/m^2	25-29.9 kg/m^2	<25 kg/m^2
Children	>95th percentile	85th-95th percentile	<85th percentile
PHYSICAL ACTIVITY			
Adults	None	1-149 min moderate or 1-74 min vigorous activity per week	≥150 min moderate or ≥75 min vigorous activity per week
Children	None	1-59 mins moderate or vigorous activity daily	≥60 mins moderate or vigorous activity daily
HEALTHY DIET SCORE*			
Adults	Meets 0-1 components	Meets 2-3 components	Meets 4-5 components
Children	Meets 0-1 components	Meets 2-3 components	Meets 4-5 components
TOTAL CHOLESTEROL			
Adults	≥240 mg/dL	200-239 mg/dL or treated to goal	<200 mg/dL untreated
Children	≥200 mg/dL	170-199 mg/dL	<170 mg/dL untreated
BLOOD PRESSURE			
Adults	SBP ≥140 mm Hg or DBP ≥90 mm Hg	SBP 120-139 mmHg or DBP 80-89 mm Hg or treated to goal	<120/<80 untreated
Children	>95th percentile	90th-95th percentile or SBP ≥120 mm Hg or DBP ≥80 mm Hg	<90th percentile untreated
FASTING GLUCOSE			
Adults	≥126 mg/dL	100-125 mg/dL or treated to goal	<100 mg/dL untreated
Children	≥126 mg/dL	100-125 mg/dL or treated to goal	<100 mg/dL untreated

*Healthy diet score consists of five components, including low sodium intake, low sugar-sweetened beverage consumption, and higher consumption of fruits/vegetables, fish, and whole grains.
DBP = diastolic blood pressure; SBP = systolic blood pressure.
Adapted from Coorey GM, Neubeck L, Mulley J, et al. Effectiveness, acceptability and usefulness of mobile applications for cardiovascular disease self-management: systematic review with meta-synthesis of quantitative and qualitative data. *Eur J Prev Cardiol*. 2018;25:505-521.

through genetic epidemiology investigations, such as the angiopoietin-like 3 gene (*ANGPTL3*), are also rapidly becoming therapeutic targets.[A22]

A second emerging focus in cardiovascular epidemiologic research has been the study of effects of interventions in populations through public health and social policies. For example, studies have demonstrated marked reductions in hospitalizations for acute myocardial infarction occurring rapidly after the initiation of indoor smoking bans in diverse settings. Modeling studies have synthesized data from numerous epidemiologic sources to show that approximately 50 to 75% of the reductions in coronary death rates in Western countries may be attributable to population changes in risk factor levels, despite being offset by a recent worsening in obesity and diabetes prevalence, with the remainder likely attributable to advances in medical and surgical therapies. The widespread availability of electronic health records and wearable device technologies offer substantial promise for future cardiovascular epidemiology studies in ever-larger and well-defined segments of the population.

41 CARDIAC AND CIRCULATORY FUNCTION

ANDREW R. MARKS

The heart has the daunting task of pumping sufficient amounts of blood to meet both its own metabolic demands and those of the other organs. Unique among all the organs, the heart's failure to perform its task for even a few minutes causes death. The heart continuously fulfills this physiologic role with a variety of electrical, contractile, and structural functions that control the flow of blood to the organs.

STRUCTURE OF THE HEART

CARDIAC DEVELOPMENT

In humans, the formation of a linear heart tube from the primary cardiac crescent occurs between days 21 and 23 of gestation. Looping of the heart tube and trabecular formation of the ventricle occur at 26 days of gestation (E-Fig. 41-1). At 6 weeks, the embryonic interventricular communication closes, followed by thickening and remodeling of the ventricular walls in the first trimester. By the end of week 7, heart development is essentially finished, although the heart continues to enlarge throughout gestation.

ELECTRICAL CELLS

The heart is a muscular pump controlled by regular electrical discharges from specialized muscle cells in the conduction system (Chapter 48). The molecular basis for the electrical activity of the heart is the activation of specific ion-conducting channels (Fig. 41-1). Coordinated activation and inactivation of cardiac ion channels regulate the membrane potential of the cardiac cells, thereby resulting in a rapid sequence of depolarization followed by repolarization. This electrical activity, which is manifested on the body surface as the electrocardiogram (ECG), is known as the action potential, and it is responsible for activating the contraction of the cardiac muscle. At a typical heart rate of 70 beats per minute, the heart beats about 100,000 times per day, or 37 million beats a year, corresponding to 3 billion beats during a lifespan of 80 years. Failure to propagate the signal throughout the heart (e.g., heart block) or abnormal rhythms (arrhythmias) that are either too slow (bradycardia) or too fast (tachycardia) can result in death (Chapter 49). Studies indicate that cardiac arrhythmias may be triggered by leak of calcium inside the cardiomyocytes, thereby suggesting a possible novel therapeutic target for a new generation of antiarrhythmic agents.

ION CHANNELS

Sodium, potassium, and calcium channels determine the electrical activity of the heart by opening and closing in a highly choreographed pattern that determines the action potential of the heart. The electrical regulation of the heart, which is reflected in the relative concentrations of ions inside and outside the heart muscle cells, determines the five phases of the action potential (Chapter 48). The action potential is initiated when the opening of sodium channels results in a rapid influx of sodium (phase 0) down its concentration gradient (≈145 mmol outside the heart muscle cell, ≈10 mmol inside). After a brief early repolarization due to activation of potassium channels (phase 1), the rapid sodium influx depolarizes the cell, thereby activating calcium channels that allow calcium influx (phase 2) down its concentration gradient (≈3 mmol outside, ≈100 nmol inside). This calcium influx triggers excitation-contraction coupling that results in pumping by the heart. Potassium channels then open and cause repolarization (phase 3) as potassium fluxes out of the cell down its concentration gradient (≈4 mmol outside, ≈135 mmol inside). The membrane potential returns to the resting level of about −90 mV (phase 4). Genetic mutations in the genes encoding ion channels have been linked to inherited forms of ventricular and atrial arrhythmias (Chapters 52 and 53).

CONDUCTION SYSTEM

Specialized pacemaker cells in the sinoatrial node (Fig. 41-2) have slightly higher (less negative) resting potentials and gradually depolarize during phase 5 owing to the activity of the potassium and calcium channels and the hyperpolarization-activated cyclic nucleotide–gated channels that are responsible for a small inward (depolarizing) current. In the normal heart, pacemaker cells are the first cells to depolarize, and they trigger the subsequent depolarization of the cells in specialized conducting fibers that propagate the electrical signal throughout the heart muscle in a highly regular and integrated fashion. Electrical activation (depolarization) spreading through the atria to the atrioventricular (AV) node is reflected as the P wave on the ECG (Chapter 42). The slowing of conduction in the AV node accounts for the PR interval on the ECG. After passing through the AV node, the depolarizing signal enters the bundle of His,

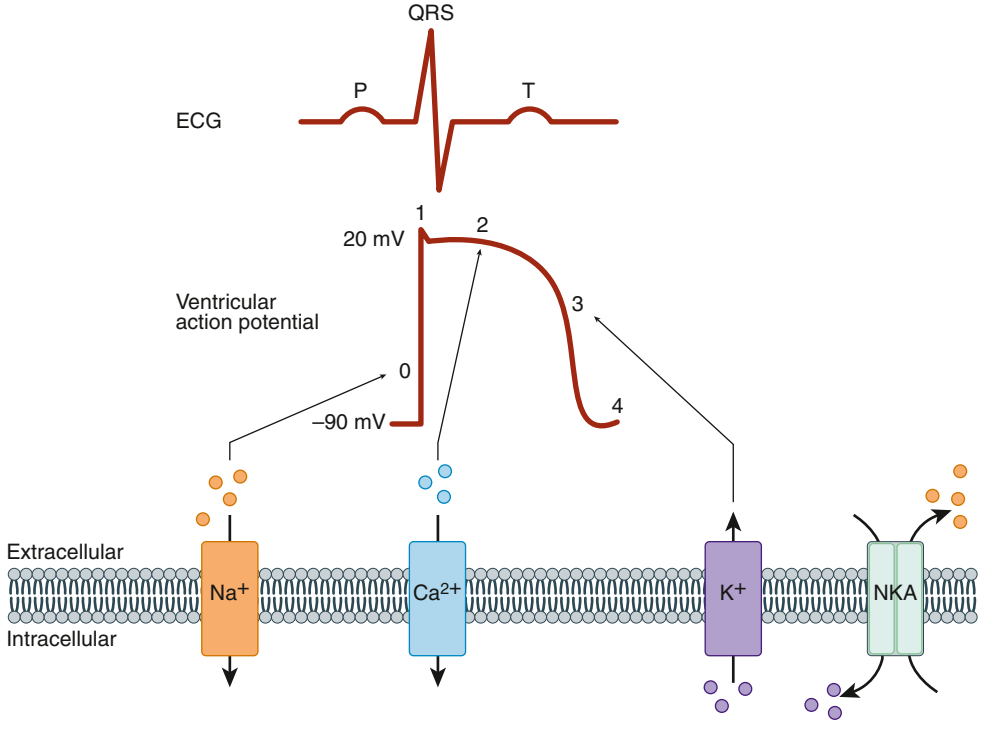

FIGURE 41-1. Cardiac action potential and ion channels. Myocardial contraction begins when sodium channels open and positively charged sodium ions flow into the cell and cause membrane depolarization (phase 0). During phases 1, 2, and 3, calcium ions flow into the cell through L-type calcium channels, while potassium flows out of the cell through voltage-gated potassium channels. These three phases correspond to myocardial contraction, which corresponds to the QRS complex on the surface electrocardiogram (ECG). The sodium-potassium adenosine triphosphatase (NKA) helps return the system to its resting state.

ABSTRACT

The heart is a large muscle with four chambers and a complex electrical system that activates contraction to supply blood flow to all organs. A reduction in heart-driven blood flow quickly results in organ failure and ultimately in death. Over the past two centuries, detailed understanding of heart development and function has been accumulated. Moreover, we also have learned a great deal about the circulatory system, how it develops, and how it is regulated. However, there is much we do not understand. For example, occlusion of coronary arteries that supply blood to the heart muscle by atherosclerosis cause heart muscle death. Loss of heart muscle leads to heart failure, but few effective drugs are available to treat this leading cause of death. Similarly, the electrical system of the heart, controlled by ion channels, results in fatal heart rhythms when ion channel function is defective. Understanding of this system also remains limited, such that safe and effective drug treatments for arrhythmias are largely lacking. Nevertheless, the heart performs an amazing function, beating steadily, for the most part, throughout life.

E-FIGURE 41-1. Folding of the heart tube during development. The primitive outflow tracts develop into the pulmonary artery and aorta. The left and right atria, along with the pulmonary veins and the superior and inferior vena cava, arise from the primitive inflow tracts. The area covered by the bulbus cordis and ventricle contributes to the development of the left and right ventricles.

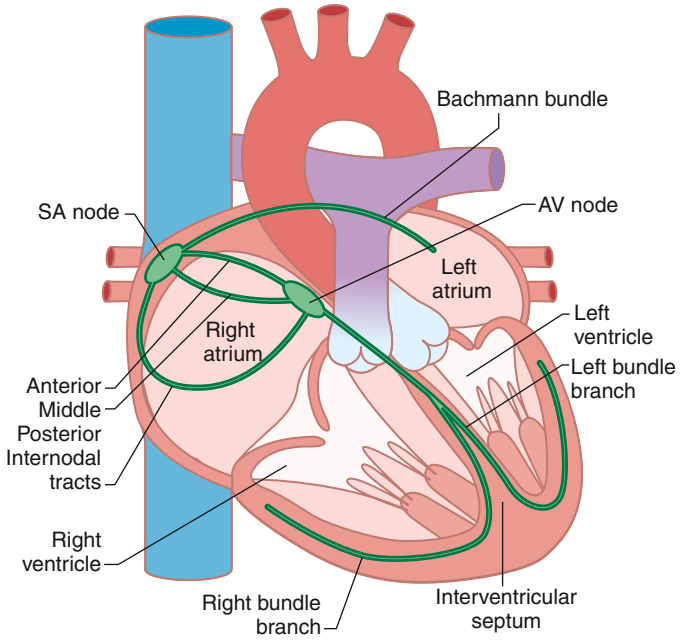

FIGURE 41-2. Cardiac anatomy. Cardiac anatomy comprises electrical and structural components. The electrical impulse that directs cardiac contraction originates in the sinoatrial (SA) node and is rapidly conducted through the atria by specialized conduction tracts. The impulses merge at the atrioventricular (AV) node, where, after a brief pause, they are rapidly conducted into the ventricles through the bundle of His, which is composed of specialized Purkinje cells. Blood moves from the atria into the ventricles through the tricuspid and mitral valves, respectively, during diastole. During systole, blood from the ventricles is pumped into the pulmonary artery and aorta through the pulmonic and aortic valves, respectively.

where conduction is rapid. The bundle of His divides into the right and left bundle branches, which conduct the depolarizing signals into the ventricles and account for the QRS complex on the ECG. Repolarization is represented by the ST segment and the T and U waves of the ECG.

CONTRACTILE CELLS

Heart muscle is composed of billions of individual cells known as cardiomyocytes, which contain an elaborate machinery required for coordinated contraction that pumps blood. Each cardiomyocyte is connected to its neighbors through specialized junctions that enable them to work as a single contractile unit.

The cardiomyocytes are filled with specialized contractile proteins arranged in highly regulated units, called sarcomeres, that give the muscles characteristic patterns known as striations (E-Fig. 41-2). Hence, like skeletal muscle, cardiac muscle is termed striated, as opposed to smooth muscles that form the vasculature and other organs such as the bladder, uterus, and stomach. Cardiomyocytes are also loaded with mitochondria that provide the energy (adenosine triphosphate [ATP]) required to fuel the heart's lifelong contractions (systole) and relaxations (diastole).

ULTRASTRUCTURE

The basic unit of the contractile system is the sarcomere, which is defined anatomically as the distance between two Z lines that anchor thin filaments composed of actin, tropomyosin, and troponin. Thin filaments slide past thick filaments (composed of myosin and titin) in a calcium-dependent manner to shorten the sarcomere length. Mutations in the genes encoding contractile proteins have been linked to dilated and hypertrophic cardiomyopathies (Chapter 47).[1,2] The contractile proteins are surrounded by a calcium-filled membrane called the sarcoplasmic reticulum. The sarcoplasmic reticulum forms specialized associations with the transverse tubules, which are invaginations of the plasma membrane and contain voltage-gated calcium channels. When the muscle is activated by depolarization of its membrane, this electrical signal travels deep into the muscle through the transverse tubules. Inside the muscle, the electrical depolarizing signal activates the voltage-gated channels, which open to allow a small amount of calcium to enter the muscle cells. This influx of calcium in turn activates the type 2 ryanodine receptor (RyR2), calcium-release channels on the sarcoplasmic reticulum. The RyR2 channels open and release enough calcium from the sarcoplasmic reticulum to raise the calcium concentration in the myoplasm about 10-fold. As a result, calcium binds to troponin C in the thin filaments and causes a conformational change that enables cross-bridging between actin and myosin, thereby leading to sliding of the filaments, shortening of the sarcomere, and muscle contraction. Hydrolysis of ATP provides the energy required for the generation of force by the actin-myosin interaction. The conversion of electrical energy (depolarization of the cell membrane) to mechanical energy is known as excitation-contraction coupling. Relaxation of the heart muscle occurs when calcium is pumped back into the sarcoplasmic reticulum through the sarcoendoplasmic reticulum ATPase.

Signals That Regulate Contraction

Contractile force can be enhanced during stress by activation of the β-adrenergic pathway, which increases both the amount of calcium released and the rate of calcium uptake in the sarcoplasmic reticulum (E-Fig. 41-3). β-Agonists (e.g., epinephrine or norepinephrine) bind to β-adrenergic receptors to activate adenylyl cyclase, which generates cyclic adenosine monophosphate and activates protein kinase A. Protein kinase A phosphorylates phospholamban, the voltage-gated calcium channel, the ryanodine receptor/calcium release channel, and sarcomeric regulatory proteins, thereby resulting in increased release of calcium from the sarcoplasmic reticulum and enhanced contractility of the heart.

Nonmuscle Cells

Although the heart is a muscular pump, 60 to 70% of its cells are cardiac fibroblasts, not muscle cells. These fibroblasts provide critical components of the extracellular matrix that determine the structure of the heart. Collagen, which is produced by the cardiac fibroblasts, is a major component of the extracellular matrix, where it forms a network that surrounds the cardiomyocytes and creates tissue that is able to withstand the stress of constant pumping. In certain pathologic conditions, including hypertension, myocardial infarction, and heart failure, the cardiac fibroblasts respond to stress by generating excess extracellular matrix, resulting in fibrosis, which can impair cardiac function.[3] Indeed, a number of commonly used therapies for heart disease, including lipid lowering with statins or fibrates and antihypertensive treatments with angiotensin-converting enzyme inhibitors, β-blockers, and angiotensin receptor blockers, exert part of their beneficial effects on cardiac fibroblasts by reducing fibrosis, thereby resulting in favorable "reverse" remodeling of the heart. Resident fibroblast lineages mediate pressure overload–induced cardiac fibrosis.

ANATOMY OF THE HEART

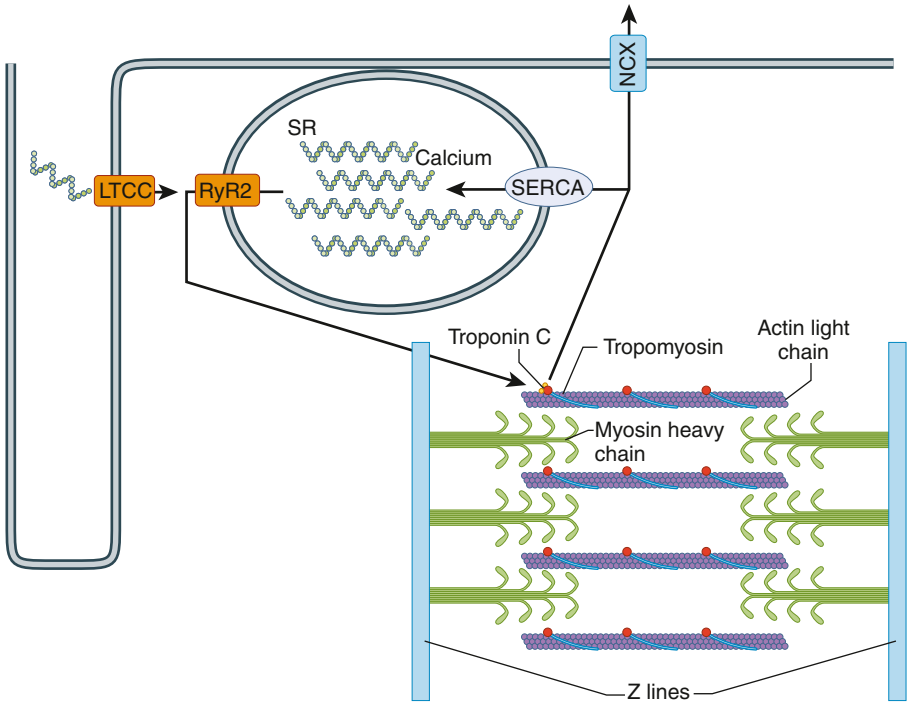
The primary pumping chamber of the heart is the thick-walled left ventricle, which is composed of billions of cardiomyocytes connected end to end through gap junctions. The right ventricle is a thinner-walled chamber, divided from the left ventricle by the *interventricular septum*. Above the ventricles are the right and left atria, which are thin-walled chambers that receive low-pressure venous blood; they are separated from the ventricles by the *tricuspid valve* on the right side and the *mitral valve* on the left side. These valves are attached to *papillary muscles* that emerge from the ventricular walls through *chordae tendineae*. The pressure gradient between the ventricles and the atria opens the AV valves. The papillary muscles help establish the positions of the valve leaflets and prevent regurgitant flow during contraction. The *aortic and pulmonary valves* separate the left and right ventricles from their arterial connections and enable blood flow out of the ventricles.

CORONARY BLOOD FLOW

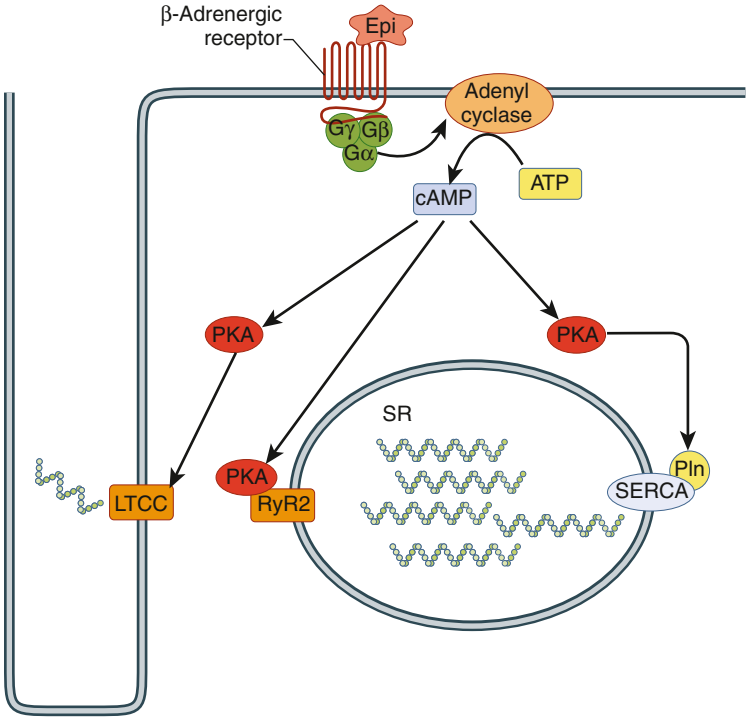
The coronary arteries receive blood from the aorta, directly above the aortic valve, and travel through the epicardium that surrounds the heart to supply blood to the heart muscle (see Fig. 59-1 in Chapter 59). The diastolic blood pressure in the ascending aorta just above the aortic valve determines most of the flow of blood into the normal (nonstenosed) coronary arteries while the heart is relaxed. During systole, coronary flow is determined by the left ventricular intracavitary pressure, which equals the pressure within the inner myocardial wall, where coronary arteries are compressed during systole. Coronary blood flows to the epicardium during both systole and diastole but flows to the endocardium predominantly during diastole.

METABOLIC REGULATION OF THE CARDIOVASCULAR SYSTEM

Cardiac muscle requires constant coronary perfusion to supply oxygen and other metabolites. Increased energy consumption due to enhanced contractility necessitated by increased pressures or higher heart rates (e.g., during exercise) can be met only by increased coronary blood flow. Signals that augment coronary blood flow (by up to six-fold) include nitric oxide, adenosine, bradykinins, prostaglandins, and carbon dioxide. The breakdown of ATP is the



E-FIGURE 41-2. Sarcomere and excitation-contraction coupling. Depolarization of the cell membrane leads to calcium influx through L-type calcium channels (LTCC), which activate ryanodine receptors (RyR2) to release the large calcium stores from the sarcoplasmic reticulum (SR). Calcium binds to troponin C and induces a conformational change in tropomyosin, which enables myosin heads to interact with actin filaments and to cause contraction. During relaxation, calcium is pumped back into the sarcoplasmic reticulum through the sarcoendoplasmic reticulum calcium ATPase (SERCA) and out of the cell through the sodium-calcium exchanger (NCX).



E-FIGURE 41-3. Cardiomyocyte signaling. Binding of catecholamines (epinephrine, norepinephrine) to β-adrenergic receptor, a G-coupled protein receptor, leads to activation of adenyl cyclase, which converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). cAMP activates protein kinase A (PKA), which phosphorylates multiple calcium-handling proteins, including L-type calcium channels (LTCC), ryanodine receptors (RyR2), and phospholamban (Pln), leading to a general increase in their activity and greater contractility. Epi = epinephrine; SERCA = sarcoendoplasmic reticulum calcium ATPase; SR = sarcoplasmic reticulum.

source of adenosine, whereas nitric oxide is produced by the action of nitric oxide synthases that metabolize the amino acid L-arginine. Autoregulatory mechanisms, including constriction in response to increased luminal pressures and dilation in response to reduced pressure, also play a role in determining coronary artery blood flow. Other metabolic factors that cause vasoconstriction include endothelin peptides, serotonin, 5-hydroxytryptamine, thromboxane, angiotensin II, and β_1-adrenergic stimulation.

Sympathetic and parasympathetic pathways of the autonomic nervous system and the renin-angiotensin system exert potent regulatory effects on cardiovascular function. The sympathetic nervous system plays the key role in the response to stress (e.g., the fight-or-flight response) by increasing heart rate and myocardial contractility and decreasing vascular tone. Regulation of cardiovascular function by the sympathetic nervous system is mediated by norepinephrine that is released at the nerve endings and by epinephrine from the adrenal gland. β-Adrenergic signaling is mediated by epinephrine, which increases the heart rate and vasodilates the central arterial bed, thereby resulting in reduced afterload, which in turn helps augment cardiac output.

The sinoatrial and AV nodes are regulated by parasympathetic innervation that slows the pacemaker's rate of firing and conduction through the AV node by the release of acetylcholine. Vasoconstriction of the venous system is mediated by the sympathetic nervous system, which limits fluid and blood loss after trauma.

The renin-angiotensin system also regulates blood pressure, peripheral vasoconstriction, and contractility in coordination with the sympathetic nervous system. Both the sympathetic nervous system and the renin-angiotensin system are chronically activated in heart failure (Chapter 45), in which the resulting maladaptive remodeling of the cardiovascular system promotes the progression of heart failure. Decreased perfusion to the kidney, decreased delivery of sodium to the macula densa, or increased sympathetic activity results in the release of the hormone renin from the macula densa cells within the juxtaglomerular apparatus of the kidney. Renin results in the production of angiotensin II, a potent constrictor of peripheral and coronary arteries. In turn, angiotensin II causes the release of the sodium-retaining hormone aldosterone from the adrenal gland (Chapter 208). Together, these signals result in sodium retention and increased arterial blood pressure.

PHYSIOLOGY OF THE HEART AND CIRCULATORY CONTROL

CARDIAC ENERGETICS

The major immediate source of energy in the heart is the oxidation of fatty acids and glucose. When oxygen supply is limited, glucose metabolism is favored because it generates more ATP per oxygen consumed. The heart has virtually no ability to conduct anaerobic metabolism (i.e., glycolysis) and therefore is dependent on oxygen for its function. For example, heart function deteriorates immediately under conditions of hypoxia, ischemia, and carbon monoxide poisoning.

Basal metabolism, total mechanical work performed by the heart, contractility, and heart rate determine the oxygen and energy consumption of the heart. During excitation-contraction coupling, two key steps require energy consumption (ATP hydrolysis): release of the myosin head–actin interaction and reuptake of calcium into the sarcoplasmic reticulum.

The mechanical work of the heart is determined by the total *pressure-volume area*, which is related to the number of actin-myosin cross-bridges formed during the contraction. It is the sum of the external work performed by the heart in pumping blood from the ventricle to the aorta (represented by the area inside the pressure-volume loop) plus energy stored in the myocardium at the end of contraction. Enhanced contractility requires increased oxygen consumption because an increased amount of calcium released from the sarcoplasmic reticulum requires increased ATP and oxygen consumption to pump the released calcium back into the sarcoplasmic reticulum through the sarcoplasmic reticular ATPase. On the basis of these principles, increasing the heart rate requires increased oxygen consumption. If the heart rate increases from 70 to 140 beats per minute during exercise or stress, oxygen consumption increases almost two-fold above the basal value.

CONTRACTILITY AND RELAXATION

The Cardiac Cycle

In resting humans, the heart beats approximately once per second. With each beat, the heart cycles through a series of four hemodynamic events represented by changes in pressures and volumes (E-Fig. 41-4) as well as electrical activity as represented by the ECG. When the heart muscle is relaxed at end diastole, the ventricular pressure is at its resting level (*end-diastolic pressure*) and the ventricular volumes are at their maximal value (*end-diastolic volume*). Aortic pressure declines as the blood ejected into the aorta during the previous ventricular contraction flows to the peripheral circulation. Atrial contraction provides a final boost to ventricular volume immediately before ventricular systole. Ventricular contraction increases the pressure in the ventricle; when this pressure exceeds the pressure in the atrium, the mitral valve closes. However, because ventricular pressure remains less than aortic pressure, the aortic valve remains closed, and no blood enters or leaves the ventricle during this first phase of the cardiac cycle, the *isovolumic contraction* phase. During systole, ventricular pressure eventually exceeds aortic pressure, at which time the aortic valve opens, blood is ejected into the aorta, and ventricular volume decreases during the *ejection* phase of the cycle. At the end of systole when contraction is maximum, ejection ends, and the ventricular volumes are at their lowest (*end-systolic volume*). The volume of the ejected blood, which is termed the stroke volume (SV), is defined as the difference between the end-diastolic and end-systolic volumes. The ejection fraction (EF), defined as the percentage of end-diastolic volume (EDV) ejected during a contraction ($EF = 100 \times SV/EDV$), is an index of heart function. The next phase in the cycle occurs when the heart muscle relaxes, ventricular pressures are less than the aorta pressure, and the aortic valve closes. During this *isovolumic relaxation* phase, ventricular volumes remain constant because, once again, both the mitral and aortic valves are closed. When ventricular pressures fall below atrial pressures, the mitral and tricuspid valves open, and blood flows from the atria into the ventricles during the *filling* phase.

These four phases of the cardiac cycle can be represented by a *pressure-volume diagram* (E-Fig. 41-5), which plots the instantaneous ventricular pressure versus volume to calculate the *pressure-volume loop*. Similar effects occur on the left and right sides of the heart, but with higher pressures on the left side (Table 41-1).

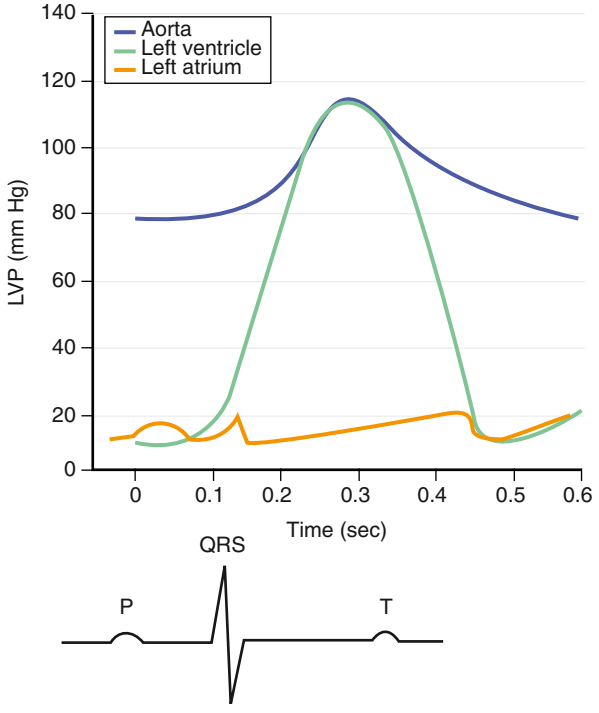
Pressure-Volume Relationships

The volume of a ventricular chamber correlates with length of its muscles and sarcomeres. In the left ventricle, with its circular cross section, Laplace's law defines the relationship among pressure in the chamber (P), muscle tension (T, force/unit cross-sectional area of the muscle), chamber wall thickness (h), and internal radius of the chamber (R): $P \approx 2 \cdot T \cdot h/R$. Both calcium and the length of the heart muscle determine force (Fig. 41-3). Each muscle is composed of a linear array of sarcomere bundles. Maximal force is achieved at a sarcomere length of about 2.2 to 2.3 μm, which results in the optimal overlap of thick and thin filaments. When the sarcomere length is less than 2.0 μm, the ends of the thin filaments contact each other, thereby resulting in a reduction in force. Conversely, when sarcomeres are stretched beyond 2.3 μm, force decreases owing to reduced overlap between myosin heads and actin.

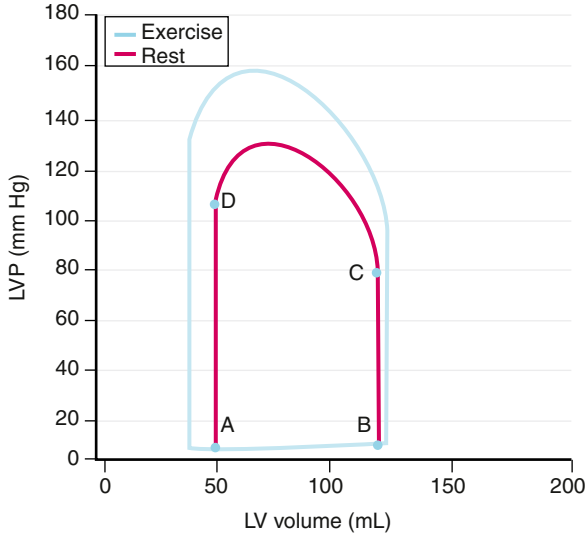
Force-length relationships, which are determined by measuring the force developed at different muscle lengths while preventing the muscle from shortening (isometric contractions), characterize the systolic and diastolic contractile properties of cardiac muscle. With increasing muscle length, end-systolic force increases to a greater degree than does end-diastolic force. The

TABLE 41-1 RANGE OF NORMAL RESTING HEMODYNAMIC VALUES

PRESSURE
Central venous (mean): 0-5 mm Hg
Right atrial (mean): 0-5 mm Hg
Right ventricular (systolic/diastolic): 20-30/0-5 mm Hg
Pulmonary artery (systolic/diastolic): 20-30/8-12 mm Hg
Left atrial (mean): 8-12 mm Hg
Left ventricular (systolic/diastolic): 100-150/8-12 mm Hg
Aortic (systolic/diastolic): 100-150/70-90 mm Hg
VOLUME-RELATED MEASURES
Right ventricular end-diastolic volume: 70-100 mL
Left ventricular end-diastolic volume: 70-100 mL
Stroke volume: 40-70 mL
Cardiac index: 2.5-4 L/min/m^2
Ejection fraction: 55-70%
ARTERIAL RESISTANCE
Systemic vascular resistance: 10-20 mm Hg · min/L
Pulmonary vascular resistance: 0.5-1.5 mm Hg · min/L



E-FIGURE 41-4. **Wiggers diagram.** Changes in aortic, left ventricular, and left atrial pressures represented graphically as a function of time, with the corresponding electrocardiogram signal for each. LVP = left ventricular pressure.



E-FIGURE 41-5. **Pressure-volume loop.** The left ventricle (LV) begins to fill when pressure in the chamber falls below that of the left atrium, and the mitral valve opens (point A). Pressure in the ventricle slowly rises as the muscle fibers are stretched by the increasing volume. When the myocardium contracts (point B), pressure in the left ventricle rises, causing the mitral valve to close and trapping the blood inside the chamber (isovolumic contraction). When the pressure in the left ventricle is higher than in the aorta, the aortic valve opens (point C), and blood is ejected out of the left ventricle. As the left ventricle stops contracting, pressure in the aorta becomes higher than that in the left ventricle, and the aortic valve closes (point D). During this period of isovolumic relaxation, the ventricle rapidly relaxes until it starts filling again. During exercise, the release of norepinephrine from sympathetic nerve terminals leads to enhanced myocardial contractility. As a result, the left ventricle generates higher pressures and ejects a greater volume of blood during each beat. LVP = left ventricular pressure.

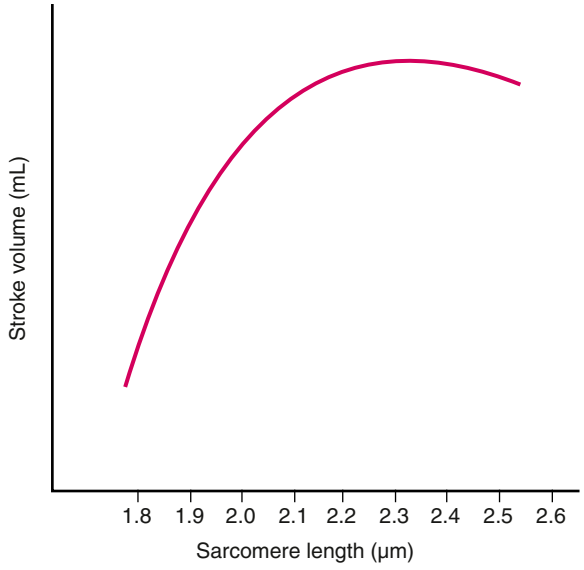


FIGURE 41-3. Frank-Starling law. Cardiac output, represented as stroke volume (end-systolic volume minus end-diastolic volume), as a function of initial sarcomere stretch. The greater the initial stretch on the fibers during diastole, referred to as preload, the more force is generated during systole.

difference in force at end diastole versus end systole increases as muscle length increases as a result of the greater developed force of the stretched muscle. This relationship of force to length is referred to as the Frank-Starling law of the heart.

Work of the Heart

Cardiovascular performance is reflected in the arterial blood pressure and cardiac output (mean arterial blood flow), which in turn are dependent on four factors: preload, afterload, ventricular contractility, and heart rate.

Preload, which refers to the degree to which sarcomeres are stretched just before systole, is defined as the end-diastolic pressure or volume. The Frank-Starling law of the heart dictates that ventricular pressure and output vary with preload, so a decrease in preload decreases end-diastolic volume and pressure, peak pressure, and stroke volume. Conversely, increased preload increases ventricular pressure and output, subject to the limits to which preload pressures can be increased. Left ventricular end-diastolic pressures of 20 to 25 mm Hg and greater cause exudation of fluid into the alveoli and pulmonary edema (Chapter 45).

Afterload refers to the stress that the ventricle must overcome to eject blood. Peak arterial pressure reflects the peak stress imposed on cardiomyocytes according to Laplace's law (described previously as $P \approx 2 \cdot T \cdot h/R$). As long as there is no left ventricular outflow obstruction, arterial pressure reflects myocyte afterload, as does *total peripheral resistance* (TPR), which corresponds to the tone of the resistance vessels. TPR is the ratio between the mean pressure decrease across the arterial system (mean arterial pressure [MAP] minus mean central venous pressure [CVP]) and cardiac output (CO): TPR = (MAP − CVP)/CO. When TPR is increased, the pressure-volume relationship shifts such that peak pressure is increased, whereas stroke volume and ejection fraction are decreased.

Contractility of cardiac muscle (*myocardial contractility*) or a ventricle (*ventricular contractility*) is the intrinsic ability to generate force independent of preload or afterload. When ventricular contractility is increased, the pressure-volume relationship shifts so that pressure, stroke volume, and ejection fraction are increased at constant preload volume and arterial resistance. By comparison, ventricular contractility is decreased in dilated cardiomyopathy (Chapter 47), and atrial contractility is decreased by the atrial myopathy that may precede and commonly follow atrial fibrillation.[3]

Cardiac output is measured in liters per minute and is equal to the amount of blood ejected at each heartbeat (stroke volume in liters per beat) multiplied by the number of beats per minute. As a result, *heart rate* is a powerful determinant of cardiac performance. Cardiac output and mean arterial pressure can be related to preload, afterload, contractility, and heart rate through the Frank-Starling curves, which plot end-diastolic pressure versus cardiac output or mean arterial pressure, to yield an overall picture of left ventricular function.

CARDIOVASCULAR RESPONSES TO STRESSORS

EXERCISE

Exercise requires dramatic increases in cardiac function combined with remodeling of the peripheral circulation to meet the enhanced metabolic demands of critical organs and to redirect blood flow to those organs. Indeed, the oxygen consumption during exercise can increase as much as 18-fold. About one third of the requirement for increased oxygen consumption is met by improved extraction of oxygen from the blood in the muscles (reducing venous saturation from about 75% to about 25%) and the remainder by increasing cardiac output as much as six-fold. Increased cardiac function is achieved largely through sympathetic stimulation and reduction in vagal tone, which combine to increase the heart rate, contractility, ejection fraction, filling rates, and systolic blood pressure and to decrease aortic impedance. In young healthy individuals, heart rate can increase from a baseline of 60 to 70 beats per minute at rest to as much as 170 to 200 beats per minute with exercise. To increase rather than to decrease cardiac output at these high heart rates, which can limit ventricular filling and stroke volume, contractility must also increase through a phenomenon known as the positive force frequency relationship, or Bowditch phenomenon. Along with increased cardiac contractility, arterial vasodilation in the aorta and other major arteries reduces the resistance to cardiac outflow. Both enhanced cardiac contractility and arterial vasodilation are triggered by the same sympathetic nervous system signals. With increased cardiac outflow, venous return also must increase so that preload can be maintained as well as possible to enhance cardiac function by the Frank-Starling mechanism. In response to the stress of repeated exercise (e.g., in trained athletes), the heart may undergo physiologic hypertrophy, which should be distinguished from the pathologic hypertrophy that is triggered by hypertension, myocardial infarction, and chronic activation of neurohormonal pathways (e.g., the renin-angiotensin system) (E-Fig. 41-6).

HEART FAILURE

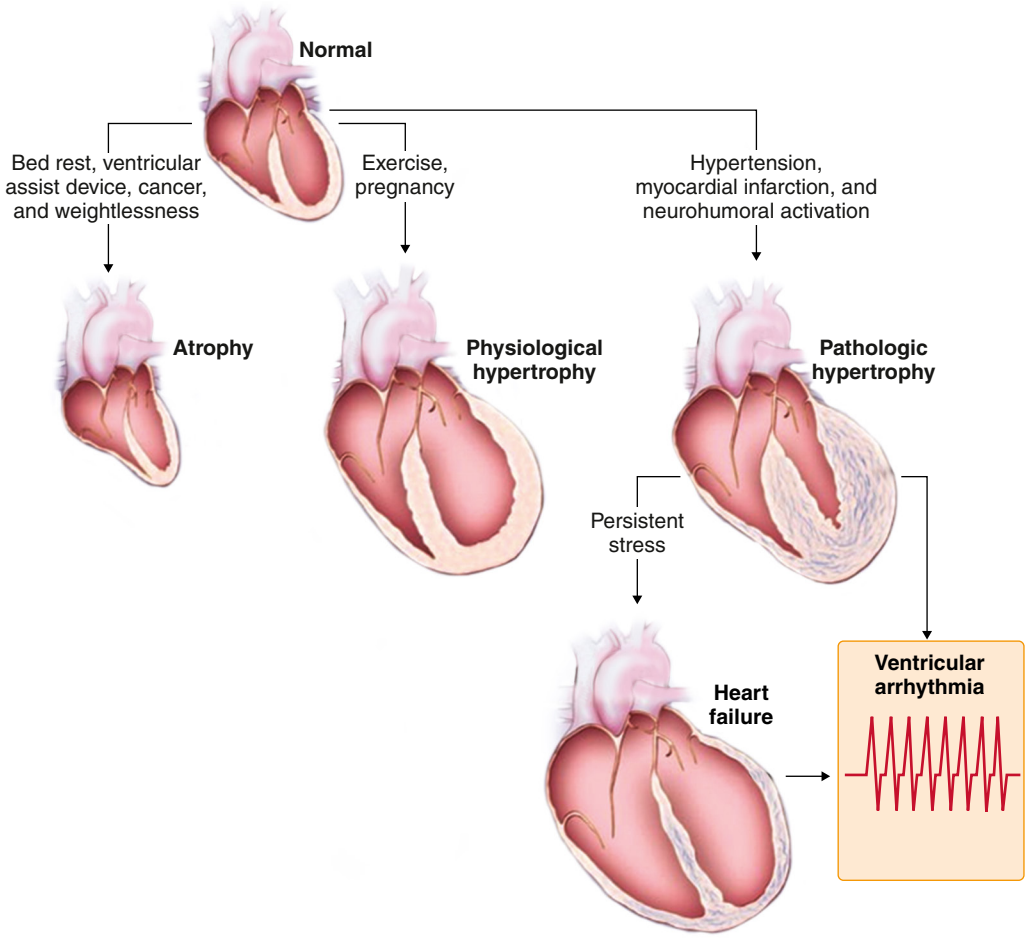
Heart failure can be defined as the inability of the heart to provide sufficient blood flow to meet the metabolic demands of the organs (Chapter 45). Heart failure can be due to systolic dysfunction with volume overload, most often as the consequence of ischemic heart disease (myocardial infarction) or as the end-stage consequence of hypertension. Systolic heart failure is characterized by increases in the size of the various cardiac chambers (rightward shift of the end-diastolic pressure-volume relationship). In another form of heart failure, known as *diastolic heart failure*, the heart is not necessarily increased in size, and systolic function is preserved.[4] Emerging data implicate altered regulation of calcium inside the cardiomyocyte in the pathogenesis of both the cardiac and skeletal muscle weakness that is seen in heart failure, as well as in atrial fibrillation,[5] which is the most common arrhythmia associated with heart failure.

AGING

Prolongation of contraction and relaxation times, which are common abnormalities in older individuals, may be related to cardiac hypertrophy as a consequence of the high prevalence of hypertension with advancing age (Chapter 64). A progressive "stiffening" of the large arteries with advancing age increases resistance, although the mechanism underlying this change is not understood. The heart rate and contractile responses to sympathetic signals are reduced and lead to a diminished ability to respond to conditions of acute overload, such as increased blood pressure or an acute myocardial infarction.

CARDIAC REGENERATION

Some animals, such as zebrafish, can regenerate substantial portions of their hearts after injury, sometimes by recruiting atrial myocytes to replace damaged ventricular myocytes. In mammals, however, cardiomyocytes stop proliferating right after birth. Any subsequent enlargement of the heart in response to stress (e.g., hypertension) or loss of myocardium (e.g., myocardial infarction) is limited to hypertrophy of existing cardiomyocytes. Studies, however, have shown that micro-RNAs (miRNAs) can activate cardiomyocyte proliferation and repair by enabling the terminally differentiated cardiomyocytes to re-enter the cell cycle and proliferate. These miRNAs are short, noncoding RNAs that downregulate target messenger RNAs by binding to partially complementary sequences and reducing the expression of the encoded proteins. In mice, miRNAs can induce cardiac regeneration and prevent loss of heart function after myocardial infarction, thereby raising the possibility for a better understanding and potential treatment of cardiac diseases. To date, however, stem cell therapy has been disappointing for heart failure[A1] and for acute myocardial infarction.[6]



E-FIGURE 41-6. Remodeling of the heart in response to stress. The heart can undergo physiologic remodeling in response to normal stress (repeated exercise), or it can undergo pathophysiologic remodeling after a myocardial infarction or in response to chronic hypertension. Atrophy, or shrinking of the heart, can occur in microgravity (space travel), weight loss, cancer cachexia, and other conditions in which the pumping work of the heart is diminished. (From Hill JA, Olson EN. Cardiac plasticity. *N Engl J Med*. 2008;358:1370-1380.)

IMPAIRED CIRCULATORY FUNCTION: ATHEROSCLEROSIS

Atherosclerosis, which is an age-dependent process of progressive damage to arterial vessels, can impair coronary blood flow and result in myocardial ischemia (Chapter 56) and infarction (Chapters 57 and 58). Atherosclerosis is linked to cardiac risk factors including elevated cholesterol levels, hypertension, cigarette smoking, obesity, genetics (positive family history), and diabetes. Atherosclerosis can lead to partial or complete blockages of arteries due to formation of atherosclerotic plaques comprised of lipoproteins, inflammatory cells, and connective tissue. Atherosclerotic plaques may rupture, thereby leading to thromboses and arterial occlusions that result in myocardial infarction (Chapters 57 and 58), ischemic stroke (Chapter 376), and peripheral arterial disease (Chapter 65). Repeated atherosclerotic-induced ischemic attacks can result in dilated cardiomyopathy and heart failure (Chapter 45). An estimated 90% of cases of myocardial infarction (Chapter 58), 60% of strokes (Chapter 376), most cases of heart failure (Chapter 45), and up to one third of all cases of dementia (Chapter 371) are due to atherosclerosis.

RISK FACTORS FOR ATHEROSCLEROSIS

The major risk factors that promote the development of atherosclerosis are an elevated low-density lipoprotein (LDL) cholesterol level (Chapter 190); cigarette smoking (Chapter 363); diabetes (Chapter 210); hypertension (Chapter 64); and a family history of coronary heart disease, ischemic stroke, or peripheral arterial disease. Other conditions that increase the risk of atherosclerotic disease or events include a low high-density lipoprotein (HDL) level (Chapter 190), obesity, hyper-triglyceridemia, high plasma levels of lipoprotein (a), hyperfibrinogenemia, homocystinuria, and physical inactivity (Chapter 40).

An atherogenic lipoprotein phenotype (characterized by the predominance of small, dense LDL particles, hypertriglyceridemia, and low plasma HDL cholesterol concentration) with the metabolic syndrome is associated with atherogenic and thrombotic factors, including raised levels of plasma fibrinogen, plasminogen activator inhibitor-1, and coagulation factor VII, as well as platelet hyperactivity. The inflammatory biomarker C-reactive protein does not cause atherosclerosis but reflects ongoing inflammation that may accelerate the atherosclerotic process.[7]

PATHOPHYSIOLOGY OF ATHEROSCLEROSIS

When LDL accumulates in the inner wall of arteries (intima), it becomes oxidized, thereby resulting in the release of chemokines and adhesion molecules that promote inflammation, chiefly marked by the recruitment of monocytes, which become macrophages (E-Fig. 41-7). Macrophages accumulate cholesterol and become cholesterol-laden foam cells. Other macrophages produce proinflammatory mediators, including tumor necrosis factor (TNF), interleukin-1, proinflammatory eicosanoids, oxygen and nitrogen free radicals, and prothrombotic factors.

PLAQUE ACTIVATION, THROMBOSIS, AND INFARCTION

The atherosclerotic process typically is silent for months, years, and even decades, and it may never result in clinical manifestations.[8] However, if the plaque ruptures thrombotic occlusion of the artery may ensue (Fig. 41-4). Platelet aggregates that form on these exposed surfaces are stabilized by a fibrin network. Tissue factor, expressed in the vascular smooth muscle cells and macrophages of the atherosclerotic plaque, is the primary cellular initiator of the blood coagulation cascade that leads to fibrin formation. Atherothrombi expand rapidly and can fill the lumen within minutes, thereby leading to ischemia and infarction.

Matrix metalloproteinases and cysteine proteinases, which are produced by macrophages, are found at sites of plaque rupture and have been implicated in rupture, but their effects on the composition and size of lesions are complex. Cell death may be an important trigger of plaque rupture. Apoptotic cells contained in the plaque are usually removed by efferocytosis. If this process fails, secondary necrosis ensues, thereby leading to reduced mechanical integrity and accumulation of prothrombotic material from dead cells.

ANTIATHEROSCLEROTIC THERAPY

Current treatment of atherosclerosis focuses on reduction of risk factors, including smoking cessation, dietary and pharmacologic reduction of LDL cholesterol (Chapter 190), management of blood pressure (Chapter 64), treatment of hyperglycemia (Chapter 210), hypertriglyceridemia (Chapter 190), obesity (Chapter 201), and physical inactivity (Chapter 14).

Cholesterol-lowering with statins,[A2] ezetimibe,[A3] and proprotein convertase subtilisin kexin type 9 (PCSK9) antibodies[A4] can reduce atherosclerotic lesions, inhibit their progression, and lower the rate of subsequent coronary events and all-cause mortality. More recently, inhibition of the hepatic synthesis of PCSK9 using a single subcutaneous injection of inclisiran has resulted in LDL cholesterol reductions of 50% or so for 18 months.[A5,A6]

Aspirin[A7] and other inhibitors of platelet aggregation,[9] β-adrenergic receptor blockers, and angiotensin-converting enzyme inhibitors or angiotensin II antagonists are also part of the routine secondary prevention of coronary heart disease (Chapters 56, 57, and 58). Inhibitors of platelet aggregation are widely used for secondary prevention of atherosclerotic cardiovascular disease. Aspirin inhibits formation of proaggregatory prostaglandins, whereas other inhibitors of platelet aggregation modulate expression of platelet adhesion molecules. In addition to medical therapies, interventional therapies such as stenting and coronary artery bypass surgery (Chapter 59) also have greatly impacted the health burden of atherosclerosis.

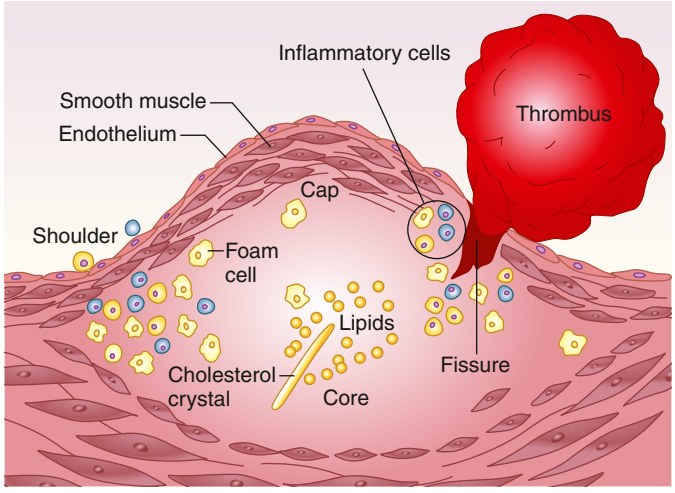


FIGURE 41-4. Plaque rupture and atherothrombosis. The advanced atherosclerotic plaque has a central core with lipids (especially cholesterol), live and dead cells, necrotic material from dead foam cells, and calcium salts. The plaque is overlaid by a fibrous cap that consists of smooth muscle cells and collagen (produced by the muscle cells) and covered by an intact layer of endothelial cells. Inflammatory cells (macrophages, T cells, mast cells, dendritic cells, and occasional B cells) are interspersed with these components and are particularly abundant in the shoulder regions of plaques, where fissures (also called ruptures) may expose thrombogenic core material (e.g., lipids, collagen, tissue factor) to blood components. This event triggers platelet aggregation and humoral coagulation, thereby leading to thrombus formation at the site of fissuring. Thrombi may expand locally to obstruct blood flow or they may detach to cause embolization.

E-FIGURE 41-7. Formation of atherosclerotic plaques. Low-density lipoproteins (LDL) transit from the blood stream to the arterial intima and accumulate under the endothelial cell layer. LDL particles undergo oxidative modification in the intima (denoted by spikes on LDL particles), thereby leading to their binding to scavenger receptors and uptake by macrophages, which accumulate cholesterol and develop into foam cells. Cholesterol efflux to high-density lipoprotein (HDL) counteracts the tendency to foam cell formation. Molecules released from oxidatively modified LDL activate endothelial cells to express leukocyte adhesion molecules that promote binding of monocytes and T cells to the surface of the artery. Chemokines stimulate monocytes and T cells to migrate into the intima, where the monocytes differentiate into macrophages and cytokines promote vascular smooth muscle cell proliferation. Some macrophages are activated, thereby leading to release of proinflammatory cytokines, eicosanoids, radicals, and proteases. T cells entering through mechanisms similar to those of monocytes can recognize local antigens, such as LDL components, which are presented to them by antigen-presenting cells (dendritic cells and macrophages) that express human leukocyte antigen (HLA) molecules. T cells whose receptors can recognize local antigens are activated, thereby leading to release of a host of cytokines that can activate macrophages and enhance vascular inflammation. Triglyceride-rich lipoprotein remnant particles, which have adverse effects on endothelial function, penetrate into the subendothelial space of normal intima and form atherosclerotic plaques. Conversely, antiatherogenic HDL particles mediate cholesterol efflux from cells by acting as acceptors of cholesterol delivered from specific transport proteins termed adenosine triphosphate–binding cassette (ABC) A1 and G1. 42 ELECTROCARDIOGRAPHY

LEONARD GANZ AND MARK S. LINK

Electrocardiography, which itself has changed surprisingly little since initially introduced by Einthoven in the early 1900s, allows simultaneous recording of myocardial activation from multiple vantage points on the body's surface, thereby permitting analysis of electrical activation in different myocardial regions. Surface electrocardiography may be supplemented with intracardiac recordings, which are particularly helpful in the diagnosis and management of cardiac arrhythmias (Chapter 49). With the advent of computerized readings and artificial intelligence, the interpretations of electrocardiograms are becoming more accurate and potentially more diagnostic of certain disease conditions.

NORMAL FUNCTION AND ELECTROCARDIOGRAM

NORMAL CARDIAC ACTIVATION

Electrical activation of the heart depends on the spread of a depolarizing wave front from pacemaker cells through cardiac muscle, as well as via specialized conducting tissues (Fig. 42-1). Under normal circumstances, cells in the sinoatrial (SA) nodal complex in the high lateral epicardial right atrium near the superior vena cava spontaneously depolarize at the highest rate and therefore constitute the dominant cardiac pacemaker (Chapter 48). This electrical wave front spreads throughout the right and left atria; specialized conducting tracts called the Bachmann bundle speed the depolarizing wave front to the left atrium. Electrical atrial activation triggers atrial muscular contraction, thereby propelling blood through the tricuspid and mitral valves into the right and left ventricles. Normally, the atrioventricular (AV) node, where conduction delay is physiologic, serves as the only electrical connection linking the atria and ventricles; the AV valve rings are insulated. The depolarizing wave front exits the AV node into the bundle of His, a specialized conducting tissue capable of rapid conduction. The bundle of His bifurcates into right and left bundle branches; the left bundle branch divides into the left anterior and left posterior fascicles. The bundle branches and their more distal ramifications of specialized conducting tissue are called the Purkinje system. From these specialized conducting tissues, the depolarizing wave front enters into and then moves through ventricular muscle. As in the atria, ventricular electrical depolarization initiates muscular contraction, which pumps blood through the semilunar valves into the pulmonary and systemic circulations. After electrical depolarization, a period of electrical recovery, or repolarization, is necessary before repeated depolarization.

At the cellular level, a complex orchestration of ion channels opening and closing determines the membrane potential throughout this process. The flow of ions into and out of the myocardial cells inscribes an action potential, which reflects depolarization and repolarization, as well as the spontaneous depolarization of pacemaker cells (Chapter 48).

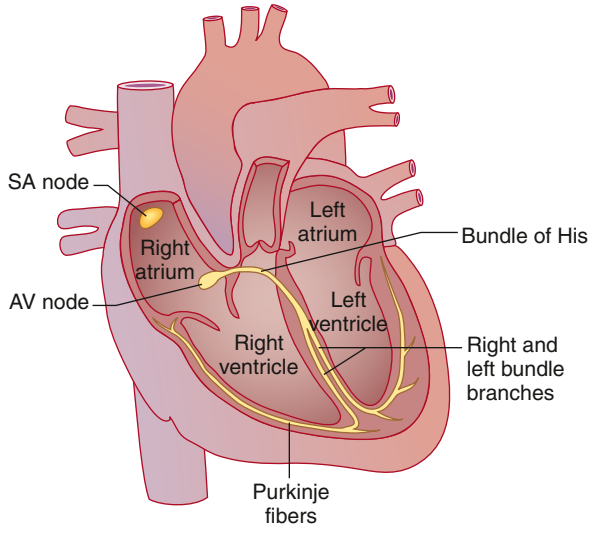

FIGURE 42-1. Cardiac conduction system. The normal conducting system consists of pacemaker cells in the sinoatrial (SA) nodal complex, specialized intra-atrial conducting tracts (including Bachmann bundle), the atrioventricular (AV) node, the His-Purkinje system, and working atrial and ventricular myocardium.

THE ELECTROCARDIOGRAPHIC WAVES

Labeled alphabetically, beginning with the P wave, the basic waves of the electrocardiogram (ECG) correspond to these electrical events (Fig. 42-2). The P wave represents atrial muscular depolarization. The morphology of the P wave is reflective of atrial structure. Under normal circumstances, the PR interval, which is the segment from the onset of the P wave to the onset of the QRS complex, represents the delay between atrial and ventricular depolarization. The QRS complex represents ventricular muscular depolarization; the disparity between ventricular and atrial muscle mass typically yields a QRS complex much larger in voltage amplitude than the P wave. Recorded from multiple vantage points, the QRS complex harbors tremendous information about the structure and function of ventricular tissue. The ST segment and T wave (and occasionally the U wave) reflect ventricular repolarization, a process of electrical recovery that must take place before the ventricle can be depolarized again. The J (junction) point denotes the end of the QRS complex and beginning of the ST segment. Atrial muscle also requires repolarization before the next depolarizing wave front. Because ventricular mass far exceeds atrial muscular mass, the low-amplitude atrial repolarization wave is buried underneath the QRS complex and therefore not manifested on the ECG.

One rarely seen ECG finding, the J wave (of Osborn), breaks with the alphabetic convention of the other electrocardiographic waves. Defined as a positive deflection on the QRS downstroke or at the J point, the J wave is seen most commonly in hypothermia (see Fig. 42-3). It also has been described in hypercalcemia and brain injury, and it may connote risk of idiopathic ventricular fibrillation (see later).

ELECTROCARDIOGRAPHY STANDARDS

A standard ECG is recorded on paper (and frequently digitally) with 1-mm ("small" boxes) as well as 5-mm ("big" boxes) gridlines (see Fig. 42-2). Voltage amplitude is measured on the vertical axis (typically 10 mm equaling 1 mV) and time on the horizontal axis. Because the usual ECG recording speed is 25 mm/sec, each 1-mm gridline (small box) represents 0.04 second

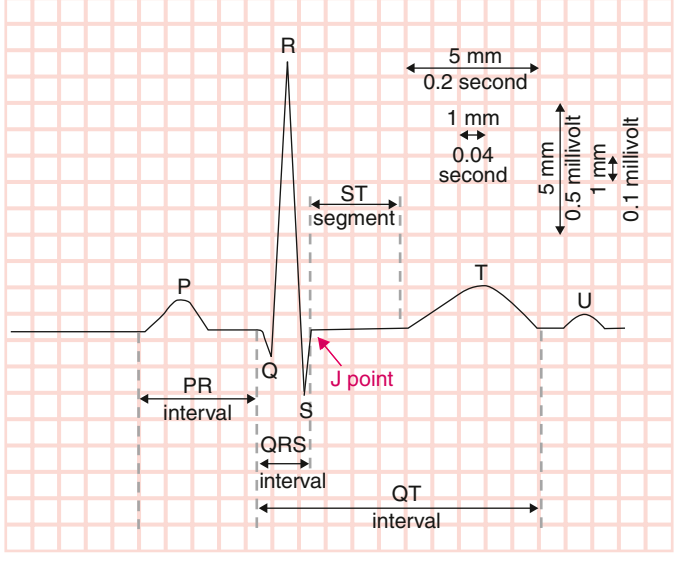

FIGURE 42-2. Inscription of a normal electrocardiogram (ECG). Sinoatrial nodal depolarization is not visible on the surface ECG; the P wave corresponds to atrial muscular depolarization. The PR interval denotes conduction through the atrial muscle, atrioventricular node, and His-Purkinje system. The QRS complex reflects ventricular muscle depolarization. The ST segment and T wave correspond to ventricular repolarization. The J point lies at the junction of the end of the QRS complex and beginning of the ST segment. The QT interval is measured from QRS onset to T wave offset. Note the gridlines. On the horizontal axis, each 1-mm line ("small" box) denotes 0.04 second (40 msec); a "big" box denotes 0.2 second (200 msec). On the vertical axis, 1 mm (small box) corresponds to 0.1 mV; 10 mm (two big boxes) therefore denotes 1 mV.

ABSTRACT
A comprehensive introduction to the theory, practice, and interpretation of the electrocardiogram.

KEYWORDS
electrocardiography
electrocardiogram
ECG
EKG

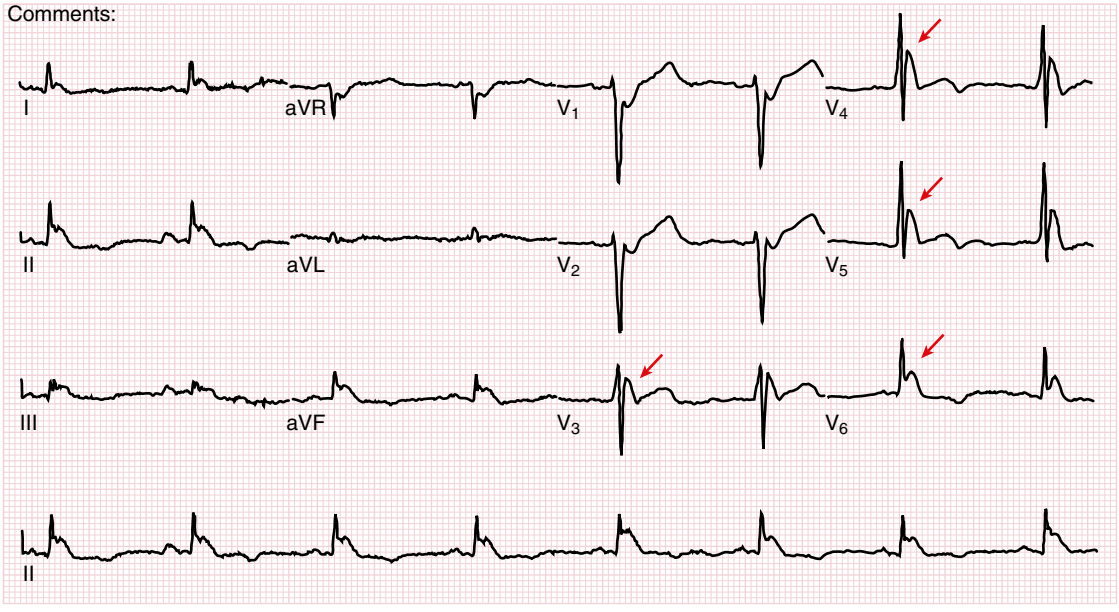

FIGURE 42-3. **J wave (of Osborn).** This ECG was recorded in a 40-year-old diabetic woman with profound hypothermia (26.6° C), diabetic ketoacidosis, and hypokalemia. Note the massive J waves in leads V_3-V_6, and smaller J waves in leads I, II, III, and aVF. Other notable findings include sinus bradycardia and QT prolongation.

(40 msec), and each 5-mm gridline (big box) equals 0.2 second (200 msec). These parameters, which are typically printed on the ECG to aid in proper interpretation, are the usual calibration or standardization, but they can be modified in unusual circumstances.

A standard ECG is recorded over a 10-second period, although a rhythm or monitor strip can be recorded for substantially longer if necessary. Multiple leads are typically recorded simultaneously from the top to the bottom of the page. The usual groupings of leads include I, II, and III; aVR, aVL, and aVF; V_1, V_2, and V_3; and V_4, V_5, and V_6 (see later). Each group of leads is recorded for 2.5 seconds. A single lead (or multilead) rhythm strip is recorded below for the entire 10 seconds. Thus, as the ECG is scanned from left to right, one sees 10 seconds of cardiac activity, with each complex recorded simultaneously in multiple leads.

NORMAL INTERVALS

Each of the various ECG waves and intervals has normal ranges, defined from large numbers of electrocardiographic recordings in (presumably) healthy subjects (Table 42-1; see Fig. 42-2).

The RR interval (identical to the PP interval in sinus rhythm), which is the measurement from R wave to R wave (or P wave to P wave), allows calculation of the heart rate. Because there are 60,000 msec in a minute, the heart rate (HR) in beats per minute can be easily calculated from the RR or PP interval in milliseconds:

$$HR = \frac{60{,}000}{RR}$$

Although traditionally the normal resting adult heart rate range has been defined as 60 to 100 beats per minute, a range of 50 to 90 at rest may actually be more reflective of normal physiology. Various stressors (exercise, pain, fever, anemia, etc.) increase the heart rate; a lower heart rate is noted after eating and during sleep. Resting heart rates tend to decrease with age. When the heart rate is grossly irregular, as in atrial fibrillation (Chapter 52), the RR interval can be averaged over a number of cardiac cycles to estimate the heart rate. Because a standard ECG records 10 seconds in time, the heart rate (beats per minute) will equal the number of beats recorded on a standard ECG multiplied by 6. Alternatively, in a regular rhythm, the heart rate can be estimated by counting the number of big boxes between consecutive QRS complexes or P waves (i.e., 2 large boxes = 150 beats per minute, 3 large boxes = 100 beats per minute, 4 large boxes = 75 beats per minute, 5 large boxes = 60 beats per minute, and so on.).

TABLE 42-1 NORMAL ELECTROCARDIOGRAPHIC INTERVALS

Heart rate	50-100 beats per minute
P wave duration	<0.12 sec (120 msec)
PR interval	0.09-0.20 sec (90-200 msec)
QRS duration	0.075-0.11 sec (75-110 msec)
QTc	males: 0.39-0.45 sec (390-450 msec); females: 0.39-0.46 sec (390-460 msec)
QRS axis	−30 to +90 degrees

P Wave Duration

The P wave duration, from the beginning to the end of a P wave, is typically less than 0.12 second (120 msec, three small boxes) in length. A broader P wave reflects an intra-atrial and/or interatrial conduction delay. Abnormalities in P wave amplitude, morphology, and axis may reflect atrial enlargement.

PR Interval

The PR interval, measured from the onset of the P wave to the onset of the QRS complex, normally lasts between 0.09 and 0.2 second (90 to 200 msec). One-to-one AV conduction with a PR interval greater than 0.2 second has traditionally been called *first-degree AV block*, but *delayed AV conduction* may be a more appropriate term. Conduction through the atrial tissue, the AV node, and the His-Purkinje system all contribute to the PR interval. When the PR interval is prolonged, delay is usually present in the AV node, although other sites of delay are possible. A short PR interval may reflect ventricular preexcitation (Wolff-Parkinson-White syndrome), a junctional rhythm, or enhanced AV nodal conduction (Chapters 49 and 52).

QRS Complex

The QRS complex, which reflects ventricular muscular electrical activation, carries important information in patients with coronary artery disease, cardiomyopathy, metabolic abnormalities, and other conditions. Capital letters (Q, R, S) denote large-amplitude deflections (≥5 mm or 0.5 mV), whereas lowercase letters (q, r, s) signify low-amplitude deflections (<5 mm or 0.5 mV). Q, q, S, and s waves are negative excursions from the isoelectric baseline, whereas R and r waves are positive deflections. Q and q waves are initial negative deflections, and S and s waves are negative deflections that follow a positive deflection (R or r wave); a QS complex is an entirely negative deflection. Q waves may reflect prior infarction (Chapters 56-58). An R′ or r′ wave refers to a second positive deflection after an S (or s) wave. The duration of the QRS complex reflects the time required for ventricular depolarization. Ventricular activation usually requires at least 0.075 second (75 msec, nearly two small boxes). There is some debate regarding the upper limit of the normal range for QRS duration; a recent consensus document specified 0.11 second (110

msec, nearly three small boxes). If the QRS duration is prolonged, an intraventricular and/or interventricular conduction delay is present. Particular patterns of interventricular conduction delay have been termed bundle branch block (see later).

QT Interval

The QT interval is measured from the onset of the QRS complex to the end of the T wave. Although the QT interval is generally felt to reflect ventricular repolarization, it also includes the time required for ventricular depolarization (QRS duration). The QT interval is generally measured in leads II, V_5, and V_6 (see later) and reported as the longest interval among the three, averaged over three to five cycles. If the QT interval cannot be accurately measured in these leads, other leads may be used. The QT interval must be corrected to allow comparison of this interval at differing heart rates. The most commonly used approach, Bazett's formula, defines a corrected QT interval (QTc):

$$QTc = \frac{QT}{\sqrt{RR}}$$

Bazett's formula works reasonably well at heart rates in the normal range but overcorrects at high rates and undercorrects at low rates. Irregular rhythms (notably atrial fibrillation) complicate calculation of the QTc. Some investigators recommend measuring at least three QT intervals to get an average, and then using an RR interval averaged over 10 cycles. More complex regression formulas have been developed to correct the QT interval at different heart rates. For example, the Fridericia formula

$$QTc = \frac{QT}{\sqrt[3]{RR}}$$

may be more accurate than Bazett's formula in atrial fibrillation and better at predicting adverse outcomes, but it has not achieved widespread clinical use.

The presence of a U wave complicates measurement of the QT (and therefore QTc) interval; it may be unclear where the T wave ends and where the U wave begins. In general the U wave should not be included as part of the QT interval; instead, the slope of the T wave to the baseline (before the P wave) should be extrapolated to determine the true QT interval. The QTc in a given patient may vary somewhat during the course of the day and is slightly longer in young and middle-aged women than in men. The upper limit of a normal QTc is somewhat debatable, but a cutoff of 0.45 second (450 msec) in men and 0.46 second (460 msec) in women is generally used. Repolarization and thus the QT interval are sensitive to drug effects as well as to abnormal electrolytes, coronary ischemia, and central nervous system events. Patients with widened QRS complexes frequently have prolonged QT and QTc intervals. In these patients, the JT interval (from J point to the end of T wave) may be a more accurate index of repolarization, but normal standards have not been established. However, a reasonable correction factor is to subtract the excess QRS interval (i.e., measured QRS – 80) from the QT interval. Patients with a prolonged QTc, whether congenital or acquired, may be at risk for torsades de pointes ventricular tachycardia (Chapter 53). A very short QTc interval (<320 to 340 msec) is unusual, and the very rare patient with the short QT syndrome is also at risk for malignant ventricular arrhythmias.

ELECTROCARDIOGRAPHIC LEADS

Recording a single ECG lead allows calculation of the heart rate and, frequently, accurate diagnosis of the heart rhythm. When the ECG is recorded from multiple skin leads simultaneously, the direction (or vector) of activation as the electrical wave front moves through the heart can be inferred. Although a number of different lead systems are possible (and some are actually used in research settings), standard electrocardiography uses 12 vantage points (i.e., leads), derived from 10 electrodes, 6 on the chest wall and 4 on the limbs. In reality, only three limb leads are actually used to generate recordings; the right leg lead serves as an electrical ground. The limb leads, called the frontal plane leads, generate bipolar and augmented unipolar lead recordings. The chest or precordial electrodes record unipolar recordings. Bipolar leads record the potential difference between two skin electrodes. In unipolar recordings, the lead of interest, the exploring electrode, is compared with a reference electrode. By convention, a positive deflection is recorded if the electrical wave front is moving toward the positive electrode in a bipolar pair or toward the exploring electrode in a unipolar lead.

The bipolar limb leads measure potential differences between electrodes on pairs of limb electrodes and closely resemble Einthoven's original string galvanometer recordings. Lead I compares the right arm (negative) and left arm (positive), lead II the right arm (negative) and left leg (positive), and lead III the left arm (negative) and left leg (positive) (E-Fig. 42-1). Because the direction of both atrial and ventricular depolarization is away from the right arm and toward the left arm, a positive P wave and QRS complex are generally recorded in lead I. Similarly, the P wave and QRS complexes are positive in leads II and III in normal sinus rhythm because atrial and ventricular activation proceeds in a craniocaudal direction.

Leads aVR, aVL, and aVF are augmented unipolar leads in which the potential in each limb is compared with a reference electrode. For lead aVR, the potential of the right arm is compared with a reference composed of the left arm and left leg electrodes. Lead aVL compares the left arm potential with a reference combining the right arm and left leg; aVF compares the left leg with a right and left arm reference. Because atrial and ventricular activation normally moves from right to left and in a craniocaudal direction, the P wave and QRS complex are negative in lead aVR but positive in lead aVF. In lead aVL, P waves and QRS complexes are generally upright, although an rS complex may be recorded, particularly in young patients.

The precordial electrodes are positioned at specific points on the chest wall (E-Fig. 42-2A). These unipolar leads compare electrical potential between the chest electrode and a reference electrode called the Wilson central terminal. The Wilson central terminal combines the right arm, left arm, and left leg potentials through 5000-Ω resistors. The six precordial leads define atrial and ventricular activation with respect to a somewhat transverse plane through the chest wall (E-Fig. 42-2B). In this plane, atrial activation moves from right to left. Initial ventricular activation involving the septum is directed from left to right; left ventricular depolarization, which dominates right ventricular depolarization because of the differential in myocardial mass, then moves apically and laterally. In lead V_1, to the right of the sternum, the P wave is biphasic (reflecting right and then left atrial activation). Initial ventricular activation of the septum inscribes an r wave, whereas subsequent activation away from lead V_1 records a dominant S wave. In lead V_6, the P wave is positive, and initial ventricular septal depolarization inscribes a tiny "septal" q wave (usually ≤0.02 second). Subsequent ventricular depolarization records a dominant R wave.

Right-sided chest leads should be recorded when right ventricular abnormalities are suspected. RV_3, the reflection of lead V_3 in the right chest, is routinely recorded in pediatric patients because of the possibility of congenital heart disease. In adults, ST elevation in lead RV_3 is quite specific for acute right ventricular infarction in patients who are being evaluated for an acute inferior wall myocardial infarction.

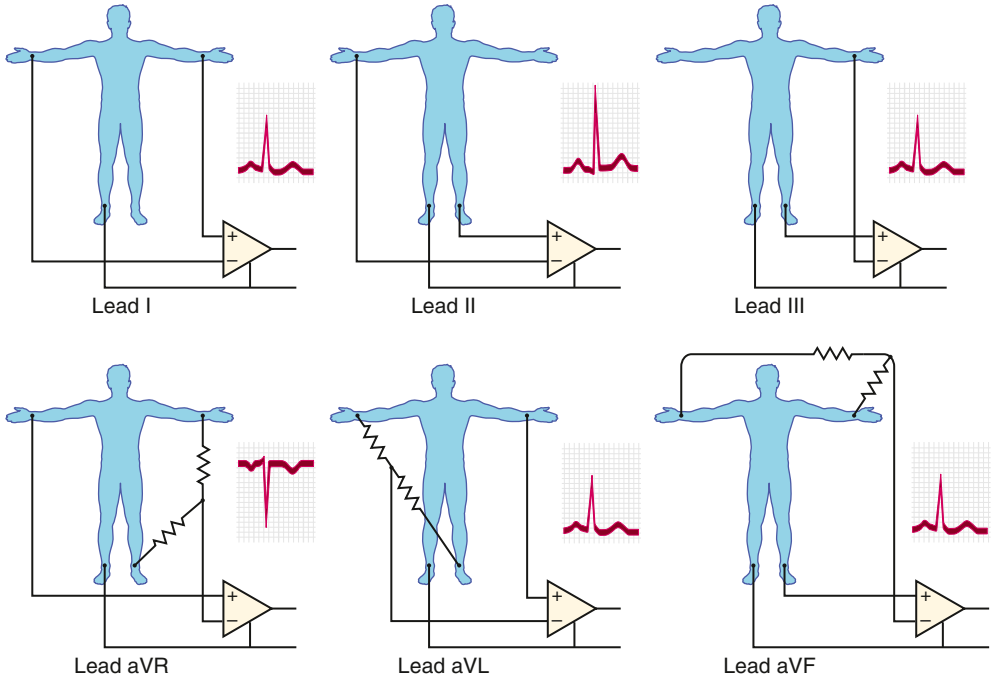
AXIS

An axis of electrical activation can be defined in the frontal plane axis by combining the bipolar and augmented unipolar limb leads (E-Fig. 42-3A). By convention, the axis parallel to lead I, toward the left, is called 0 degrees. A frontal plane axis between −30 and +90 degrees is normal; other axes are abnormal (E-Fig. 42-4). Mild right axis deviation beyond +90 degrees is a normal variant in children and adolescents. The frontal plane axis can be estimated by identifying the limb lead in which the QRS complex is most nearly isoelectric (a similar amplitude of positive and negative deflections); the axis is perpendicular to this lead (see E-Fig. 42-3B). Because two lines pointing 180 degrees apart can be drawn perpendicular to any given line, examination of the other limb leads defines the direction in which the axis points. If the QRS complex is positive in any given limb lead, the axis will be oriented toward that limb lead, not away from it. Alternatively, the axis is in the normal range if the QRS complexes are primarily positive in both leads I and II.

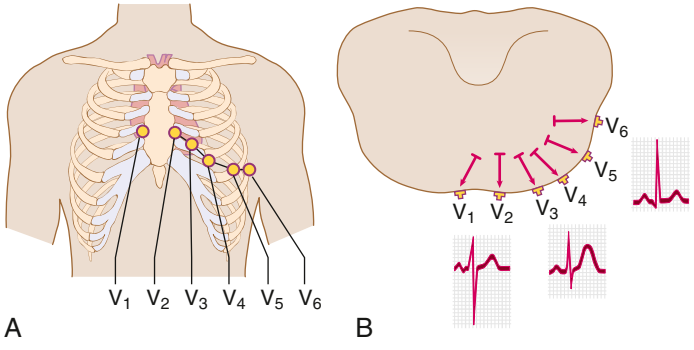
An axis per se is not defined in the precordial leads. Rather, because the typical progression from leads V_1 to V_6 is from a predominantly negative to a positive QRS complex, the transition point is usually defined as the point at which the amplitude of the R wave first exceeds the amplitude of the S wave. Clockwise rotation (transition zone at V_4 or later) may portend a higher risk of future coronary events, and counterclockwise rotation (transition zone at V_3 or earlier) a lower risk of events.

APPROACH TO INTERPRETING THE ELECTROCARDIOGRAM

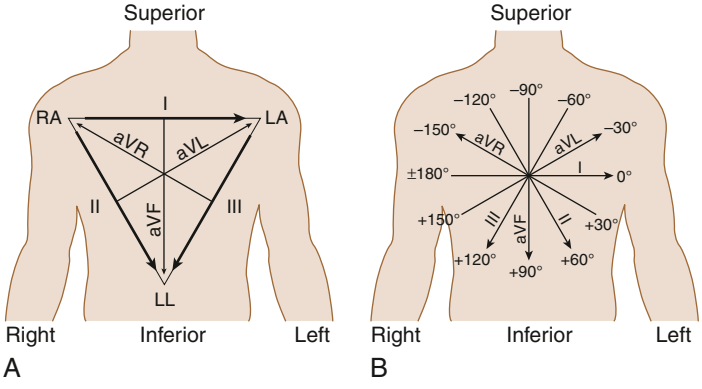
Physicians' deficiencies in ECG interpretation[1] can be reduced by using a stepwise approach to ensure that no features of the tracing will be overlooked (Table 42-2).[2]



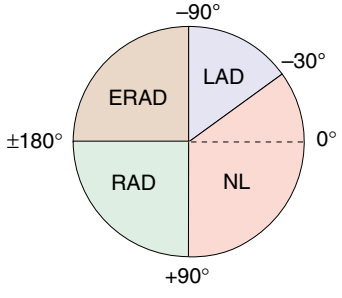
E-FIGURE 42-1. Normal cardiac activation as manifested in the limb leads. Under normal circumstances, P waves and QRS complex are typically upright in leads I, II, III, and aVF and inverted in aVR. In lead aVL, P waves are usually upright, although QRS complexes may be either upright or inverted. The right leg electrode serves to ground the system.



E-FIGURE 42-2. Precordial leads. A, Positioning of the precordial leads on the chest wall. **B,** Normal cardiac activation as manifested in the precordial leads. Note the small r wave and deep S wave in lead V_1, the transition at around V_3 or V_4, and the "septal" q wave and large R wave in lead V_6.



E-FIGURE 42-3. Axis of electrical activation. A, Vectors for the limb leads in the frontal plane. **B,** Hexaxial reference for determining the frontal plane axis. Note that the vectors for leads I, II, and III are in the same direction as in **A**, but now, like the augmented limb leads, these standard limb lead vectors have been moved so that they emanate from the center of the figure.



E-FIGURE 42-4. Chart of frontal plane axes. Normal (NL) = –30 to +90 degrees; left axis deviation (LAD) = –30 to –90 degrees (moderate –30 to –45 degrees; marked –45 to –90 degrees); right axis deviation (RAD) = +90 to +180 degrees (moderate +90 to +120 degrees; marked +120 to +180 degrees); extreme right axis deviation (ERAD) = –90 to ±180 degrees. Mild RAD is considered normal in children, adolescents, and young adults.

TABLE 42-2 STEPWISE APPROACH TO INTERPRETING THE ELECTROCARDIOGRAM

Estimate the heart rate
Define the heart rhythm as regular vs. irregular
  Note the relationship of P waves to QRS complexes
  Identify any pauses or premature beats
  If an unsustained arrhythmia is present, note its rate, onset (gradual vs. acute), and termination
Measure intervals (PR, QRS duration, QT)
Calculate/estimate QTc
Estimate QRS axis
Examine P wave morphology, duration, and axis
Examine QRS progression and transition in precordial leads
Examine QRS complexes in regional groupings (septal leads [V_1, V_2], anterior leads [V_2, V_3, V_4], lateral leads [I, aVL, V_5, V_6], inferior and posterior leads [II, III, aVF, V_1, V_2])
Examine ST segments in regional groupings
Examine T waves in regional groupings

NORMAL ELECTROCARDIOGRAM

Figure 42-4 is an example of a normal ECG. Sinus rhythm occurs at about 78 beats per minute, with minor variations in the RR intervals (sinus arrhythmia). The PR interval, QRS duration, and QTc are all normal. The QRS complex is most nearly isoelectric in lead aVL, so the QRS axis will be perpendicular to lead aVL. Because aVL points to −30 degrees, the QRS axis must be approximately −120 or +60 degrees. Because the QRS complex is positive in leads I and II (large R waves), the QRS axis is approximately +60 degrees. The transition in the precordial leads is typically at lead V_3 or V_4. The P wave is biphasic in lead V_1 and then positive in the other precordial leads. Septal q waves, reflecting not lateral infarction but rather normal early septal depolarization, are present in leads V_5 and V_6. Small q waves in the inferior leads are a normal variant.

ABNORMAL ELECTROCARDIOGRAM

Electrocardiography in patients with coronary artery disease is reviewed in Chapters 56 to 58 and in patients with arrhythmias in Chapters 48 to 54.

Conduction Abnormalities and Axis Deviation

Abnormalities of the specialized conduction system (i.e., His-Purkinje system) reflect slow or absent conduction in a particular structure (Table 42-3 and Fig. 42-5). Left anterior or posterior fascicular block does not prolong QRS duration beyond 120 msec. Incomplete bundle branch refers to QRS patterns that are morphologically similar to left or right bundle branch block, but with a duration of less than 0.12 second (120 msec). An interventricular conduction delay is generally defined as a QRS duration of more than 0.11 second (110 msec). When the QRS has a duration of at least 0.12 second (120 msec), it often has the configuration of a specific bundle branch block. An isolated left bundle branch block in an otherwise healthy person is associated with a two-fold higher risk for development of a cardiovascular event or dying of a cardiovascular cause. As a result, this finding should trigger an evaluation for possible cardiac disease. By comparison, a complete right bundle branch block generally has not traditionally been associated with an increased risk, although one study suggested up to a 30% increased risk in cardiovascular mortality.

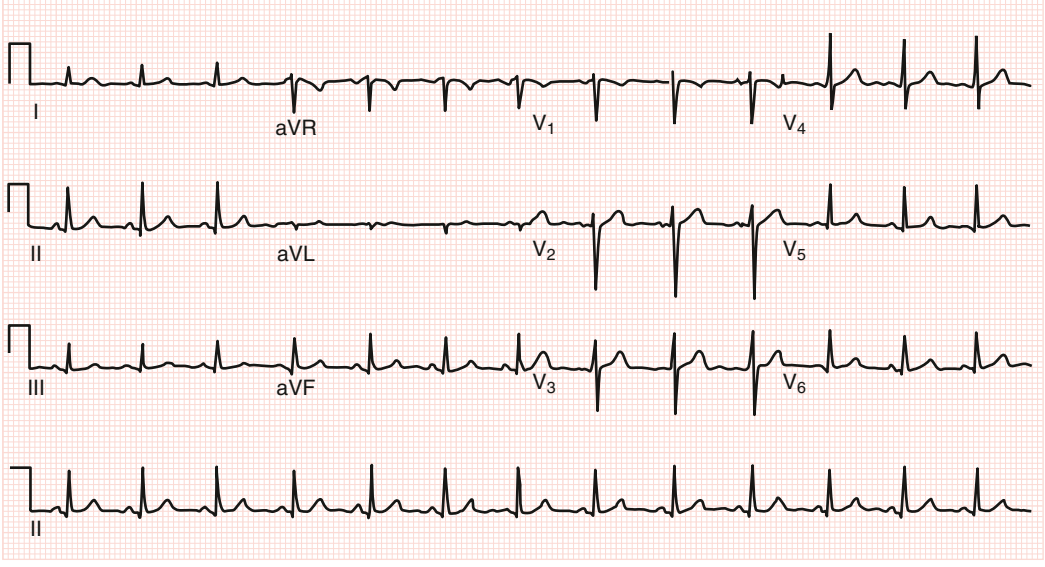


FIGURE 42-4. Normal electrocardiogram. The heart rate is approximately 78 beats per minute, with minor irregularity. Sinus arrhythmia is present. The axis is approximately +60 degrees. The PR, QRS, and QT intervals are approximately 140, 90, and 360 msec, respectively. P wave morphology, duration, and axis are normal. The transition is at lead V_4. No abnormal Q waves are present. ST segments are isoelectric, and T waves are concordant with QRS complexes.

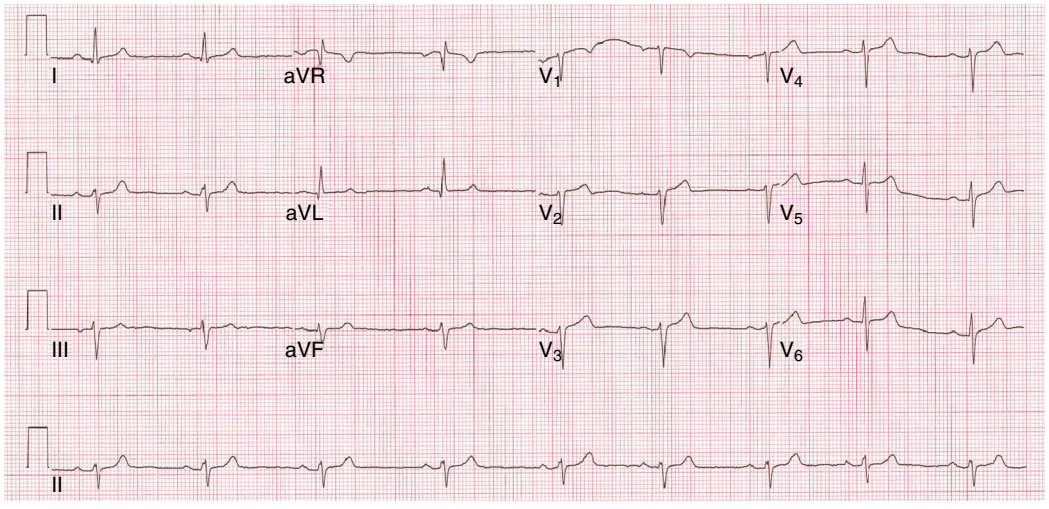
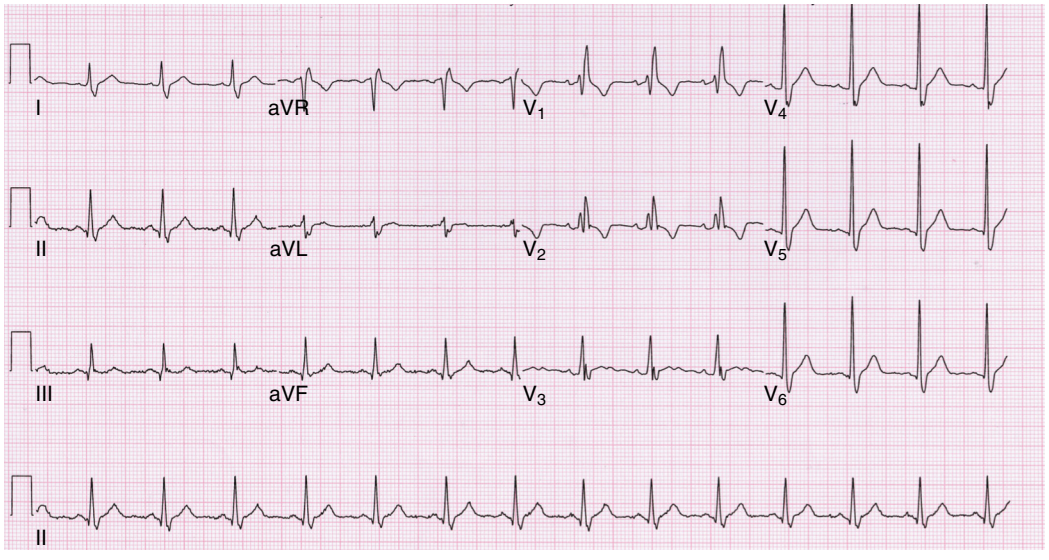
TABLE 42-3 FASCICULAR AND BUNDLE BRANCH BLOCKS

	QRS DURATION	AXIS	QRS MORPHOLOGY	ST SEGMENTS AND T WAVES
LAFB	<0.12 sec (120 msec)	−45 to −90 degrees	Delayed transition across the precordium qR aVL	Normal
LPFB	<0.12 sec (120 msec)	+90 to +180 degrees	Delayed transition across the precordium rS I, aVL qR in III, aVF	Normal
RBBB	≥0.12 sec (120 msec)	Normal	rsr′, rsR′, rSR′ in V_1 (and usually V_2); wide S in V_6 and I	Discordant in V_1 and V_2
RBBB with LAFB	≥0.12 sec (120 msec)	−45 to −90 degrees	rsr′, rsR′, rSR′ in V_1 (and usually V_2); wide S in V_6 and I	Discordant in V_1 and V_2
RBBB with LPFB	≥0.12 sec (120 msec)	+90 to +180 degrees	rsr′, rsR′, rSR′ in V_1 (and usually V_2); wide S in V_6 and I	Discordant in V_1 and V_2
LBBB	≥0.12 sec (120 msec)	Variable	rS or QS in V_1 (S wide and notched); wide notched R without q in V_5, V_6, and I Wide notched R with or without small q in aVL	Discordant in V_1 to V_6

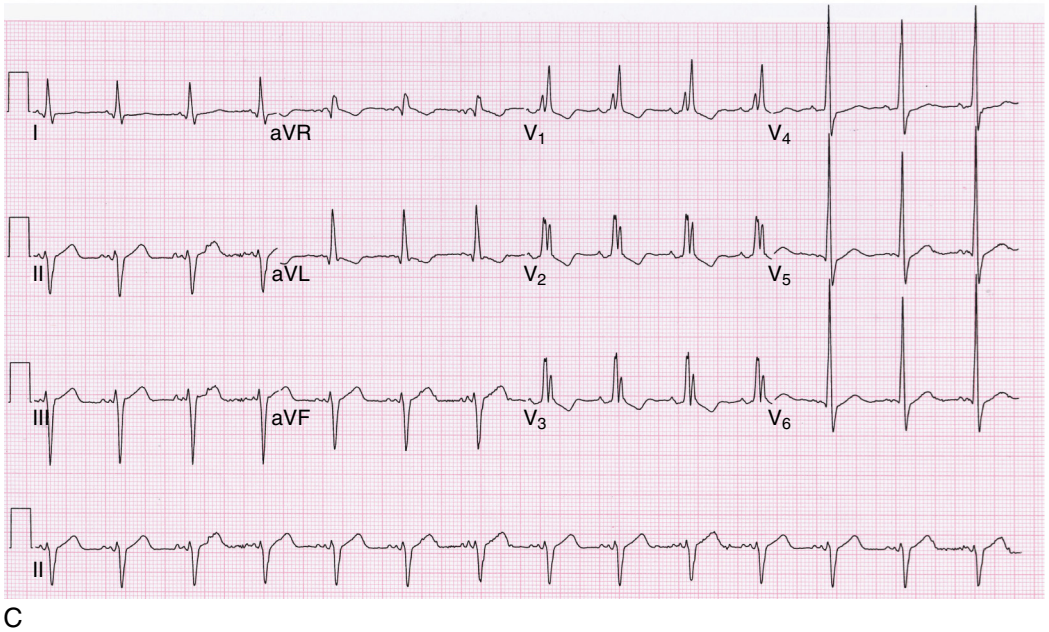
LAD = left axis deviation; LAFB = left anterior fascicular block; LBBB = left bundle branch block; LPFB = left posterior fascicular block; RBBB = right bundle branch block.



A



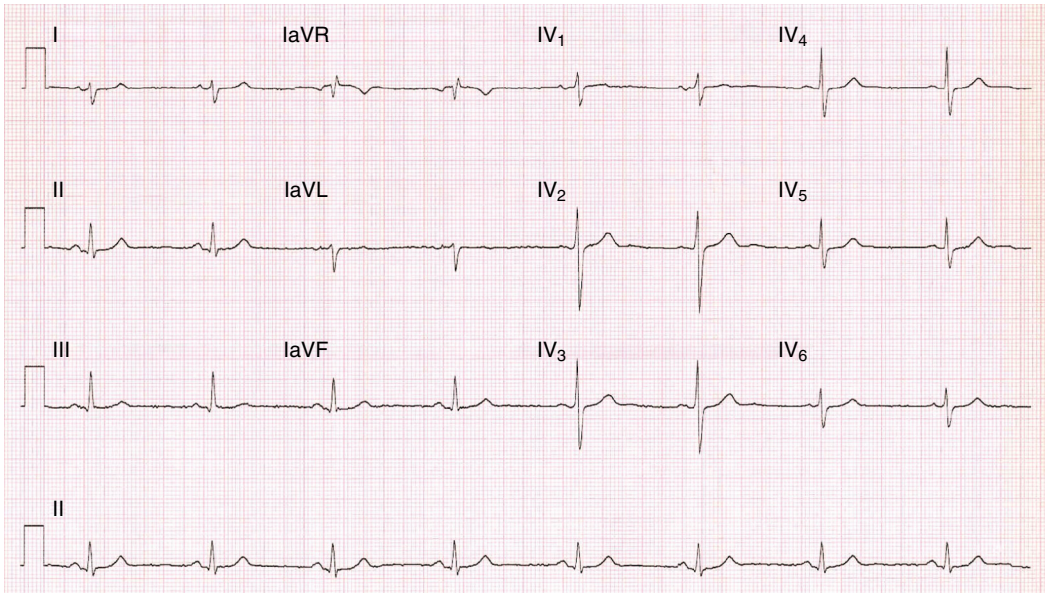
B



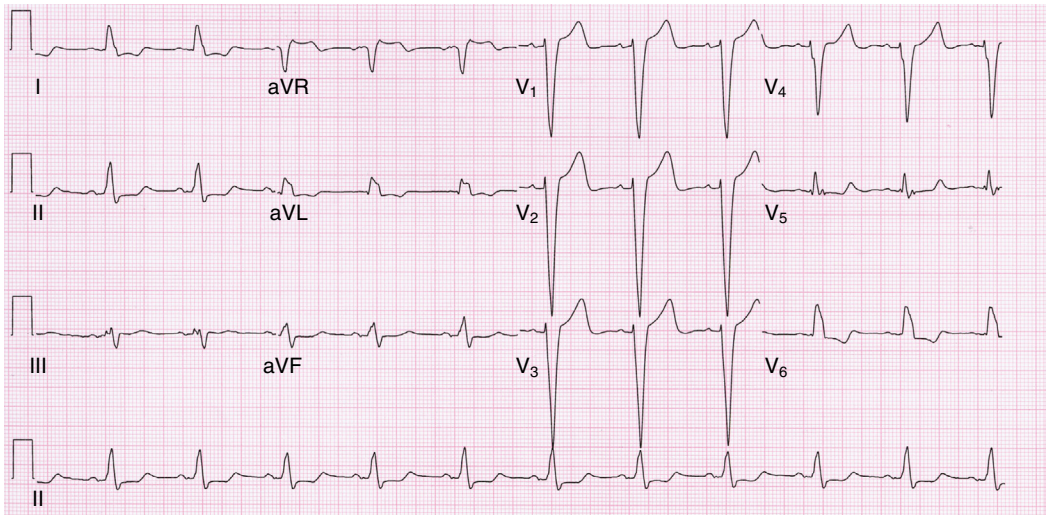
C

FIGURE 42-5. Fascicular and bundle branch blocks. A, Left anterior fascicular block (LAFB). Left axis deviation is present; the axis is approximately −60 degrees. The QRS duration is normal, and there is a delay in R wave progression across the precordial leads (late transition). Small q waves are present in leads I and aVL and small r waves in leads II, III, and aVF. **B,** Right bundle branch block (RBBB). The QRS is widened, with an rsR′ pattern in lead V_1 and a wide terminal S wave in lead V_6. ST segments are downsloping, and T waves are discordant with the QRS complex in the right precordial leads. The axis is normal, and signs of normal septal activation (q waves in lead V_6) are present. **C,** RBBB and LAFB. In addition to features diagnostic of RBBB, an axis of −60 degrees is present.

Continued



D



E

FIGURE 42-5, cont'd. **D, Left posterior fascicular block (LPFB). Right axis deviation (+120 degrees) is present. QRS duration is normal, and R wave progression across the precordial leads is delayed. Leads I and AVL have rS complexes, and the inferior leads have insignificant q waves. E, Left bundle branch block (LBBB). The QRS is widened, with a broad, notched complex in leads I, aVL, and the left precordial leads. Small r waves and broad, deep S waves are present in the right precordial leads. With LBBB, the axis is usually normal or deviated to the left. ST segments and T waves are discordant with the QRS complex throughout the precordium.**

Chamber Hypertrophy

A number of criteria for defining left ventricular hypertrophy (LVH; Fig. 42-6) and right ventricular hypertrophy (RVH) have been proposed. All of the LVH criteria suffer from poor sensitivity (ranging from 30 to 50%), although the specificity is reasonable (85 to 95%). The Cornell voltage criterion, developed with an echocardiographic standard for LVH, simply adds the S wave amplitude in V_3 and the R wave amplitude in aVL; a total greater than 2.0 mV in women and 2.8 mV in men implies LVH. In many clinical settings, the Cornell criterion has replaced the more complicated Romhilt-Estes criteria, which assign points for QRS amplitude, repolarization abnormalities ("strain" pattern), left axis deviation, and other electrocardiographic features. These criteria adjusted for body weight also appear to be the preferred method for detecting LVH in obese individuals. RVH is much less common than LVH. Electrocardiographic criteria for diagnosing RVH have even lower sensitivity (10 to 20%) than for LVH, although the specificity is similar. The Sokolow-Lyon criterion for RVH adds the R wave amplitude in V_1 to the S wave amplitude in lead V_5 or V_6; a sum of 1.05 mV or greater implies RVH.

Low QRS Voltage

Low QRS voltage is defined as limb lead voltage less than 5 mm (0.5 mV) in all leads or precordial voltage less than 10 mm (1 mV) in all leads. The differential diagnosis is broad (Table 42-4), and many patients will not have a clinically apparent underlying explanation.

Repolarization Abnormalities

Abnormalities of the ST segment or T waves, or both, are extremely common (Table 42-5). T waves may be in the same direction (concordant) with the QRS complex or discordant. Electrolyte and other metabolic abnormalities, drug effects (particularly digoxin and antiarrhythmic drugs), and secondary effects caused by LVH, bundle branch block, or pacing are all commonly encountered. Abnormal depolarization patterns frequently beget abnormal repolarization.

Early repolarization, which is a relatively common pattern of ST segment elevation and which was previously thought to be benign, occurs more commonly in patients who have idiopathic ventricular fibrillation compared with controls and also has been associated with an increased relative risk of cardiac mortality. The absolute risk of sudden death in apparently healthy patients with the early repolarization pattern remains quite low, however. Whether the "early repolarization syndrome" is a distinct arrhythmic syndrome or a predisposing factor in patients with other arrhythmic substrate(s) is unclear.

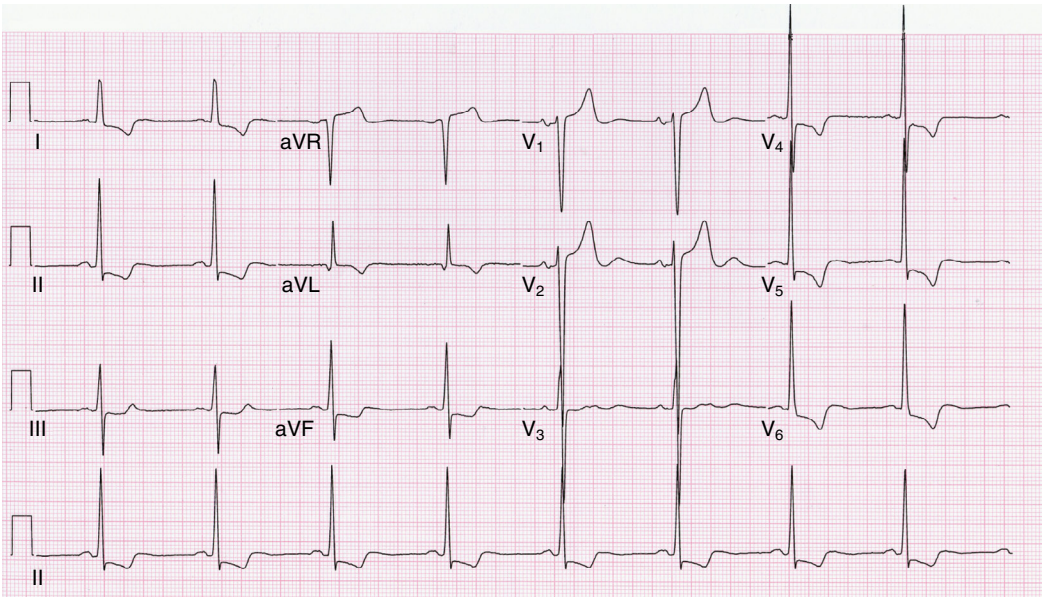


FIGURE 42-6. Left ventricular hypertrophy. Note the striking S wave amplitude in the right precordial leads and R wave amplitude in the left precordial leads. Repolarization abnormalities are present in the left precordial leads, as well as the limb leads. The S wave amplitude in V_3 (2.4 mV) plus the R wave amplitude in aVL (1.0 mV) total 3.4 mV, easily satisfying the Cornell voltage criteria in this 76-year-old hypertensive man. Sinus bradycardia (50 beats per minute) is present as well.

COMPUTERIZED ELECTROCARDIOGRAPHIC READINGS

Automatic computerized ECG interpretations are generally accurate for calculating heart rates, axes, and intervals, but most if not all such systems require over-reading by a physician who will also compare the current ECG to older ECGs. In one large study of patients who received a prehospital ECG, automated interpretation for ST elevation MI (STEMI) had sensitivity and specificity of about 93% and 99%, respectively. False-positive interpretations were due primarily to artifact and nonischemic causes of ST elevation; false-negatives were rare, but related primarily to algorithmic shortcomings. Another study comparing three automated algorithms, however, reported much lower sensitivities and specificities. However, computerized readings are not reliable for diagnosis of rhythm disturbances,[3] and an over-reading by a physician remains mandatory to confirm the cardiac rhythm.

Despite these current limitations, emerging artificial intelligence systems are more accurate than cardiologists with regard to a number of ECG characteristics, such as timing intervals, P-wave morphology, QRS morphology, and left ventricular hypertrophy.[4,5] For example, artificial intelligence ECG analysis can diagnose left ventricular systolic dysfunction in patients who present with dyspnea,[6] predict which patients are at risk for developing atrial fibrillation or ischemic stroke,[7,8] and diagnose hypertrophic cardiomyopathy. These and other enhancements are likely to revolutionize ECG reading in the future.

ELECTROCARDIOGRAMS IN ATHLETES

Extensive physical training leads to structural, electrophysiologic, and autonomic adaptations that can appear abnormal on an uninformed ECG reading.[9] Among the most important are rhythms suggesting hypervagotonia, early repolarization, and increased chamber size (Table 42-6 and Fig. 42-7). Differentiation between physiologic adaptations to exercise and potentially life-threatening abnormalities can be difficult and often requires expert consultation. The early repolarization pattern is seen frequently in athletes and may not necessarily imply significant risk in this setting.

ELECTROCARDIOGRAM IN CORONAVIRUS-19 DISEASE

Patients with coronavirus-19 disease (COVID-19; Chapter 336) may have a variety of tachyarrhythmias related to fever, hypoxia, and myocardial

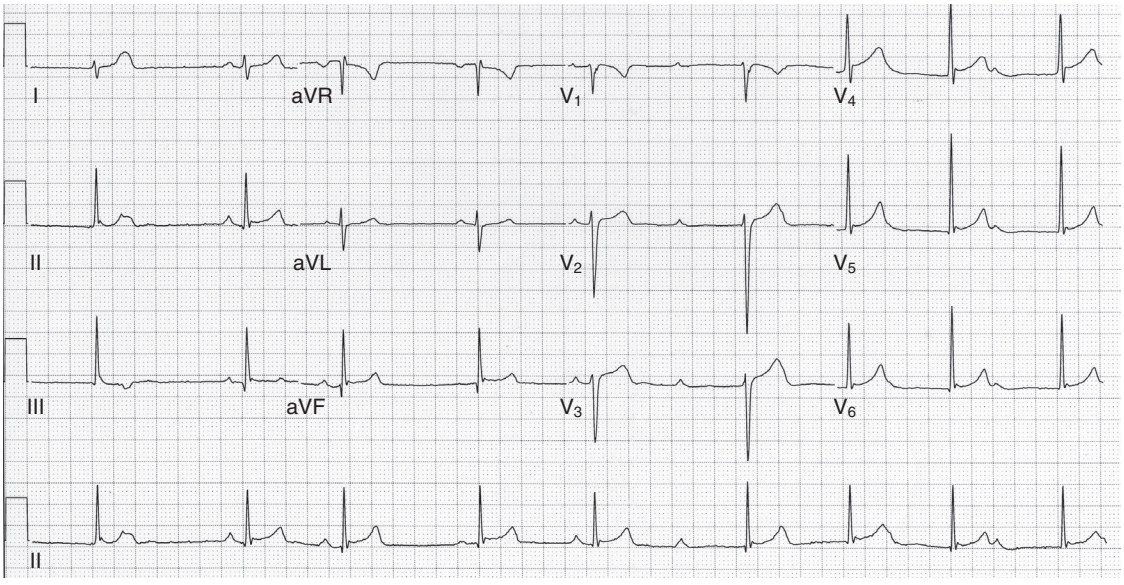

FIGURE 42-7. Athlete's heart. Bradycardia, variable P wave morphology, Mobitz I (Wenckebach) second-degree AV block, and junctional escape beats all reflect hypervagotonia in this thin, 18-year-old athlete. Mild right axis deviation is present, not uncommon in adolescents and young adults. Prominent S waves are present in leads V_2 and V_3, though formal voltage criteria for LVH are absent. Note sinus P waves following junctional beats that are blocked; this is not abnormal physiology.

involvement. New-onset atrial fibrillation (Chapter 52), QT-interval prolongation, ST-segment and T-wave changes, and ventricular arrhythmias (Chapter 53) are associated with a poorer prognosis, although they likely are markers of a poor prognosis rather than mediators.[10,11]

SCREENING ELECTROCARDIOGRAMS

Though frequently recommended by cardiologists and primary care physicians, screening ECGs and exercise ECGs (i.e., exercise stress test) have not been shown to improve outcomes in asymptomatic adults. The U.S. Preventive Services Task Force recommends against obtaining a screening resting or exercise ECG in asymptomatic adults who are at low risk of coronary heart disease events (Chapter 12).[A1,12] For asymptomatic adults at intermediate or high risk, evidence is insufficient to make a recommendation. The American College of Cardiology specifically recommends against performing pre-procedure ECG screening in low-risk, asymptomatic patients (Chapter 399).[13] Electrocardiographic screening of competitive athletes prior to participation remains controversial,[14] as does whether improved ECG interpretation should lead to reconsidering a screening ECG in the military.[15]

AMBULATORY ELECTROCARDIOGRAPHY

Ambulatory electrocardiography (Chapter 49) is used primarily to correlate symptoms, such as palpitations and light-headedness, with intermittent cardiac arrhythmias. Wearable devices such as smartwatches to screen for arrhythmias, especially atrial fibrillation, can increase the ability to detect asymptomatic events by about 10-fold and can guide the institution of prophylactic anticoagulant treatment, with about a 1% net absolute benefit in persons age 75 years after 7 years of follow-up.[A2] The reliability and validity of wearable devices to detect myocardial ischemia is less proven.[16]

43 ECHOCARDIOGRAPHY

CATHERINE M. OTTO

Echocardiography is the clinical standard for evaluation of cardiac function in patients with known or suspected heart disease.[1] This chapter reviews the basic principles of echocardiography, standard imaging approaches, quantitative measurements, and clinical indications.[2,3] The specific indications for echocardiography and additional echocardiographic images are presented in other chapters on individual types of cardiovascular diseases.

ECHOCARDIOGRAPHIC IMAGING PRINCIPLES

Echocardiography is based on the use of a piezoelectric crystal that converts electrical to mechanical energy, and vice versa, allowing both transmission and reception of an ultrasound signal. The frequency of ultrasound waves used for diagnostic imaging ranges from 2 to 10 MHz, with lower frequencies having greater tissue penetration and higher frequencies providing better image resolution. Each transducer consists of a complex array of piezoelectric crystals arranged to provide images in a fanlike two- or three-dimensional image, with the narrow top of this sector scan indicating the origin of the ultrasound signal. Transducers also include an acoustic lens that determines the focal depth, height, and width of the ultrasound beam.

Images are generated on the basis of the reflection of ultrasound from acoustic interfaces, for example, the boundary between the blood in the left ventricle and the myocardium. The time delay between transmission and reception is used to determine the depth of origin of the ultrasound reflection. The depths of the reflected signals from multiple ultrasound beams are combined to generate an image. The speed of signal analysis allows acquisition of two-dimensional images at slower frame rates. Ultrasound is strongly attenuated by bone and air, so echocardiography relies on acoustic "windows," where ultrasound can penetrate to the heart while avoiding the ribs and lungs. With transthoracic imaging, the patient is positioned to bring the cardiac structures close to the chest wall, usually in a left lateral decubitus position, and the transducer is placed on the chest, with use of gel to provide acoustic coupling between the transducer and skin. Standard transthoracic acoustic windows are parasternal, apical, subcostal, and suprasternal notch.

43 ECHOCARDIOGRAPHY

CATHERINE M. OTTO

Echocardiography is the clinical standard for evaluation of cardiac function in patients with known or suspected heart disease.[1] This chapter reviews the basic principles of echocardiography, standard imaging approaches, quantitative measurements, and clinical indications.[2,3] The specific indications for echocardiography and additional echocardiographic images are presented in other chapters on individual types of cardiovascular diseases.

ECHOCARDIOGRAPHIC IMAGING PRINCIPLES

Echocardiography is based on the use of a piezoelectric crystal that converts electrical to mechanical energy, and vice versa, allowing both transmission and reception of an ultrasound signal. The frequency of ultrasound waves used for diagnostic imaging ranges from 2 to 10 MHz, with lower frequencies having greater tissue penetration and higher frequencies providing better image resolution. Each transducer consists of a complex array of piezoelectric crystals arranged to provide images in a fanlike two- or three-dimensional image, with the narrow top of this sector scan indicating the origin of the ultrasound signal. Transducers also include an acoustic lens that determines the focal depth, height, and width of the ultrasound beam.

Images are generated on the basis of the reflection of ultrasound from acoustic interfaces, for example, the boundary between the blood in the left ventricle and the myocardium. The time delay between transmission and reception is used to determine the depth of origin of the ultrasound reflection. The depths of the reflected signals from multiple ultrasound beams are combined to generate an image. The speed of signal analysis allows acquisition of two-dimensional images at slower frame rates. Ultrasound is strongly attenuated by bone and air, so echocardiography relies on acoustic "windows," where ultrasound can penetrate to the heart while avoiding the ribs and lungs. With transthoracic imaging, the patient is positioned to bring the cardiac structures close to the chest wall, usually in a left lateral decubitus position, and the transducer is placed on the chest, with use of gel to provide acoustic coupling between the transducer and skin. Standard transthoracic acoustic windows are parasternal, apical, subcostal, and suprasternal notch.

ABSTRACT

Echocardiography is the clinical standard for evaluation of cardiac function. Imaging allows accurate diagnosis of structural heart disease and measurement of left ventricular ejection fraction. Doppler velocity data provide quantitative measures of cardiac output, diastolic function, valve stenosis and regurgitation, and congenital heart disease. Stress echocardiography is appropriate for diagnosis of coronary disease based on inducible wall motion abnormalities with stress. Transesophageal echocardiography is more accurate than transthoracic imaging for diagnosis of endocarditis, evaluation of prosthetic valves, and visualization of posteriorly located cardiac structures. Point-of-care echocardiography increasingly is used by many clinicians in the acute care setting but does not replace a complete diagnostic study for clinical decision making.

diastolic function
regurgitation

STANDARD IMAGE PLANES

From the parasternal window, the image plane is adjusted manually by an experienced health care provider to obtain long and short axis views. Standard cardiac imaging planes are aligned relative to the axis of the heart, with the long axis defined as the plane that intersects the cardiac apex and the middle of the aortic valve. Short axis views are perpendicular to this long axis, with standard image planes at the cardiac base (aortic valve level), mitral valve, and midventricular levels. From the apical window, the transducer is rotated to provide three views oriented 60 degrees from each other, producing a four-chamber, a two-chamber, and a long axis view (Fig. 43-1; Video 43-1). These image planes also can be acquired with three-dimensional ultrasound transducers, which allow structures to be seen in a cutaway three-dimensional anatomic view or in reconstructed standard two-dimensional planes.

MEASUREMENTS

Echocardiography provides accurate cardiac dimensions and volumes from 3D and 2D recordings. The measurements typically provided include left ventricular end-diastolic and end-systolic chamber diameter and wall thickness, left atrial diameter or volume, and aortic sinus diameter. Left ventricular ejection fraction (EF) is determined from three-dimensional data sets or two orthogonal two-dimensional views (Figs. 43-2 and 43-3; Video 43-2). End-diastolic and end-systolic ventricular volumes (EDV and ESV, respectively) are calculated by validated formulas, and the EF is calculated as:

$$EF = (EDV - ESV)/EDV$$

LIMITATIONS

Echocardiography is an accurate, widely available imaging approach. In some patients, image quality may be suboptimal because of poor tissue penetration (e.g., excessive adipose tissue, position of the lungs relative to the heart), but images are nondiagnostic in less than 5% of patients. Reflections are stronger when the interface is perpendicular to the ultrasound beam, so structures that are parallel to the beam may not be visible, an artifact called *echo dropout*. This potential limitation is avoided by using multiple transducer positions and imaging planes. Ultrasound artifacts, such as beam width, shadowing, and reverberations, may be misinterpreted by inexperienced observers.

DOPPLER ECHOCARDIOGRAPHY

PRINCIPLES

Ultrasound energy that is backscattered from moving red blood cells is shifted to a higher frequency when the blood is moving toward the transducer and a lower frequency when it is moving away. The magnitude of this Doppler shift corresponds to the velocity of blood flow.

MODALITIES

Pulsed Doppler allows measurement of flow velocity at a specific intracardiac site with the advantages of high spatial and temporal resolution. However, spatial localization is based on intermittent sampling at a time interval corresponding to the depth of interest. The sampling frequency, which is depth dependent, limits the maximum detectable velocity because of a phenomenon called *signal aliasing*. Pulsed Doppler usually allows recording of normal intracardiac flow velocities, which are about 1 m/second.

Continuous-wave Doppler allows measurement of high velocities along the entire length of the ultrasound beam, but the origin of the high-velocity signal must be inferred from the two-dimensional images. With stenotic and regurgitant valves, blood flow velocities may be as high as 5 to 6 m/second, requiring the use of the continuous-wave Doppler mode. Both pulsed and continuous-wave Doppler velocities are displayed as a graph of velocity versus time, with the density of the spectral display corresponding to signal strength.

Color Doppler flow imaging is a modification of pulsed Doppler in which the flow velocity is displayed across a two-dimensional or three-dimensional image with a color scale to indicate direction and velocity. The advantage is a visually appealing display of intracardiac flow patterns. Disadvantages are low temporal resolution (frame rates of 10 to 30 per second) and poor velocity resolution due to signal aliasing.

Tissue Doppler uses the Doppler principle to record the velocity of motion of the myocardial wall. Tissue Doppler recordings of the myocardium adjacent to the mitral annulus are used to evaluate diastolic ventricular function. Speckle tracking strain imaging allows direct evaluation of myocardial mechanics (E-Fig. 43-1).

MEASUREMENTS

A standard echocardiographic study includes pulsed Doppler measurement of antegrade flow velocities (transmitral and transaortic), evaluation for valve regurgitation by continuous-wave and color Doppler modalities, and estimation

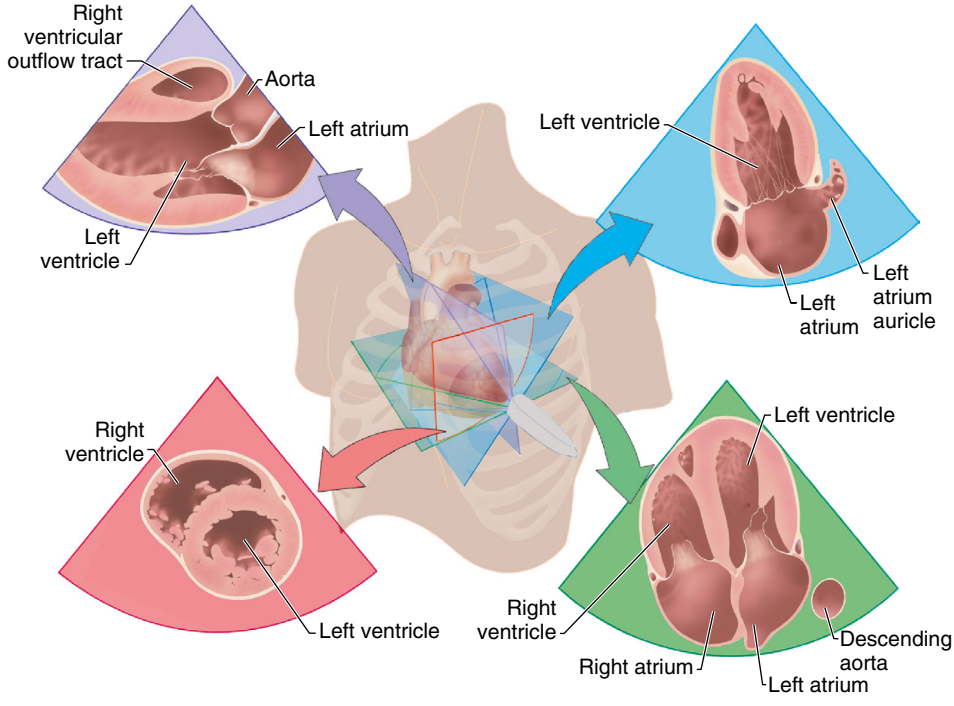

FIGURE 43-1. The four basic image planes used in transthoracic echocardiography. A parasternal transducer position, or "window," is used to obtain long and short axis views. The long axis view (*purple outline*) extends from the left ventricular apex through the aortic valve plane. The short axis view is perpendicular to the long axis view, resulting in a circular view of the left ventricle (*red outline*). The transducer is placed at the ventricular apex to obtain the two-chamber (*blue outline*) and four-chamber (*green outline*) views, each of which is about a 60-degree rotation from the long axis view and perpendicular to the short axis view. The four-chamber view includes both ventricles and both atria. The two-chamber view includes the left ventricle and left atrium; sometimes the atrial appendage is visualized. See Video 43-1. (From Otto CM. *Textbook of Clinical Echocardiography*. 6th ed. Philadelphia: Elsevier; 2018.)

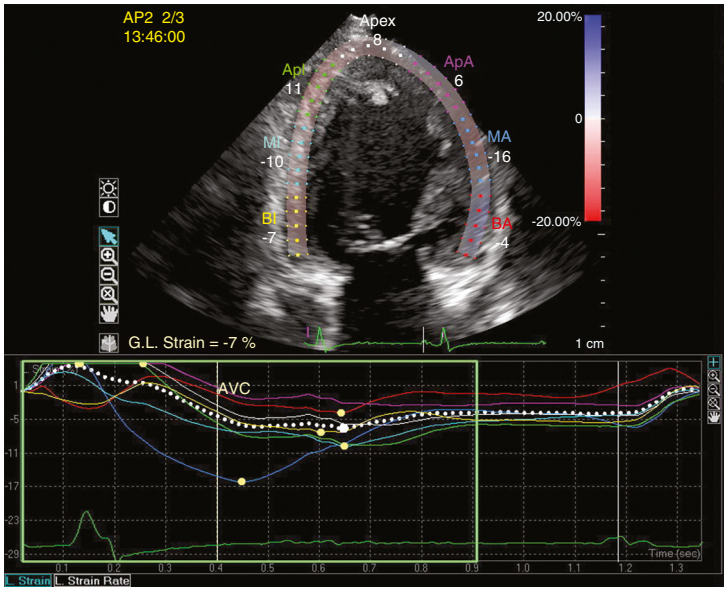

E-FIGURE 43-1. Speckle tracking strain imaging. In an apical four-chamber view, myocardial strain is calculated by the change in distance (divided by the original distance) between echogenic myocardial speckles for each segment as shown by the colored dots. The relationship of time (*x*-axis) with strain (*y*-axis) is shown in colors corresponding to the colors on the two-dimensional image, with global longitudinal strain shown in white. This image is from the same patient as in Figs. 43-2 and 43-3 and shows reduced (only 7%) global longitudinal strain (normal is −16% to −22%).

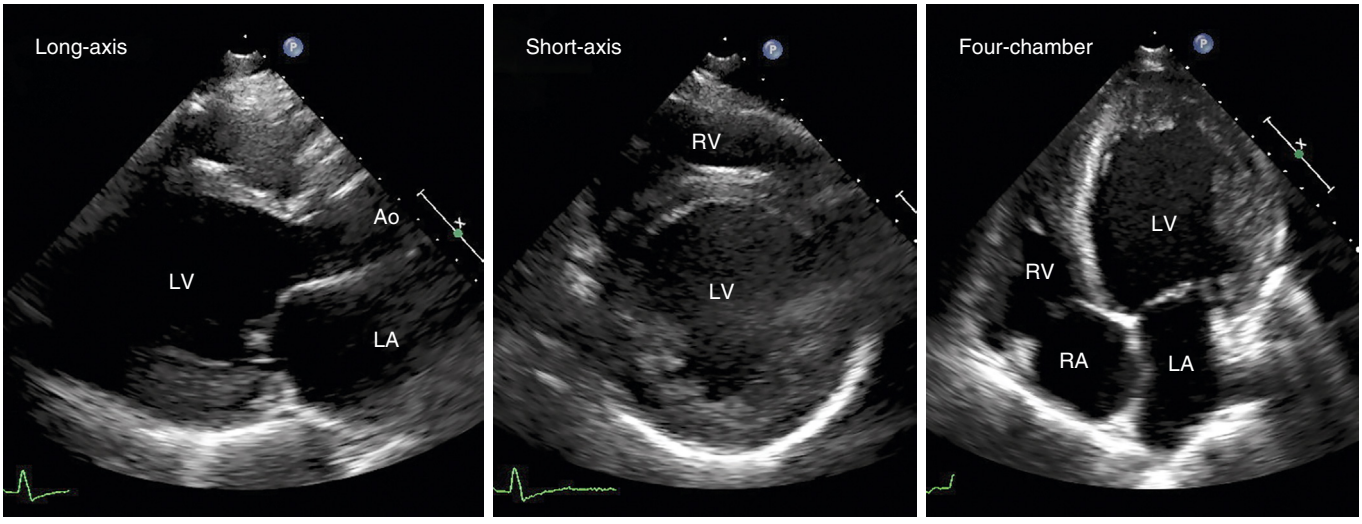

FIGURE 43-2. Dilated cardiomyopathy on echocardiography. This example shows severe left ventricular dilation and systolic dysfunction in standard image planes of the (A) parasternal long axis (*left*), (B) parasternal short axis (*center*), and (C) apical four chamber (*right*). Ao = aorta; LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle. See Video 43-2.

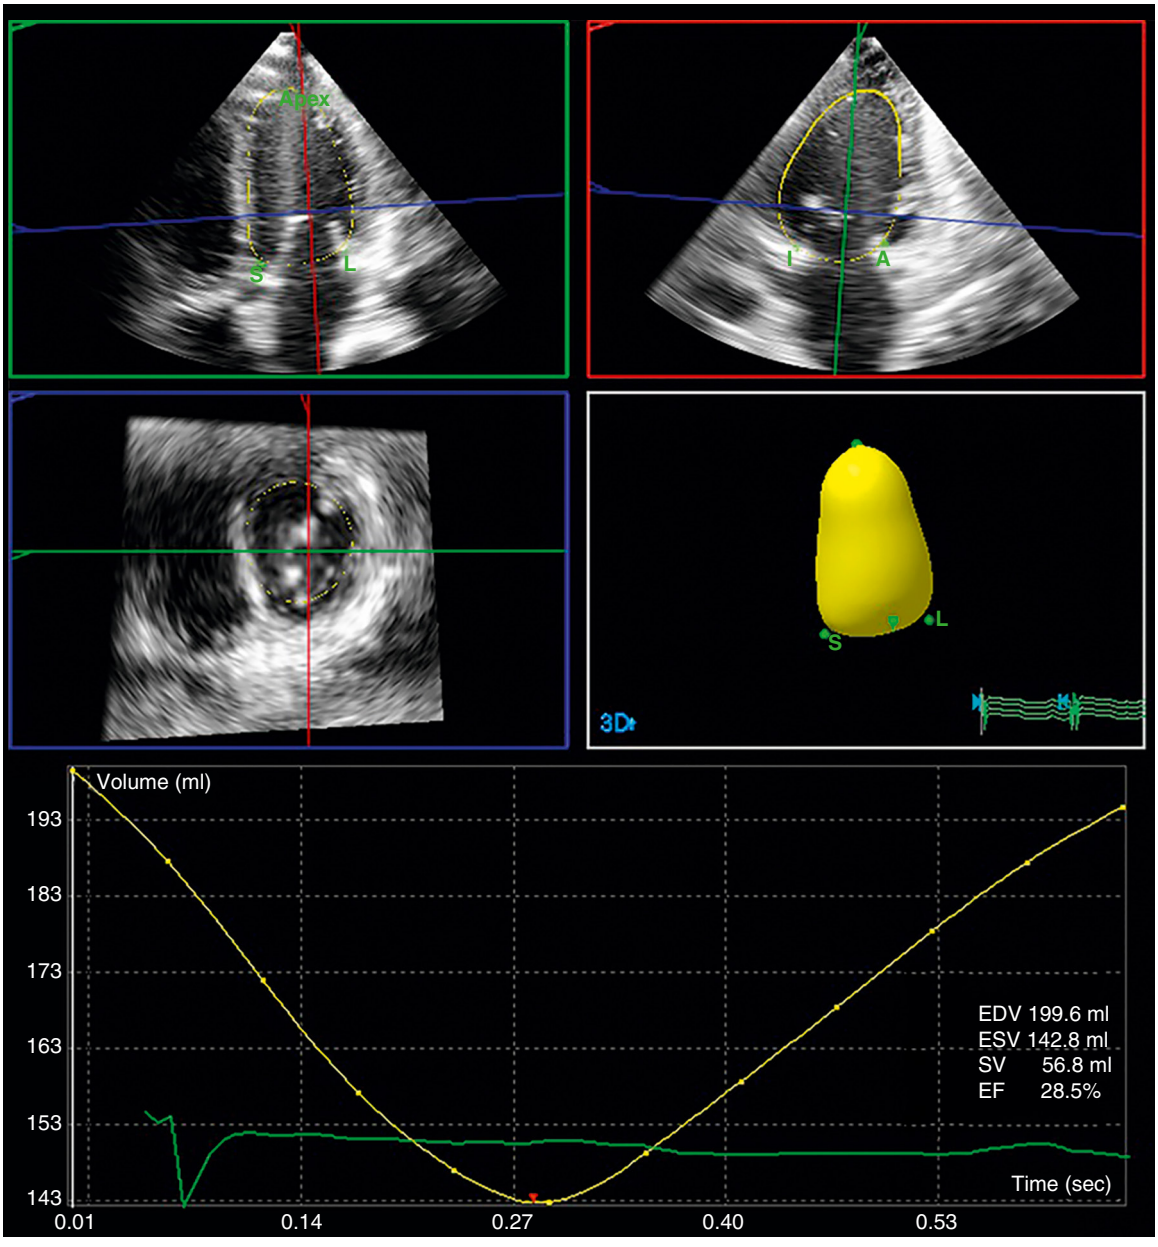

FIGURE 43-3. Three-dimensional echocardiographic measurement of left ventricular volumes and ejection fraction. Three-dimensional imaging shows the ventricle in four-chamber (*upper left*), two-chamber (*upper right*), and short axis (*lower left*) views derived from the three-dimensional image acquisition. The left ventricular chamber is reconstructed in the lower right. The ejection fraction is 28.5%.

of pulmonary systolic pressure based on the velocity of tricuspid regurgitation. Other Doppler measurements depend on the specific clinical indication.

Quantitative measurements using Doppler data are derived from two basic concepts: volume flow rate and the pressure-velocity relationship. Stroke volume (SV, in cubic centimeters) is calculated as the volume of a cylinder, where the base is the spatial cross-sectional area (CSA, in square centimeters) of flow, determined as the area of a circle from a two-dimensional diameter measurement. The height of the cylinder is the distance the average blood cell travels in one cardiac cycle, which is the velocity-time integral (VTI, in centimeters) of flow. Therefore,

$$SV\,(cm^3) = CSA\,(cm^2) \times VTI\,(cm)$$

This approach has been validated to measure transaortic, transmitral, and transpulmonic flow. Measurement of volume flow rate at two different intracardiac sites allows quantitation of intracardiac shunts and valvular regurgitation.

The relationship between the pressure gradient (ΔP) across a narrowing and the velocity (v) of blood flow is described by the simplified Bernoulli equation:

$$\Delta P = 4v^2$$

This equation calculates the maximum and mean gradients across stenotic valves, estimates pulmonary systolic pressure, and evaluates intracardiac hemodynamics with regurgitant valves.

ECHOCARDIOGRAPHIC APPROACHES

Transthoracic echocardiography is the standard clinical approach in most patients with suspected or known cardiac disease (Table 43-1). Advantages are that it is noninvasive, has no known adverse effects, and provides detailed data on cardiac anatomy and physiology. Limitations include poor image quality in some patients, limited visualization of structures distant from the transducer (e.g., atrial septum, left atrial appendage), and inability to visualize structures distal to prosthetic heart valves due to acoustic shadowing.

Transesophageal echocardiography offers superior image quality because of a shorter distance between the transducer and the heart, the absence of interposed bone or lung, and the use of a higher-frequency transducer (Table 43-2). Transesophageal echocardiography usually is well tolerated, but it entails some risk, because most clinicians do this procedure with the patient under moderate sedation. Transesophageal echocardiography is much more sensitive than transthoracic echocardiography for detection of left atrial thrombus (95% vs. 50%), valvular vegetations (99% vs. 60%), and prosthetic mitral valve regurgitation (Fig. 43-4).

Point-of-care ultrasound refers to the use of smaller, less expensive ultrasound systems carried by the physician to perform quick, limited examinations in the emergency department, at the inpatient bedside, or in the outpatient setting (Table 43-3).[4] Point-of-care echocardiography units range from pocket sized to laptop sized. Some are very simple, with only two-dimensional imaging and limited controls; other systems provide high-quality imaging and all Doppler modalities. Point-of-care imaging does not replace a complete echocardiogram but instead serves as an adjunct to the physical examination, particularly in the acute care setting, such as to distinguish ventricular dilation from a pericardial effusion, to estimate ventricular systolic performance, or to screen for aortic stenosis.

Contrast echocardiography may be performed with intravenous injection of agitated saline to opacify the heart chambers. These microbubbles are relatively large and do not pass through pulmonary capillaries. Therefore, appearance of contrast material in the left atrium within one or two beats after right heart opacification is consistent with an intracardiac shunt. Although blood flow occurs predominately from the left to right atrium for most atrial-level shunts, a small amount of right-to-left shunting, which is the basis of this approach, also occurs.

Contrast echocardiography also may be performed with commercially available microbubbles in the range of 1 to 5 μm. Because these microbubbles are smaller than the pulmonary capillaries, opacification of the right heart chambers is followed by opacification of the left ventricle, which can enhance the evaluation of systolic function when image quality is suboptimal, especially during stress echocardiography (Fig. 43-5).

Three-dimensional echocardiography is recommended to quantify left ventricular function and to evaluate complex structural heart disease. It also is essential to guide complex transcatheter interventions (Fig. 43-6; Video 43-3).

Stress echocardiography is a standard approach for evaluating patients with known or suspected coronary artery disease with a high sensitivity (85 to 95%) and specificity (80 to 90%).[5] Although myocardial infarction results in thinning and akinesis of the affected wall, resting myocardial function is normal in the absence of infarction, even when severe epicardial coronary disease is present. The increased myocardial demand associated with exercise or pharmacologic stress leads to myocardial ischemia, which results in a regional wall motion abnormality, often before the onset of chest pain or electrocardiographic changes (Fig. 43-7; Video 43-4).

In patients who can exercise, standard views of the left ventricle are recorded at baseline and immediately after maximal treadmill or bicycle exercise, with the rest and exercise images compared in a side-by-side format. Myocardial ischemia is present if resting wall motion is normal but hypokinesis or akinesis is seen after exercise. The pattern of regional wall motion accurately identifies the area of myocardium at risk and is reasonably reliable for identification of the affected coronary artery. With three-vessel coronary disease, rather than a regional wall motion abnormality, the only clue on imaging may be an absence of the expected decrease in chamber size at peak exercise, caused by diffuse ischemia. Interpretation of an exercise echocardiogram includes exercise duration, hemodynamic response, symptoms, and electrocardiographic changes in addition to the echocardiographic images.

TABLE 43-1 INDICATIONS FOR TRANSTHORACIC ECHOCARDIOGRAPHY IN PATIENTS WITH CARDIAC SIGNS OR SYMPTOMS AND IN THE ACUTE CARE SETTING

CARDIAC SIGNS AND SYMPTOMS
• Cardiac symptoms including chest pain, shortness of breath, palpitations, syncope/presyncope, TIA, stroke, or peripheral embolic event • Abnormal cardiac murmur (any diastolic murmur or systolic murmur grade 3 or louder) • Atrial fibrillation, SVT, VT, frequent or exercise-induced VPCs • Evaluation of pulmonary hypertension • Suspected infective endocarditis (native or prosthetic valve) with positive blood cultures or a new murmur
ACUTE CARE SETTING
• Hypotension or hemodynamic instability of suspected cardiac etiology • Acute chest pain with suspected MI but nondiagnostic ECG • Elevated cardiac biomarkers without other features of ACS • Suspected complications of acute MI • Evaluation of ventricular function after ACS • Respiratory failure of uncertain etiology • Guidance of therapy with acute pulmonary embolism

ACS = acute coronary syndrome; ECG = electrocardiogram; MI = myocardial infarction; SVT = supraventricular tachycardia; TIA = transient ischemic attack; VPCs = ventricular premature contractions; VT = ventricular tachycardia.
Modified from Otto CM. *Textbook of Clinical Echocardiography*. 6th ed. Philadelphia: Elsevier; 2018.

TABLE 43-2 INDICATIONS FOR TRANSESOPHAGEAL ECHOCARDIOGRAPHY AS THE INITIAL OR SUPPLEMENTAL TEST

• Suspected endocarditis with a moderate or high pretest probability (e.g., staphylococcal bacteremia, fungemia, prosthetic heart valve, or intracardiac device) • Suspected complications of endocarditis (e.g., abscess, fistula) • Suspected prosthetic mitral valve dysfunction • Evaluation of posterior structure (e.g., atrial baffles) in patients with congenital heart disease • Evaluation of patients with atrial fibrillation or flutter to facilitate clinical decision making with regard to anticoagulation, cardioversion, or radio frequency ablation • Evaluation for cardiac source of embolus with no identified source on TTE • Evaluation of valve structure and function to evaluate suitability for surgical or transcatheter valve interventions • Suspected acute aortic disease, including dissection and transection (although CT preferred for this indication) • Guidance for transcatheter interventions for structural heart disease, such as closure of a patent foramen ovale or atrial septal defect, or transcatheter edge-to-edge repair for valve regurgitation • Reevaluation for interval changes compared with prior TEE when a change in therapy is anticipated

CT = computed tomography; PFO/ASD = patent foramen ovale/atrial septal defect; TEE = transesophageal echocardiography; TTE = transthoracic echocardiography.
Modified from Otto CM. *Textbook of Clinical Echocardiography*. 6th ed. Philadelphia: Elsevier; 2018.

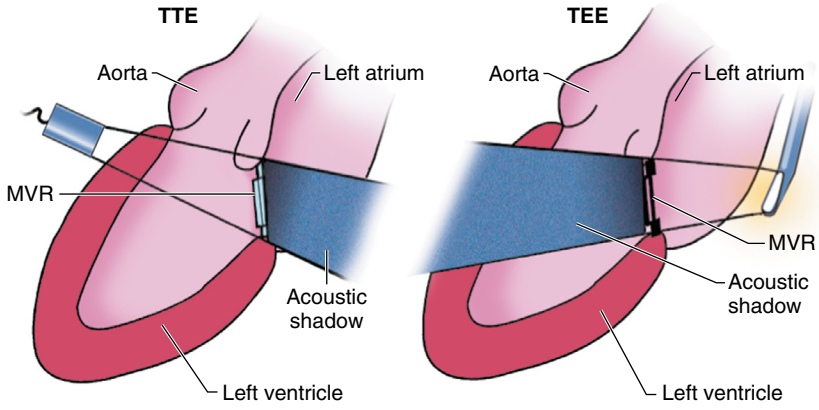

FIGURE 43-4. **The problem of acoustic shadowing from a prosthetic mitral valve replacement (MVR).** ***Left***, **With transthoracic echocardiography (TTE), the acoustic shadow distal to the prosthetic valve obscures the left atrium, limiting assessment of valve regurgitation by Doppler techniques.** ***Right***, **With transesophageal echocardiography (TEE), the left atrium now can be evaluated for valvular regurgitation. However, the acoustic shadow now obscures the left ventricle. (From Otto CM.** ***Textbook of Clinical Echocardiography*****. 5th ed. Philadelphia: Elsevier; 2018.)**

TABLE 43-3 INDICATIONS FOR POINT-OF-CARE ECHOCARDIOGRAPHY

Urgent clinical evaluation (emergency department or intensive care unit)
- Left ventricular size (volume status) and systolic function
- Right ventricular size and systolic function
- Pericardial effusion/tamponade

Screening at-risk populations (athletes, rheumatic heart disease, etc.)
Frequent serial exams for known abnormality (e.g., response to heart failure therapy)

In patients who are unable to exercise, stress testing can be performed with a graded intravenous infusion of dobutamine, beginning at 5 to 10 μg/kg/minute and gradually increasing to a maximum dose of 40 μg/kg/minute. If needed, atropine is used to achieve 85% of the maximum predicted heart rate. In addition to evaluation for myocardial ischemia, myocardial viability is evidenced by an improvement in endocardial motion from baseline to low-dose dobutamine, with subsequent worsening of function at higher doses—the "biphasic" response.

Intracardiac echocardiography is performed with an ultrasound probe on a catheter that is inserted into the right side of the heart through the femoral vein. Intracardiac echocardiography is used in the cardiac catheterization laboratory to guide percutaneous closure of a patent foramen ovale (PFO) and other procedures. In the electrophysiology laboratory, intracardiac echocardiography can help guide catheter positioning and identify complications.

CARDIAC FUNCTION MEASUREMENTS

In addition to qualitative descriptions of cardiac anatomy and physiology, echocardiography provides precise and accurate quantification of cardiac function (including ventricular systolic and diastolic function), the severity of valve stenosis and regurgitation, and a noninvasive estimate of pulmonary pressures.[6]

SYSTOLIC VENTRICULAR FUNCTION

Left ventricular volumes and ejection fractions are routinely measured by two-dimensional biplane or three-dimensional imaging approaches. When actual measurements are not possible, overall left ventricular systolic function is graded by visual estimation, with an approximate correspondence to EF as follows: normal (EF > 55%), mildly reduced (EF, 40 to 55%), moderately reduced (EF, 20 to 40%), and severely reduced (EF < 20%). Cardiac output calculations are not routine but may be helpful for noninvasive monitoring of therapy in patients with heart failure. Because EF measurements are affected by preload and afterload, measures that are less dependent on loading conditions, including the end-systolic dimension or volume, are generally preferred for clinical decision making in situations such as the timing of surgery for chronic valvular regurgitation.

Speckle tracking strain imaging is less load-dependent than standard imaging and allows evaluation of global and regional ventricular function. A reduction in global longitudinal strain may be seen before a detectable reduction in the ejection fraction in patients with inherited cardiomyopathies or after treatment with cardiotoxic chemotherapy.[7]

Quantitative evaluation of right ventricular function by echocardiography is difficult because of the complex shape of the chamber. Useful measurements include the basal diameter, the tricuspid annular plane systolic excursion, and the systolic Doppler tissue velocity at the annulus. Cardiac magnetic resonance imaging provides more accurate quantitation of right ventricular volumes and function when it is clinically needed.

DIASTOLIC VENTRICULAR FUNCTION

Evaluation of diastolic ventricular function is challenging because the patterns of ventricular filling are affected by preload, heart rate, and coexisting valvular regurgitation in addition to the diastolic properties of the ventricle. However, echocardiography can classify diastolic function on the basis of the combination of left ventricular inflow, pulmonary vein flow, tissue Doppler velocities, and isovolumic relaxation time. An estimate of left ventricular filling pressure (e.g., left ventricular end-diastolic pressure) also can be inferred by these approaches.

VALVULAR STENOSIS

Echocardiography is the clinical standard for evaluating patients with known or suspected valvular heart disease and is far more accurate than cardiac auscultation for diagnosis.[8] When significant valvular stenosis is a concern but echocardiography is not diagnostic or seems discordant with other clinical information, measurement of valve calcification by computed tomography (Chapter 44) or of a serum brain natriuretic protein level may be helpful. In current practice, cardiac catheterization is rarely performed to diagnose the severity of valve stenosis, although coronary arteriography may be indicated before valve surgery to evaluate the coronary anatomy and to determine whether concomitant myocardial revascularization may be indicated (Chapter 56).

In patients with aortic stenosis, the most direct measure of stenosis severity is the antegrade velocity across the valve, indicating mild (<3 m/second), moderate (3 to 3.9 m/second), or severe (≥4 m/second) valve obstruction. The maximum and mean transaortic pressure gradients also can be calculated by the Bernoulli equation. Accurate evaluation depends on a careful examination by an experienced echocardiographer.

Aortic valve area (AVA) is calculated by the continuity equation, based on the concept that volume flow rates proximal to and within the narrowed orifice are equal:

$$AVA \times VTI_{AS} = CSA_{LVOT} \times VTI_{LVOT}$$

or

$$AVA = (CSA_{LVOT} \times VTI_{LVOT}) / VTI_{AS}$$

where LVOT is left ventricular outflow tract, VTI is velocity-time integral, CSA is cross-sectional area, and AS is aortic stenosis (Fig. 43-8). It is especially important to calculate the AVA when left ventricular systolic dysfunction accompanies aortic valve disease. In some patients, low-dose dobutamine stress echocardiography is helpful in distinguishing ventricular dysfunction caused by severe aortic stenosis from primary myocardial disease with concurrent moderate stenosis.

The evaluation of mitral stenosis (see Fig. 60-4) focuses on the calculation of valve area, both from direct planimetry of the area of the orifice on three-dimensional or two-dimensional images and from the deceleration slope of the

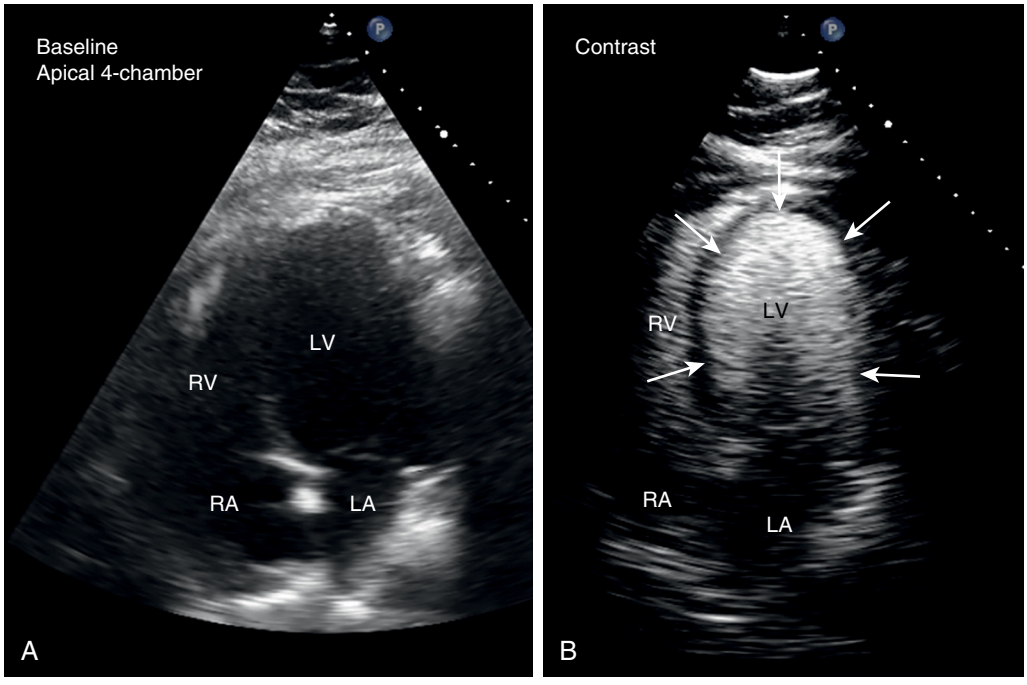

FIGURE 43-5. **Poor-quality apical view (A) with marked improvement in definition of the left ventricular cavity after opacification by contrast echocardiography (B).** The arrows indicate improved identification of the left ventricular endocardial border for calculation of ejection fraction. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

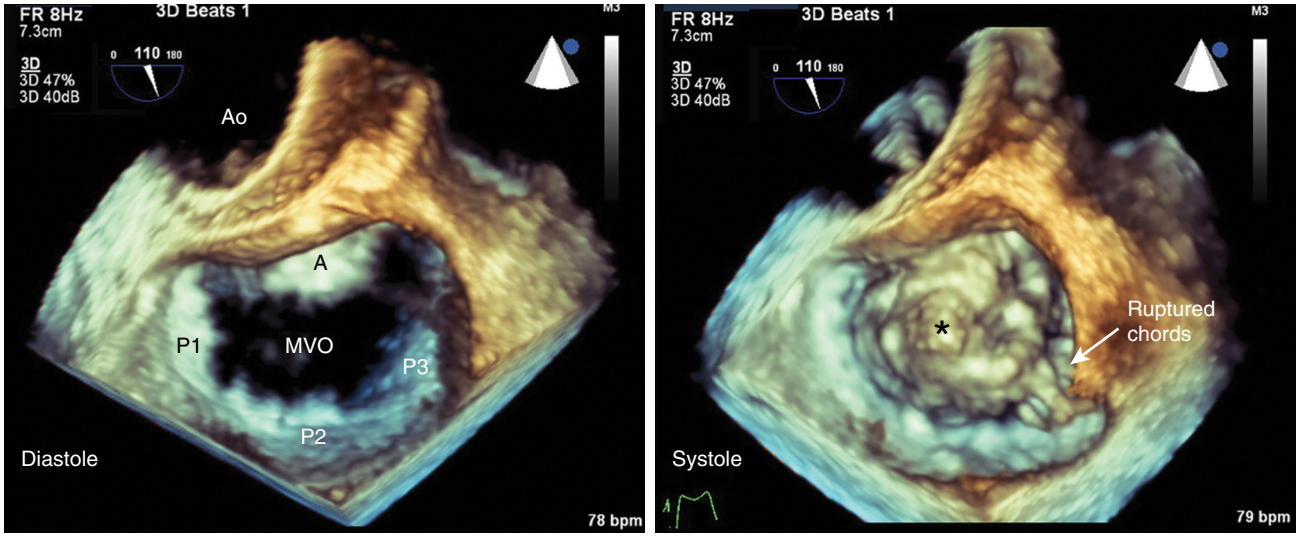

FIGURE 43-6. **The surgeon's three-dimensional view of the mitral valve from the left atrial side of the valve with the aortic valve at the top of the image.** In diastole, the anterior (A) leaflet and posterior leaflet (with P1, P2, and P3 scallops) are seen in the open position, with the normal mitral valve orifice (MVO). In systole (B), severe prolapse of the anterior leaflet is seen, particularly one bulging section (*asterisk*), and a flail segment with two small ruptured chords (*arrow*) is well visualized. These abnormalities cause severe, posteriorly directed mitral regurgitation. Ao = aorta. See Video 43-3. (From Otto CM. *Textbook of Clinical Echocardiography*. 6th ed. Philadelphia: Elsevier; 2018.)

Doppler curve (pressure half-time method). The mean transmitral gradient, which is dependent on the heart rate and volume flow rate as well as the severity of the stenosis, is not recommended to define the severity of mitral stenosis.

VALVULAR REGURGITATION

The current approach to evaluating valvular regurgitation (see Figs. 60-5 and 60-8) is based on the proximal geometry of the regurgitant jet, with measurement of the narrowest jet width (vena contracta). When further quantification is needed, regurgitant volume, regurgitant fraction, and regurgitant orifice area are calculated. Although color flow visualization of the flow disturbance may be helpful for detecting regurgitation and for understanding the mechanism of valve dysfunction, this approach should no longer be used to evaluate severity.

For aortic regurgitation, a narrow vena contracta (<3 mm) indicates mild regurgitation, whereas a wide vena contracta (>6 mm) indicates severe regurgitation. Additional evaluation of the severity of aortic regurgitation is based on the presence of holodiastolic flow reversal in the abdominal aorta and the density and slope of the continuous-wave Doppler velocity curve. The approach to evaluating mitral regurgitation (see Fig. 60-5) is similar, beginning with measurement of the vena contracta. In addition to calculation based on transmitral versus transaortic volume flow rates, the proximal acceleration of flow into the regurgitant orifice allows evaluation with central regurgitant jets based on the proximal isovelocity surface area method.

PULMONARY PRESSURES

Estimation of pulmonary artery systolic pressure (PAP) is a standard component of any echocardiographic study. The systolic pressure difference between the right ventricle and right atrium is calculated from the peak velocity in the tricuspid regurgitant (V_{TR}) jet, with use of the Bernoulli equation. Then, the right atrial pressure (RAP) is estimated from the size and appearance of the inferior vena cava. Because right ventricular and pulmonary artery systolic pressures are equal (in the absence of pulmonic stenosis),

$$PAP = 4(V_{TR})^2 + RAP$$

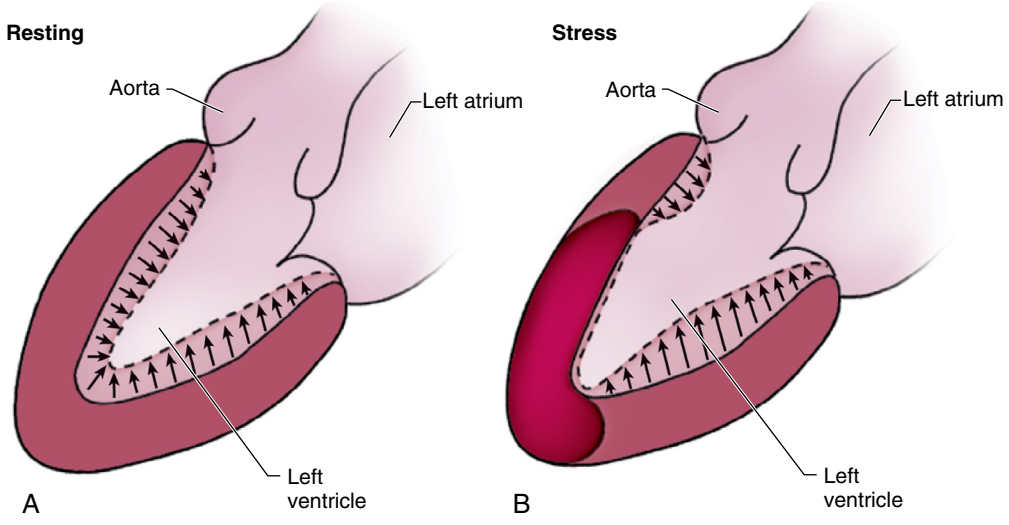

FIGURE 43-7. **The concept of stress echocardiography in a patient with 70% stenosis in the proximal third of the left anterior descending coronary artery.** At rest (A), endocardial motion and wall thickening are normal. After stress (B), either exercise or pharmacologic, the middle and apical segments of the anterior wall become ischemic, showing reduced endocardial wall motion and wall thickening. If the left anterior descending coronary artery extends around the apex, the apical segment of the posterior wall also will be affected, as shown here. The normal segment of the posterior wall shows compensatory hyperkinesis. See Video 43-4. (From Otto CM. *Textbook of Clinical Echocardiography*. 6th ed. Philadelphia: Elsevier; 2018.)

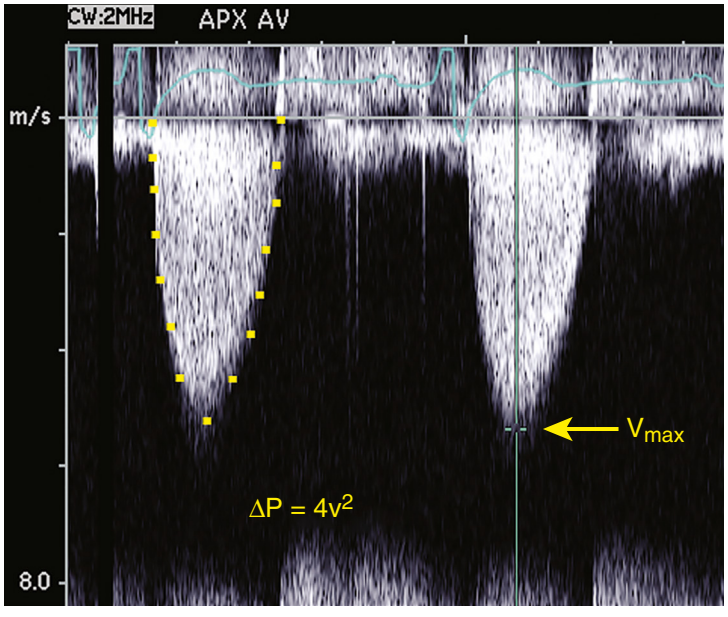

FIGURE 43-8. **In a patient with aortic stenosis, the aortic jet velocity is recorded with continuous-wave Doppler from the window that yields the highest-velocity signal.** Maximum velocity (V_{max}) is used to calculate the maximum systolic gradient. The Doppler curve is traced, as shown, to calculate the mean systolic gradient with the Bernoulli equation, by which the pressure gradient (ΔP) equals four times the square of the velocity.

A small amount of tricuspid regurgitation is present in most patients, so pulmonary pressures can be estimated with this approach in more than 90% of patients. Because this approach measures only pulmonary systolic pressure, not pulmonary vascular resistance, invasive evaluation may still be needed in some clinical situations (Chapter 69).

THE ECHOCARDIOGRAPHIC EXAMINATION

CLINICAL INDICATIONS

Currently, echocardiography is not recommended for screening of the general population in developed countries, but it is an effective approach to the initial evaluation of many cardiac signs and symptoms (Table 43-4),[9] with a better sensitivity than the clinical evaluation for detecting left ventricular dysfunction and valvular heart disease. Screening can also be effective in low-resource settings with a high prevalence of rheumatic heart disease.[10] A transthoracic examination is appropriate initially in most patients, although transesophageal imaging is needed for some specific diagnoses, such as concern for para-valvular abscess in patients with infected endocarditis and to exclude left atrial thrombosis before cardioversion (Chapter 52). Resting echocardiography is not helpful for diagnosis of coronary artery disease; stress imaging is needed if this diagnosis is suspected (Chapter 56). In patients with known cardiac disease, echocardiography is used to evaluate severity, to assess the results of medical and surgical interventions, and to guide procedures. Point-of-care ultrasound is useful for rapid screening to evaluate overall left ventricular function and to detect pericardial effusion (Fig. 43-9; Video 43-5).[11–13]

NORMAL FINDINGS

Trace to mild valve regurgitation is considered "physiologic" and is seen with 70 to 80% of mitral valves, 80 to 90% of tricuspid valves, and 70 to 80% of pulmonic valves in normal individuals. The prevalence of aortic regurgitation increases with age, but it is found in only 5% of young normal adults; the presence of aortic regurgitation raises the possibility of subtle aortic valve or root abnormalities.

A patent foramen ovale (Chapter 55) is present in 25 to 35% of normal individuals and may be identified by color Doppler or by contrast echocardiography. Use of the Valsalva maneuver enhances identification of a patent foramen ovale because the slight elevation in right atrial pressure may lead to a brief right-to-left shunt. The significance of a patent foramen ovale in patients without clinical events is unclear. Other common anatomic variants seen on echocardiography include aberrant chords (or "webs") in the left ventricle; small, linear, mobile echoes associated with the valves (Lambl's excrescences); and normal ridges in the left and right atria.

Unexpected abnormal findings also may be found on studies requested for other indications. A bicuspid aortic valve is present in 1 to 2% of the population; most of these patients are asymptomatic until late in life, so many cases are diagnosed "incidentally" by echocardiography. Aortic valve sclerosis, which is a frequent unexpected echocardiographic diagnosis, is a marker of cardiovascular disease and an increased risk of myocardial infarction even if valve function is normal.

INTEGRATING THE ECHOCARDIOGRAPHIC AND CLINICAL FINDINGS

The echocardiographic request should indicate the specific reason for the study and any relevant symptoms or signs. The echocardiographic examination then can be tailored to answer the clinical question.

The echocardiographic results should be interpreted in conjunction with other clinical data. If the echocardiographic data seem discrepant with the clinical data, the requesting physician should review the images with the echocardiographer to identify areas of uncertainty and to determine the next best diagnostic step.

TABLE 43-4 INDICATIONS FOR TRANSTHORACIC ECHOCARDIOGRAPHY (TTE) BY KNOWN DIAGNOSIS

CLINICAL DIAGNOSIS	KEY ECHOCARDIOGRAPHIC FINDINGS	LIMITATIONS OF ECHOCARDIOGRAPHY	ALTERNATIVE APPROACHES
VALVULAR HEART DISEASE (CHAPTER 60)			
Valve stenosis	Cause of stenosis, valve anatomy Transvalvular ΔP, valve area Chamber enlargement and hypertrophy LV and RV systolic function Associated valvular regurgitation	Possible underestimation of the stenosis severity Possible coexisting coronary artery disease	Cardiac catheterization; CMR
Valve regurgitation	Mechanism and cause of regurgitation Severity of regurgitation Chamber enlargement LV and RV systolic function PA pressure estimate	TEE may be needed to evaluate mitral regurgitant severity and valve anatomy (especially before MV repair)	Cardiac catheterization; CMR
Prosthetic valve function	Evidence for stenosis Detection of regurgitation Chamber enlargement Ventricular function PA pressure estimate	TTE is limited by shadowing and reverberations TEE is needed for suspected prosthetic MR due to "masking" of the LA on TTE	Cardiac catheterization; fluoroscopy
Endocarditis (Chapter 61)	Detection of vegetations (TTE sensitivity, 70-85%) Presence and degree of valve dysfunction Chamber enlargement and function Detection of abscess Possible prognostic implications	TEE more sensitive for detection of vegetations (>90%) A definite diagnosis of endocarditis also depends on bacteriologic criteria TEE more sensitive for detection abscess	Blood cultures and clinical findings also are diagnostic criteria for endocarditis
CORONARY ARTERY DISEASE			
Acute myocardial infarction (Chapters 57 and 58)	Segmental wall motion abnormality reflects "myocardium at risk" Global LV function (EF) Complications: Acute MR vs. VSD Pericarditis LV thrombus, aneurysm, or rupture RV infarct	Coronary artery anatomy itself is not directly visualized	Coronary angiography (by catheterization or CT) Radionuclide or PET imaging for myocardial perfusion
Angina (Chapter 56)	Global and segmental LV systolic function Exclude other causes of angina (e.g., AS, HCM)	Resting wall motion may be normal despite significant CAD Stress echocardiography is needed to induce ischemia and wall motion abnormality	Coronary angiography Radionuclide or PET imaging ETT
Pre-revascularization/ post-revascularization (Chapter 59)	Assess wall thickening and endocardial motion at baseline Improvement in segmental function after procedure	Dobutamine stress or contrast echocardiography is needed to detect viable but nonfunctioning myocardium	CMR Coronary angiography Radionuclide or PET imaging Contrast echocardiography
End-stage ischemic disease	Overall LV systolic function (EF) PA pressures Associated MR LV thrombus RV systolic function	—	Coronary angiography (by catheterization or CT) Radionuclide or PET imaging CMR for myocardial viability
CARDIOMYOPATHY (CHAPTERS 45-47)			
Dilated	Chamber dilation (all four) LV and RV systolic function (qualitative and EF) Coexisting atrioventricular valve regurgitation PA systolic pressure LV thrombus	Indirect measures of LVEDP Accurate EF may be difficult if image quality is poor	CMR for LV size, function, and myocardial fibrosis LV angiography with left and right heart hemodynamics
Restrictive	LV wall thickness LV systolic function LV diastolic function PA systolic pressure	Must be distinguished from constrictive pericarditis	Cardiac catheterization with direct, simultaneous RV and LV pressure measurement after volume loading CMR
Hypertrophic	Pattern and extent of LV hypertrophy Dynamic LVOT obstruction (imaging and Doppler) Coexisting MR Diastolic LV dysfunction	Exercise echo to detect inducible LV outflow tract obstruction	CMR Strain and strain rate imaging
HYPERTENSION (CHAPTER 64)			
	LV wall thickness and chamber dimensions LV hypertrophy LV diastolic dysfunction LV systolic function Aortic valve sclerosis Mitral annular calcification	Diastolic dysfunction precedes systolic dysfunction, but detection is challenging because of age and other factors	Speckle tracking; strain and strain rate imaging LV twist and torsion
PERICARDIAL DISEASE (CHAPTER 62)			
	Pericardial thickening Detection, size, and location of PE Two-dimensional signs of tamponade physiology Doppler signs of tamponade physiology	Diagnosis of tamponade is a hemodynamic and clinical diagnosis Constrictive pericarditis is a difficult diagnosis Not all patients with pericarditis have an effusion	Intracardiac pressure measurements for tamponade or constriction CMR or CT to detect pericardial thickening

TABLE 43-4 INDICATIONS FOR TRANSTHORACIC ECHOCARDIOGRAPHY (TTE) BY KNOWN DIAGNOSIS—cont'd

CLINICAL DIAGNOSIS	KEY ECHOCARDIOGRAPHIC FINDINGS	LIMITATIONS OF ECHOCARDIOGRAPHY	ALTERNATIVE APPROACHES
DISEASES OF THE AORTA (CHAPTER 63)			
Aortic root dilation	Cause of aortic dilation Accurate aortic root diameter measurements Anatomy of sinuses of Valsalva (especially Marfan syndrome) Associated aortic regurgitation	The ascending aorta is only partially visualized on TTE in most patients	CT CMR TEE
Aortic dissection	Two-dimensional images of ascending aorta, aortic arch, descending thoracic and proximal abdominal aorta Imaging of dissection "flap" Associated aortic regurgitation Ventricular function	TEE more sensitive (97%) and more specific (100%) Cannot assess distal vascular beds	Aortography CT CMR TEE
CARDIAC MASSES (CHAPTER 47)			
LV thrombus	High sensitivity and specificity for diagnosis of LV thrombus Suspect with apical wall motion abnormality or diffuse LV systolic dysfunction	Technical artifacts can be misleading 5-MHz or higher frequency transducer and angulated apical views needed	LV thrombus may not be recognized on radionuclide or contrast angiography
LA thrombus	Low sensitivity for detection of LA thrombus, although specificity is high Suspect with LA enlargement, MV disease	TEE needed to detect LA thrombus reliably	TEE
Cardiac tumors	Size, location, and physiologic consequences of tumor mass	Extracardiac involvement is not well seen Cannot distinguish benign from malignant tumor or tumor from thrombus	TEE CT CMR (with cardiac gating) Intracardiac echocardiography
PULMONARY HYPERTENSION (CHAPTER 69)			
	PA pressure estimate Evidence of left-sided heart disease to account for increased PA pressures RV size and systolic function (cor pulmonale) Associated TR	Indirect PA pressure measurement Difficult to determine pulmonary vascular resistance accurately	Cardiac catheterization
CONGENITAL HEART DISEASE (CHAPTER 55)			
	Detection and assessment of anatomic abnormalities Quantitation of physiologic abnormalities Chamber enlargement Ventricular function	No direct intracardiac pressure measurements Complicated anatomy may be difficult to evaluate if image quality is poor (TEE is helpful)	CMR with three-dimensional reconstruction Cardiac catheterization TEE Three-dimensional echocardiography

AS = aortic stenosis; CAD = coronary artery disease; CMR = cardiac magnetic resonance; CT = computed tomography; EF = ejection fraction; ETT = exercise treadmill test; HCM = hypertrophic cardiomyopathy; LA = left atrium; LV = left ventricle; LVEDP = left ventricular end-diastolic pressure; LVOT = left ventricular outflow tract; MR = mitral regurgitation; MV = mitral valve; ΔP = pressure gradient; PA = pulmonary artery; PE = pericardial effusion; PET = positron emission tomography; RV = right ventricle; TEE = transesophageal echocardiography; TR = tricuspid regurgitation; TTE = transthoracic echocardiography; VSD = ventricular septal defect.

44 NONINVASIVE CARDIAC IMAGING

CHRISTOPHER M. KRAMER, VASKEN DILSIZIAN, AND KLAUS D. HAGSPIEL

RADIOGRAPHY OF THE HEART

Chest radiography is a widely available, relatively inexpensive, and rapid imaging modality, with an average effective radiation dose of 0.03 to 0.1 mSv. The heart is best evaluated on posteroanterior (PA) and lateral radiographs, with the heart closest to the image detector.

On the chest radiograph, the heart appears as a homogeneous shadow surrounded by lungs, so diagnostic assessment of the heart and great vessels is based on the size and shape of the cardiac silhouette, rather than on direct visualization of the heart's internal anatomy. Nevertheless, the size and shape of the heart and their changes over time, together with the appearance of the pulmonary vasculature, aid in the diagnosis of cardiac diseases. The radiographic appearance of the heart is also influenced by the radiographic technique, projection, body habitus, degree of inspiration, and whether the patient is supine or erect during the examination.

On the PA projection, the normal heart is located in the middle mediastinum, with approximately two thirds projecting to the left of the midsternum (Fig. 44-1). The superior segment of the right heart border is a more or less straight line formed by the superior vena cava and right innominate vein. The inferior segment is convex and formed by the right atrium. The left heart border consists of three segments: the aortic arch superiorly, the main pulmonary artery in the middle, and the left ventricle inferiorly. The left atrial appendage is situated in the junction between the lower and middle segments; if enlarged, it can appear as a separate, prominent segment. The inferior border of the heart sometimes is not well differentiated from the diaphragm (see Fig. 44-1).

On lateral chest images, the right ventricle and its outflow tract form the anterior heart border, with the right ventricle in contact with the lower third of the sternum. Lung between the sternum and the posteriorly curving right ventricle and its outflow tract forms the retrosternal clear space. The posterior heart border, which is seen between the carina and the diaphragm on lateral images, consists of the left atrium superiorly and the left ventricle inferiorly. The inferior vena cava courses obliquely upward before it joins the right atrium. The ascending aorta, aortic arch, and proximal descending thoracic aorta are usually well seen on lateral images (see Fig. 44-1).

Alterations of the contour of the heart are generally caused by dilation of the atria, ventricles, or blood vessels. Chest images are not sensitive for detecting cardiac hypertrophy unless it is severe.

Comprehensive cardiovascular analysis of chest radiographs requires evaluation of the size and morphology of the heart and the great vessels, the pulmonary vasculature, and the presence and positioning of any calcifications or implanted devices such as valves, pacemakers, and defibrillators.

RADIOGRAPHIC ASSESSMENT OF HEART SIZE

The cardiothoracic ratio (see Fig. 44-1) estimates the size of the heart. A value of less than 0.5 is considered normal on a radiograph taken during

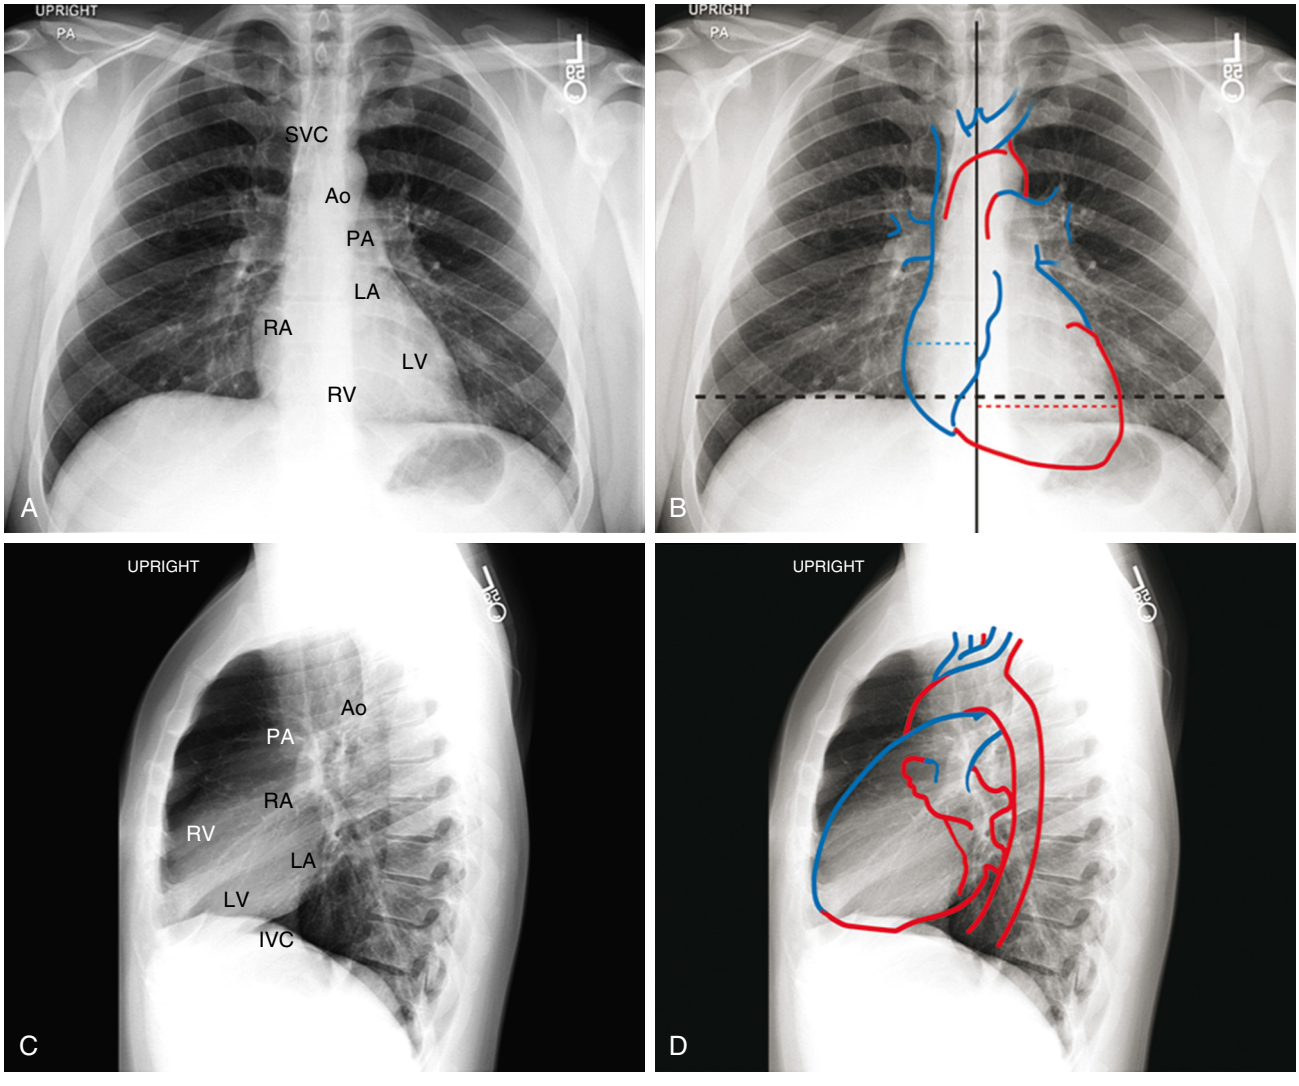

FIGURE 44-1. Normal anatomy. Posteroanterior (**A**) and lateral (**B**) chest radiograph projections in a healthy 28-year-old man. The cardiac chambers and the great vessels are marked on the corresponding drawings (**B, D**). The cardiothoracic ratio (**C**) is calculated by dividing the maximum transverse diameter of the cardiac silhouette (*blue line:* widest distance of the right heart border from the midpoint of the spine; *red line:* widest distance from the left heart border to the midpoint of the spine) through the distance between the internal margin of the ribs at the top of the right diaphragm (*black line*). Ao = aorta; IVC = inferior vena cava; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle; SVC = superior vena cava. WWW.BOOKBAZ.IR

ABSTRACT

This chapter reviews noninvasive cardiac imaging technologies other than echocardiography. Chest radiography is a widely available, relatively inexpensive, and rapid imaging modality that can be used to assess heart size, presence of a pulmonary effusion, size of the pulmonary vasculature, calcifications, and location of cardiac devices. Nuclear cardiology permits the noninvasive imaging of myocardial perfusion under stress and resting conditions and of resting regional and global function to assess myocardial viability and prognosis. Coronary computed tomography (CT) angiography can capture a three-dimensional image of the heart in one to two heartbeats and provide coronary artery calcium scoring without the use of contrast and with little radiation. Recent studies demonstrate the equivalence of coronary CT to stress testing in the initial evaluation of patients with low-intermediate-risk chest pain. Cardiac magnetic resonance is a versatile and flexible imaging modality that is accurate in the evaluation of myocardial ischemia and viability in coronary heart disease, as well as the cause and prognosis of cardiomyopathies, congenital heart disease, aortic disease, pericardial disease, and cardiac masses.

deep inspiration. Pectus excavatum deformities (Chapter 86) and epicardial fat pads can result in an abnormally large cardiothoracic ratio despite a normal-sized heart. Dilation of the left ventricle, which increases the cardiothoracic ratio, appears as a concave mid-left heart border and lengthening of the entire left heart border, with a downward pointing apex projecting below the diaphragm on PA views (Fig. 44-2). Extension of the posterior margin of the left ventricle more than 2 cm posterior to the inferior vena cava on the lateral film is considered a sign of left ventricular enlargement. Localized rather than global left ventricular enlargement usually indicates the presence of ventricular aneurysms (Chapter 58). Left ventricular hypertrophy without dilation usually is not detectable on chest radiographs.

The most common cause of left atrial enlargement is secondary to left ventricular dysfunction, especially left ventricular dilation. Isolated enlargement of the left atrium is usually a sequela of mitral valve abnormalities or atrial fibrillation. Enlargement of the left atrium can also occur with left ventricular hypertrophy without dilation in patients with aortic stenosis (Chapter 60) or hypertrophic cardiomyopathy (Chapter 47). Straightening of the left heart border between the main pulmonary artery and the left ventricle just below the left main bronchus owing to enlargement of the left atrial appendage is one of the earliest signs of left atrial enlargement; with increasing size, this segment becomes convex. A double contour within the right cardiac border (double density sign), splaying of the carina, and elevation of the right main bronchus are less frequent signs (Fig. 44-3).

The right ventricle normally does not form part of the heart's border on PA radiographs, but significant right ventricular enlargement can lead to an abnormal convexity of the left heart border, with elevation and leftward displacement of the cardiac apex. The best radiographic indication of right ventricular enlargement is obliteration of the retrosternal clear space in the lateral view owing to dilation of the right ventricular outflow tract (Fig. 44-4).

Dilation of the right atrium causes the lower segment of the right heart border to become more prominent and increasingly round. In more severe cases, the entire right heart border is enlarged, and in extreme cases, the right atrium can become border-forming on the lateral view (see Fig. 44-3).

PERICARDIAL EFFUSION

Large pericardial effusions cause significant enlargement of the cardiac silhouette despite a normal superior mediastinum—the so-called water-bottle sign. The fluid in the pericardial sac will obscure the hilar vessels on a PA chest film (Fig. 44-5), unlike cardiomegaly without effusion, in which the hilar structures often are relatively conspicuous. Posterior displacement of the pericardial fat line on lateral images is also a valuable finding for the detection of pericardial effusions.

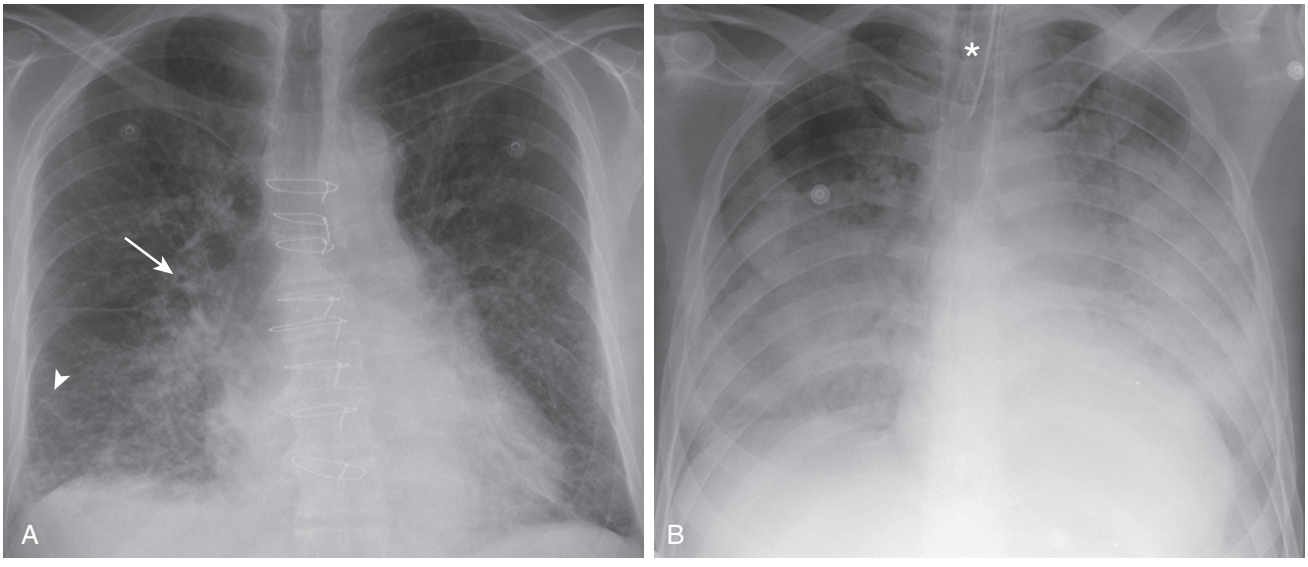

FIGURE 44-2. Left ventricular enlargement and pulmonary edema in two different patients. The image on the left (**A**) was obtained in a patient who had acute myocardial infarction and who had previously undergone aortic bypass grafting (sternotomy wires and bypass clips are seen). Interstitial edema is evidenced by the presence of vascular redistribution, Kerley B lines (*arrowhead*), and peribronchial cuffing (*arrow*). The image on the right (**B**) was obtained in a patient with cardiogenic alveolar edema. The left ventricle is significantly enlarged, and there is extensive bilateral air space consolidation with air bronchogram. Note normal position of an endotracheal tube (*asterisk*) and a nasogastric tube.

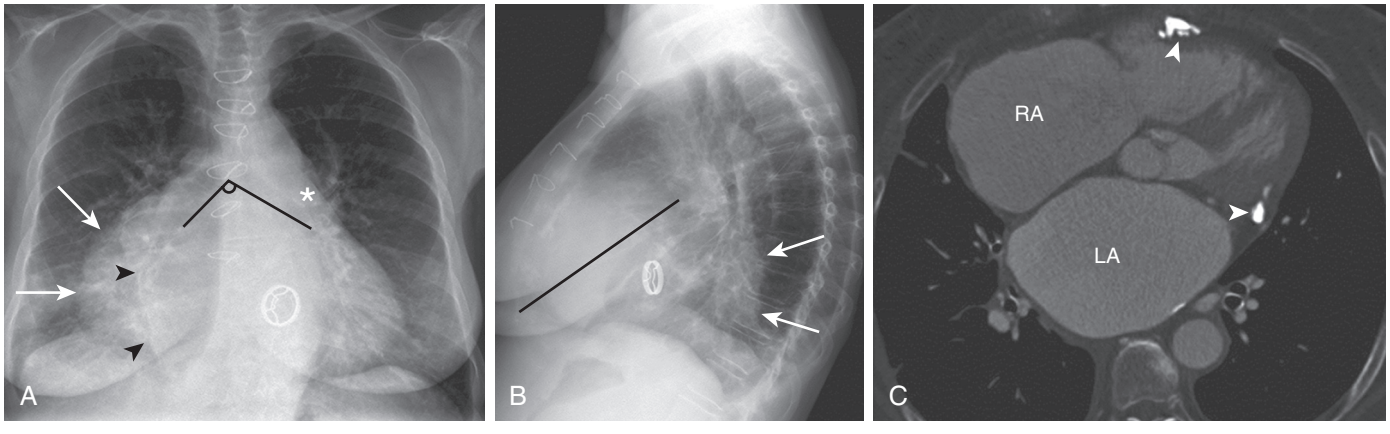

FIGURE 44-3. Biatrial enlargement in a patient who has undergone mitral valve repair. The posteroanterior (**A**) chest radiograph shows a prominent left atrial appendage (*asterisk*), the double density sign (*arrowheads*), and splaying of the carina. There is also enlargement of the right atrium, as evidenced by prominence and round shape of the right side border on the posteroanterior view (*arrows*). Posterior bulging of the heart (*arrows*) owing to biatrial enlargement is seen on the lateral view (**B**). Interstitial pulmonary edema is present. The location of the cardiac valves is best assessed on a lateral view (**B**) by drawing a line from the carina to the anterior costophrenic recess (*black line*). The pulmonic and aortic valves usually are positioned superior to this line, and the tricuspid and mitral valves are inferior to it. A computed tomographic image (**C**) also demonstrates biatrial enlargement as well as pericardial calcifications (*arrowheads*). LA = left atrium; RA = right atrium.

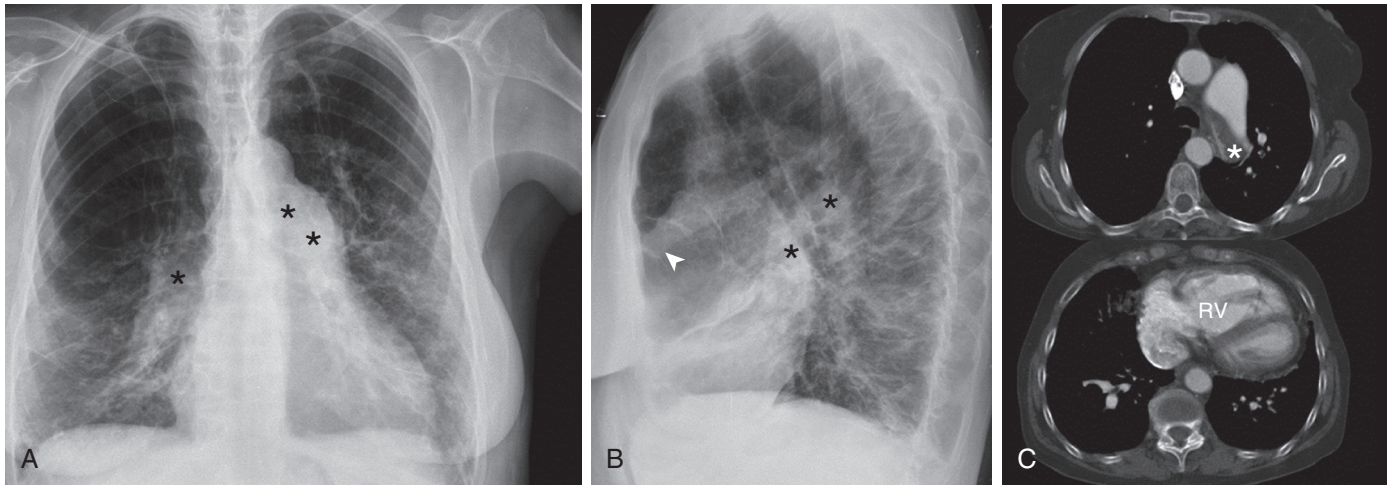

FIGURE 44-4. Pulmonary arterial hypertension in a patient with severe pulmonary emphysema and chronic pulmonary embolism. Enlarged central pulmonary arteries (*asterisks*) and the pruned-tree sign can be seen on the posteroanterior (**A**) and lateral (**B**) projections. Hyperlucency in both upper lobes is present owing to extensive pulmonary emphysema. Right ventricular enlargement has obliterated the retrosternal clear space on the lateral view (*arrowhead*) (**B**). The computed tomographic scan demonstrates dilated central pulmonary arteries with wall-adherent chronic pulmonary embolus (*asterisk*) (**C**) as well as right ventricle (RV) dilation and hypertrophy.

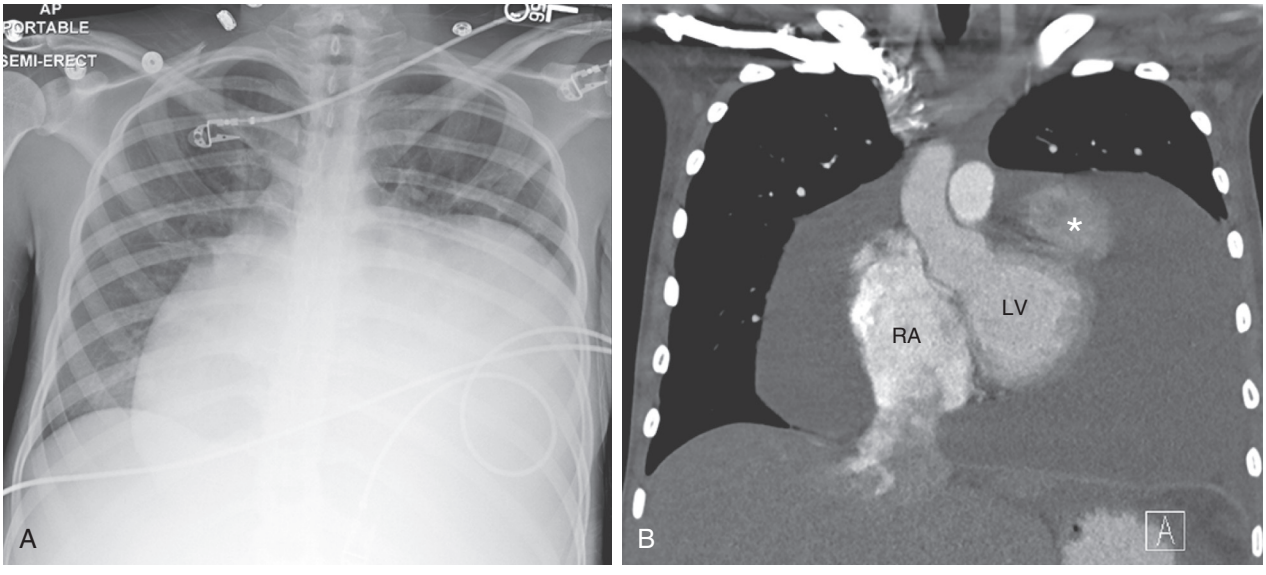

FIGURE 44-5. A 17-year-old girl presenting with massive pericardial effusion. The posteroanterior radiograph (**A**) shows the water-bottle sign; the hilar vessels are obscured. A coronal reformatted computed tomographic scan (**B**) shows the fluid in the pericardial sac as well as dilation of the right atrium and the left atrial appendage (*asterisk*). LV = left ventricle; RA = right atrium.

PULMONARY VASCULATURE

The large and medium-sized pulmonary arteries and veins can be seen on the radiograph as linear shadows, and their size and appearance correlate with pulmonary blood flow and pulmonary venous pressure. The vessels in the lower lung zones are normally larger than in the upper zones as a result of the normal distribution of pulmonary blood flow (see Fig. 44-1). In patients with right-to-left shunts (Chapter 55), the pulmonary vasculature is decreased in caliber. In left-to-right shunts, the vascularity is increased, and the vessels are sharply outlined if the patient does not have heart failure (Fig. 44-6). With increasing pulmonary venous pressure, as is seen in heart failure (Chapters 45 and 46), the vessels in the upper zone enlarge on the chest radiograph. With further increases in pulmonary venous pressures, fluid extravasates into the pulmonary interstitium, and the pulmonary vessels lose their sharp demarcation. Horizontal lines in the periphery of the lungs (Kerley B) and vertical lines in the upper lobes (Kerley A) represent thickened interlobular septae. Fluid in the interstitium of the bronchial walls causes peribronchial thickening or cuffing (see Fig. 44-2). In more advanced cases, the lungs show a diffuse ground-glass appearance that masks the vascular structures, and pulmonary edema ultimately develops (see Fig. 44-2). Long-standing pulmonary arterial hypertension leads to dilation of the central pulmonary arteries with abrupt change in caliber instead of the normal tapering. The size and number of the peripheral arterial branches diminish, resulting in a pruned-tree appearance (see Fig. 44-4).

CALCIFICATIONS

Calcifications can often be seen on chest radiographs. In the heart, calcifications most frequently involve the valves and the mitral annulus (Chapter 60). Most aortic valvular calcifications are degenerative in nature and occur in otherwise normal valves, but their incidence is increased in bicuspid valves or in patients who have had rheumatic fever. Calcification of the mitral annulus is common and usually an asymptomatic finding. Coronary artery calcifications are frequent but are rarely seen on chest radiographs. Calcifications of the ventricles are most often seen in patients with prior myocardial infarction or ventricular aneurysms (Fig. 44-7). Pericardial calcifications tend to be thicker than calcifications in the myocardium and, in severe cases, can entirely surround the heart (see Fig. 44-3).

IMPLANTED DEVICES

A great number of devices can be seen on a chest radiograph, and it is important to be familiar with their appearance to assess their correct position and integrity. The accurate assessment of device position can occasionally require cross-sectional imaging (see Figs. 44-2, 44-3, and 44-7).

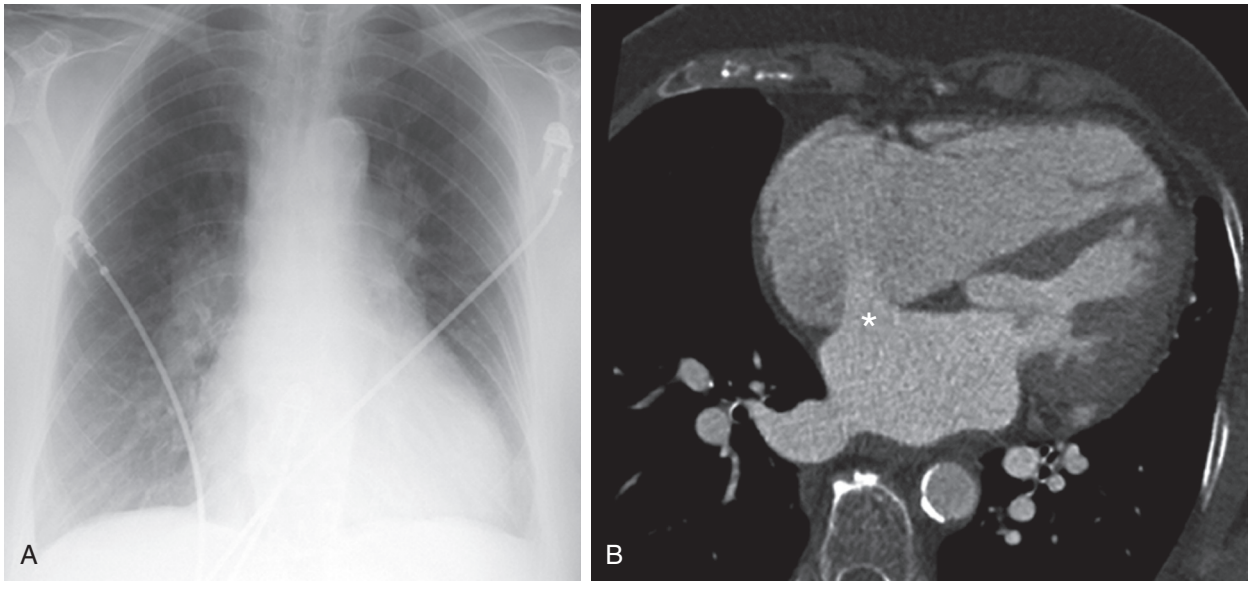

FIGURE 44-6. Female patient with known secundum type atrial septal defect. The posteroanterior radiograph (**A**) shows enlargement of the pulmonary arteries, shunt vascularity, and enlargement of the right heart border. A computed tomographic scan (**B**) shows the septal defect (*asterisk*) with left-to-right shunt. Enlargement of the right heart is also seen.

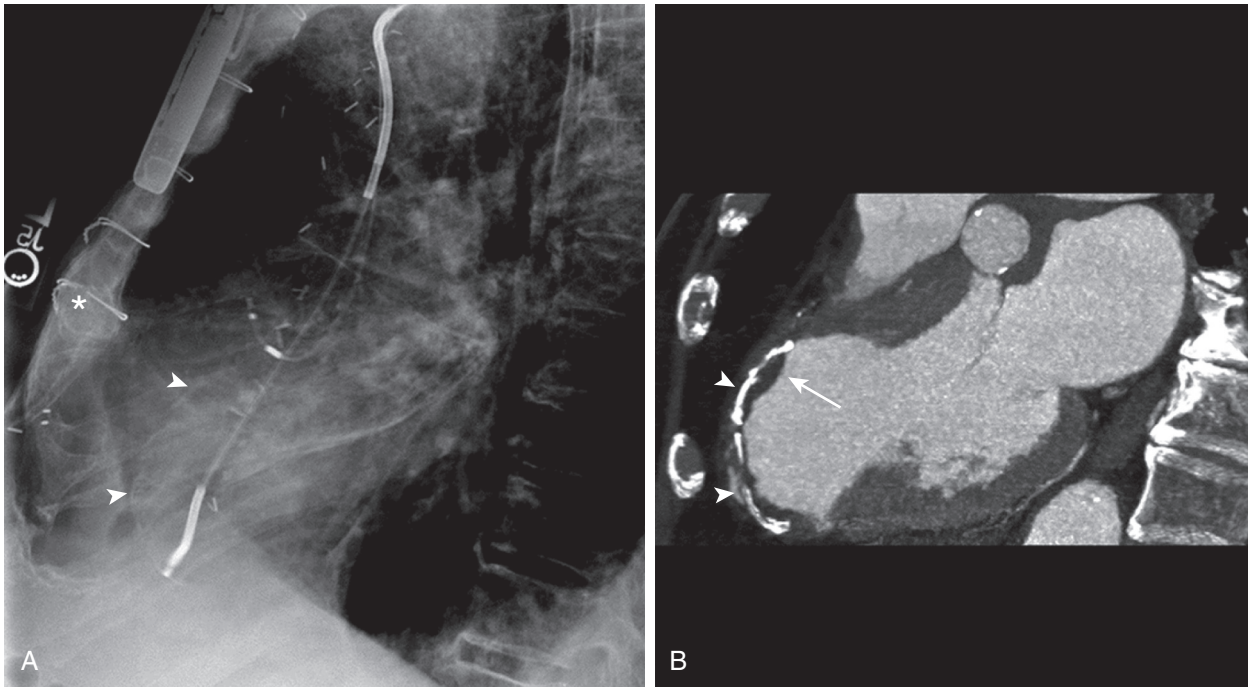

FIGURE 44-7. Calcified chronic myocardial infarction. Lateral radiograph (**A**) demonstrates thin curvilinear calcifications (*arrowheads*) in the region of the left ventricular apex. A reformatted cardiac computed tomographic scan (**B**) shows aneurysmal dilation and thinning of the apex, curvilinear calcifications, and thrombus (*arrow*). Dual-chamber pacer leads, aortocoronary bypass clips, and fracture of the most inferior sternotomy wire (*asterisk*) are also seen on the lateral radiograph (**A**).

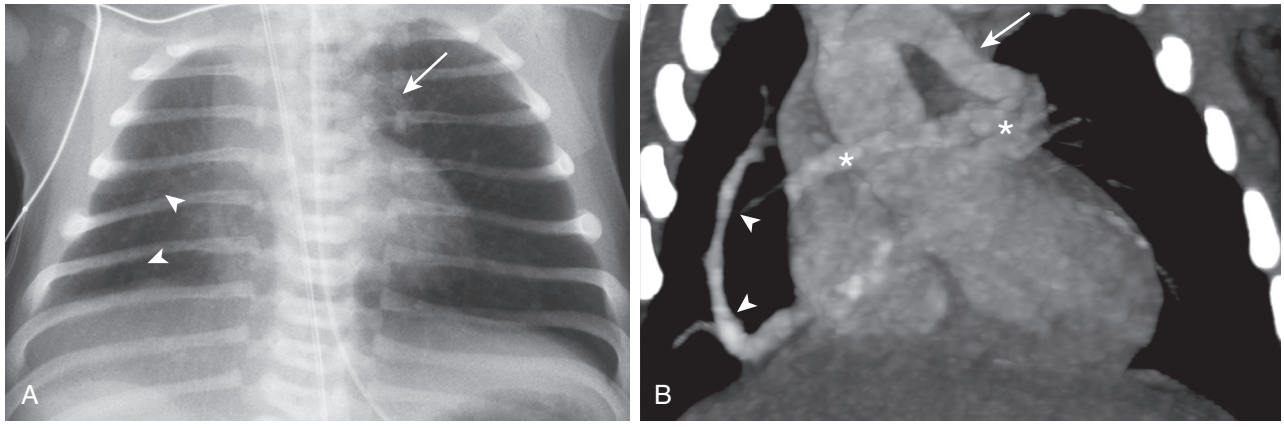
CHARACTERISTIC APPEARANCE OF CARDIAC SILHOUETTE

Certain constellations of findings on chest radiographs can be characteristic of specific disorders. For example, in mitral stenosis, left atrial enlargement, pulmonary venous hypertension, a small aortic knob, and enlargement of the main pulmonary artery are typical findings. In aortic stenosis, left ventricular enlargement, calcifications of the aortic valve, and dilation of the ascending aorta are often present. In pulmonic valve stenosis, enlargement of the pulmonary trunk is the most common radiographic sign, with or without signs of right ventricular enlargement. In atrial septal defects, the heart is usually normal in size, with prominent pulmonary vasculature (shunt vascularity). In ventricular septal defects, the left atrium and left ventricle are prominent, and shunt vascularity is present. A number of classic chest radiographic signs have been described for patients with more complex congenital heart disease (Chapter 55). These findings include the egg-on-a-string sign in transposition of the great arteries, the gooseneck sign in endocardial cushion defects, the boot-shaped heart in tetralogy of Fallot (E-Fig. 44-1), the figure-of-3 and reversed figure-of-3 signs in coarctation of the aorta, the box-shaped heart in Ebstein anomaly, the snowman sign in total anomalous pulmonary venous return, and the scimitar sign in partial anomalous pulmonary venous return. Due to earlier diagnosis and treatment of congenital heart disease, the diagnostic role of chest radiography for these conditions is limited today, but it remains a useful technique for monitoring the progression of disease and its response to treatment.

NUCLEAR CARDIOLOGY

The techniques of nuclear cardiology permit the noninvasive imaging of myocardial perfusion, function, metabolism, and innervation by use of radionuclide imaging agents and gamma or positron cameras with associated computer processing.[1,2] All these techniques are based on acquiring images of radioactivity



E-FIGURE 44-1. Infant with tetralogy of Fallot, pulmonary atresia, and partial anomalous pulmonary venous return. Anteroposterior radiograph (**A**) shows the classic boot-shaped heart seen with tetralogy of Fallot; the scimitar sign, owing to abnormal right pulmonary vein draining into the inferior vena cava (*arrowheads*); and abnormal superior parasternal left-sided mediastinal density caused by a left upper pulmonary vein draining into the left innominate vein (*arrow*). Coronal reformatted computed tomography (**B**) confirms these findings. The pulmonary arteries are diminutive (*asterisks*).

emanating from tracers localized in heart muscle or in the blood pools of the left and right ventricles. Myocardial perfusion imaging is the most commonly performed nuclear cardiology technique, most often in conjunction with either exercise or pharmacologic stress intended to produce flow heterogeneity between relatively hypoperfused and normally perfused myocardial regions.

MYOCARDIAL PERFUSION IMAGING

AGENTS AND TECHNIQUES

For the assessment of myocardial perfusion using single-photon emission computed tomography (SPECT) technology, ^{99m}Tc-labeled perfusion agents or thallium-201 (^{201}Tl) are used for exercise or pharmacologic stress perfusion imaging to evaluate patients with suspected or known coronary heart disease (CHD). Of the various ^{99m}Tc-labeled agents, ^{99m}Tc-sestamibi and ^{99m}Tc-tetrofosmin are the most common. These ^{99m}Tc agents permit simultaneous assessment of regional and global left ventricular function and volumes with ECG-gated SPECT technology. Advantages of positron emission tomography (PET) myocardial perfusion imaging compared with SPECT include higher sensitivity and specificity for the detection of coronary artery disease at a lower radiation dose, reduced image acquisition time (less likelihood of patient motion), higher resolution images, and better soft tissue attenuation (such as for the breast and diaphragm), with added information regarding absolute quantitative hyperemic myocardial blood flow and reserve flow (Chapter 59).

In patients with chest pain or shortness of breath, myocardial perfusion imaging is commonly performed with exercise so as to induce coronary hyperemia and link the symptoms during exercise to the location, extent, and severity of abnormal perfusion patterns. In patients who are unable or incapable of exercising to greater than 85% of the maximum predicted heart rate for their age, pharmacologic stress testing with a vasodilator can be used to induce coronary hyperemia. Vasodilator stress typically causes a modest increase in heart rate and decline in arterial pressure. Options include dipyridamole, adenosine, the selective A_{2A} adenosine receptor agonist regadenoson, or the inotropic/chronotropic agent dobutamine. Dobutamine stress is preferred in patients who have bronchospasm or a history of asthma, or who have consumed caffeine, which is an adenosine receptor antagonist, within 12 hours before testing. Patients who experience side effects such as hypotension and chest pain during vasodilator infusion should be treated with intravenous aminophylline, which is an adenosine antagonist. Unlike exercise stress, however, the perfusion defect induced with pharmacologic vasodilator stress may merely represent the heterogeneity in coronary flow rather than true myocardial ischemia.

Exercise or pharmacologic stress myocardial perfusion images are compared with images acquired at rest. Stress-induced perfusion abnormalities in regions that exhibit normal perfusion at rest are termed reversible perfusion defects, and such regions represent viable, ischemic myocardium with blunted coronary blood flow reserve (Fig. 44-8). Conversely, perfusion abnormalities that are seen both on stress and rest myocardial perfusion images are termed fixed or irreversible defects and most often suggest an area of prior myocardial infarction, particularly if the defect is severe.

CLINICAL APPLICATIONS

The major indications for stress and rest myocardial perfusion imaging are to diagnose coronary heart disease, to assess prognosis, and to detect myocardial viability.

Detection of Coronary Heart Disease

Exercise or pharmacologic stress myocardial perfusion imaging in patients with chest pain yields a sensitivity for detecting coronary heart disease of 88% for SPECT and 93% for PET. The specificity for excluding coronary heart disease is 76% for SPECT and 81% for PET. Exercise or pharmacologic stress SPECT perfusion imaging has sensitivities and specificities that are superior to those of exercise electrocardiography (ECG) testing alone.

SPECT and PET cameras can help combined with a computed tomography (CT) scanner, which allows for multimodality hybrid imaging of anatomy and physiology. Myocardial perfusion imaging can be added to coronary CT angiography (see later) if the latter shows an intermediate coronary stenosis of 50 to 70% in diameter. Conversely, the CT angiogram can be performed after an equivocal SPECT or PET study to distinguish between true-positive and false-positive perfusion defects. Hybrid imaging also permits combined coronary artery calcium scoring with myocardial perfusion.

Assessment of Prognosis

Stress myocardial perfusion imaging does not appear to add any useful prognostic information over exercise ECG testing alone in patients who achieve 10 metabolic equivalents or more of workload (Chapter 39) without ischemic ST segment depression on the exercise ECG or in low-risk women with good physical capacity. In other situations, however, the extent of fixed and reversible defects on SPECT and PET perfusion image can provide important incremental prognostic information when added to clinical characteristics, the resting left ventricular ejection fraction, and exercise ECG stress test variables. For example, nondiabetic patients with chest pain and a normal stress myocardial perfusion scan have a less than 1% per year rate of subsequent cardiac death or myocardial infarction and are generally appropriate candidates for medical therapy (Chapter 56) or even further diagnostic evaluation to search for a noncardiac cause of chest pain (Chapters 39 and 123). Conversely, patients with high-risk stress imaging results, such as transient ischemic left ventricular cavity dilation on stress images (E-Fig. 44-2), may benefit from early referral for coronary angiography and possible coronary revascularization (Chapter 59), even if symptoms are mild.

One significant limitation of SPECT myocardial perfusion imaging is its inability to identify multivessel and left main coronary artery disease in some patients who have balanced ischemia, in which uptake of the imaging agent at peak stress is homogeneously diminished throughout the left ventricular

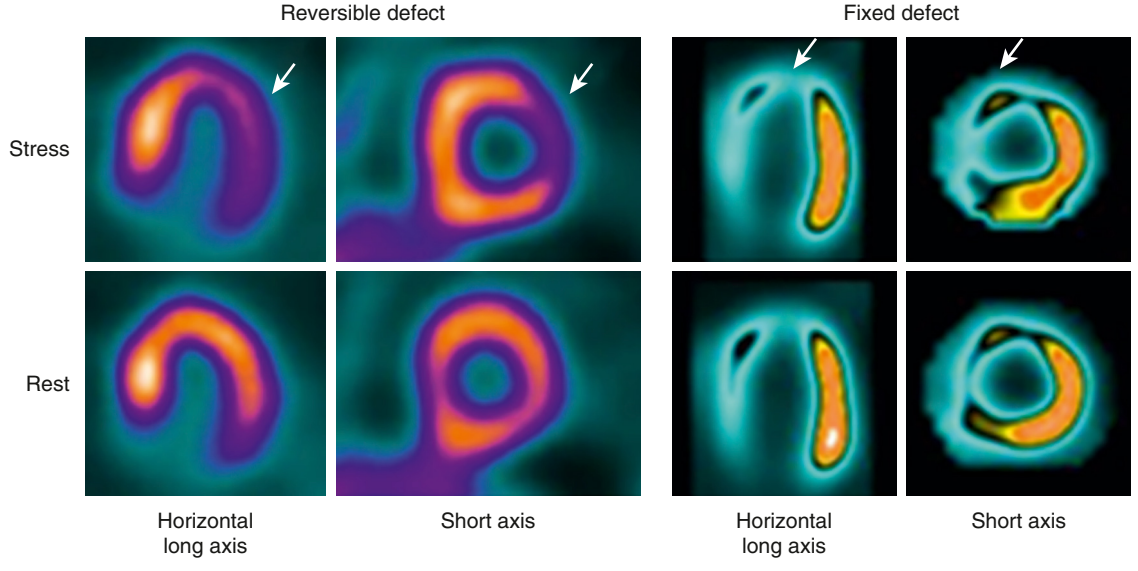


FIGURE 44-8. Examples of reversible and fixed myocardial perfusion defects. A, Paired stress and rest images show a reversible defect in the lateral region, thereby indicating myocardial ischemia related to the left circumflex coronary artery territory. **B,** Fixed defects in the anterior, apical, and interventricular septum, representing prior transmural myocardial infarction related to the left anterior descending coronary artery.

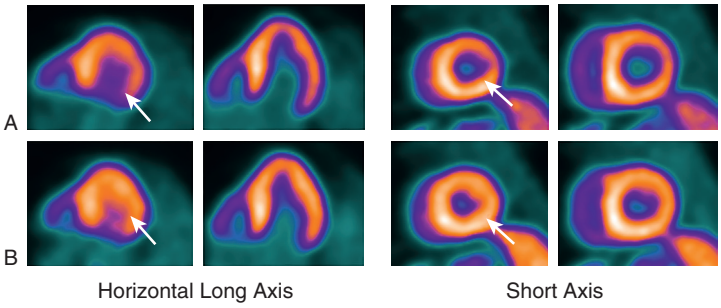

E-FIGURE 44-2. Exercise (A) and resting (B) myocardial perfusion images. Note stress-induced transient ischemic dilatation of the left ventricular cavity (see *arrows* in exercise panels) associated with extensive multivessel myocardial ischemia.

myocardium because of diffusely reduced flow in regions supplied by all three major coronary arteries. Quantitative PET myocardial perfusion imaging will identify these patients by demonstrating regional and/or global reduction in absolute hyperemic myocardial blood flow and an abnormal coronary flow reserve.[3]

Determination of Myocardial Viability

In some patients, fixed perfusion defects may not represent permanently infarcted myocardium but rather represent stunned or hibernating viable myocardium that has the potential to recover function after coronary revascularization. Myocardial viability usually is assessed using PET technology, with fluorine-18-labeled 2-deoxyglucose (FDG) to assess regional myocardial metabolism, and either nitrogen-13 (^{13}N) ammonia or rubidium-82 (^{82}Rb) to assess regional myocardial perfusion. FDG is a glucose analogue that is taken up initially in myocardial cells and is trapped by conversion to FDG-6-phosphate. In dysfunctional myocardial regions, increased FDG activity on clinical PET images in areas of diminished regional blood flow (termed mismatch defect) is indicative of hibernating but viable myocardium. After coronary revascularization, the left ventricular ejection fraction can improve by about 10 percentage points in such patients. However, this postintervention improvement in ejection fraction does not predict which patients with ischemic cardiomyopathy will have better survival after coronary revascularization.[A1,A2] Conversely, decreased (or absent) glucose utilization in dysfunctional myocardial regions with concomitant reduction of blood flow (termed match defect) is indicative of permanently scarred, infarcted myocardium.

INFILTRATIVE CARDIOMYOPATHIES

CARDIAC SARCOIDOSIS

The combination of PET perfusion imaging with FDG can diagnose the inflammation of cardiac sarcoidosis (E-Fig. 44-3) and monitor its response to therapy (Chapters 47 and 83).[4] The high cellular uptake of FDG in sarcoidosis is related to the inflammatory cell infiltrates that have high glycolytic activity to satisfy their large energy demands.

CARDIAC AMYLOIDOSIS

Transthyretin cardiac amyloidosis (Chapters 47 and 174) can be diagnosed with Tc-99m-pyrophosphate (^{99m}Tc-PYP) scintigraphy. In a patient with typical features of cardiac amyloid on echocardiography or cardiac magnetic resonance (MR), Grade 2 or 3 ^{99m}Tc-PYP uptake in the absence of a clonal plasma cell process (Chapter 173) is diagnostic of transthyretin cardiac amyloidosis (E-Fig. 44-4).[5]

IMAGING OF VENTRICULAR FUNCTION

Although echocardiography (Chapter 43) is the dominant noninvasive tool for measuring ventricular function, it can also be measured with radionuclide angiography using technetium-99m (^{99m}Tc)-labeled red blood cells or other ^{99m}Tc-labeled agents that are injected intravenously. Because ^{99m}Tc remains within the blood pool, serial imaging studies can be acquired during several hours. Acquisition of the images is synchronized with the QRS complex on the ECG through a multigated approach by which each cardiac cycle is divided into multiple frames. A uniform diminution of left ventricular systolic function without regional wall motion abnormalities suggests nonischemic dilated cardiomyopathy (Chapter 47), whereas depressed global function associated with regional wall motion abnormalities suggests ischemic heart disease. Left ventricular function can also be assessed by gated SPECT myocardial perfusion imaging.

CARDIAC COMPUTED TOMOGRAPHY

For CT, imaging with high spatial and temporal resolution and ECG gating during a breath-hold yields snapshots of the heart reconstructed from the same phase of the cardiac cycle.[6] Coronary CT angiography can capture a three-dimensional image of the heart in one to two heartbeats on the latest generation scanners as well as provide coronary artery calcium scoring without the use of contrast and with little radiation. Coronary CT angiography requires 60 to 80 mL of iodinated contrast. With latest generation scanners, radiation doses of 1 to 2 mSv are achievable although radiation can still be on the order of 5 to 20 mSv on older 64-detector scanners. β-Blockade is often used to achieve a heart rate of 60 beats per minute or less to optimize imaging, and irregular rhythms such as atrial fibrillation may diminish image quality.

CORONARY ARTERY CALCIUM SCORING

Coronary calcium is an indicator of the burden of atherosclerotic plaque, although there is no correlation of the amount of local coronary calcium with the physiologic or anatomic significance of an underlying coronary stenosis. Calcium scores are generally calculated as an Agatston score, which corresponds to each coronary lesion's calcium area multiplied by the maximal CT attenuation value of that lesion, and then summed for the entire coronary tree (Fig. 44-9). High scores confer an increased risk for future cardiac events and death, with overall 15-year mortality rates in asymptomatic patients ranging from 3 to 28% with coronary artery calcification scores from 0 to 1000 or greater.[7] Calcium scores are age, gender, and race dependent, but they predict coronary heart disease events independently of standard risk factors. The utility of calcium scoring is highest in patients who are at intermediate risk for coronary heart disease, based on Framingham risk data (Chapter 40). By comparison, a calcium score in otherwise low- or high-risk patients will rarely change management, although very high calcium scores may sometimes encourage cardiac stress testing.

CORONARY COMPUTED TOMOGRAPHIC ANGIOGRAPHY

Coronary CT angiography is an excellent technique to diagnose anomalous coronary arterial anatomy in adults (E-Fig. 44-5). For detection of coronary artery disease, positive-predictive values are in the range of 64 to 91%, and negative-predictive values approach 99%. Thus, the technique is an excellent

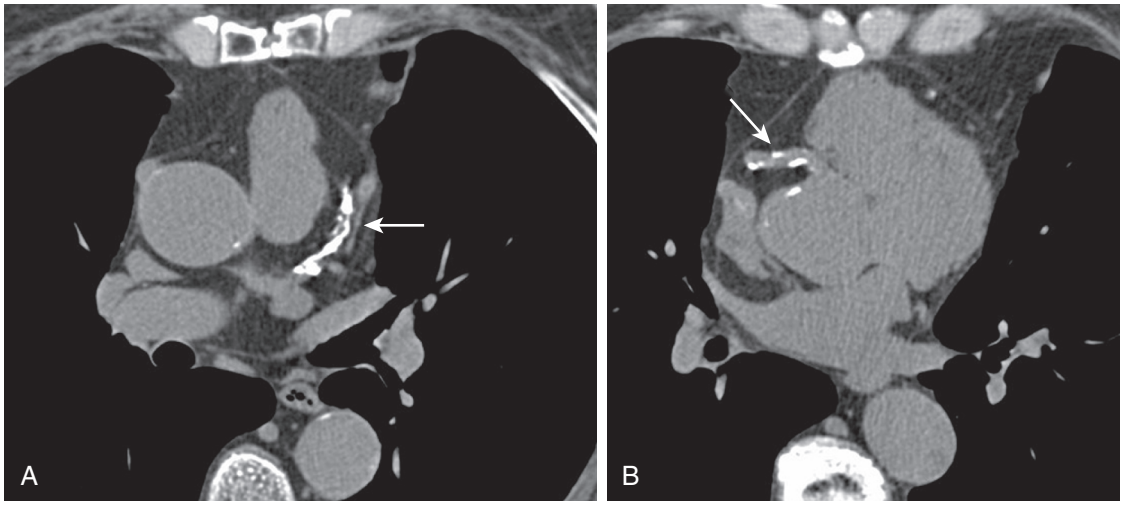

FIGURE 44-9. Non-contrast-enhanced computed tomography axial slices through the heart at two locations for coronary calcium scoring as risk assessment in an asymptomatic patient. A, The slice includes the left anterior descending artery with extensive calcification in its proximal portion (*arrow*). **B,** The slice includes the right coronary artery with proximal spotty calcification (*arrow*). This patient's calcium score was 457, putting him in a higher risk group regardless of his Framingham risk score.

Stages	Perfusion/FDG Patterns			
	Perfusion Defect		FDG-Uptake	
Normal	None		No/ Low	Early	None		FDG uptake high	Progressive	Mild			Peak active	Moderate			Progressive myocardial impairment	Severe			Fibrosis	Severe		Low	
E-FIGURE 44-3. Cardiac sarcoidosis. Various stages of cardiac sarcoidosis with associated patterns of perfusion defects and fluorine-18-labeled 2-deoxyglucose (FDG) metabolism. In the normal stage, no regional perfusion defect is seen with FDG in the cardiac blood pool. As the disease progresses, variable combinations of regional perfusion and metabolic patterns are seen. In the fibrosis/scarred stage, a focal perfusion defect represents a non-caseating granuloma without a corresponding inflammatory FDG metabolic signal in the myocardium. (Adapted from Skali H, Schulman AR, Dorbala S. 18F-FDG PET/CT for the assessment of myocardial sarcoidosis. *Curr Cardiol Rep*. 2013;15:352.)

(Adapted from Chen W, Ton VK, Dilsizian V. Clinical phenotyping of transthyretin cardiac amyloidosis with bone seeking radiotracers in heart failure with preserved ejection fraction. *Curr Cardiol Rep*. 2018; 8;20:23.)

E-FIGURE 44-5. Contrast-enhanced computed tomographic angiogram in a young patient with chest pain and an anomalous right coronary artery (RCA). The RCA originates with a slitlike origin from the left coronary cusp (*arrow*) and passes anteriorly between the aorta and right ventricular outflow tract. The left main coronary artery originates normally from the left cusp.

way to exclude (Fig. 44-10) or detect significant coronary artery disease in the three major coronary vessels (Fig. 44-11). A limitation of the technique, however, is its lower specificity in heavily calcified vessels, which are more common in elderly patients. The accuracy for detecting stenoses in bypass grafts is quite high, although evaluation of native vessel coronary artery disease is limited in these patients owing to extensive calcification and smaller size vessels. Imaging within most coronary stents has proved difficult. Measurement of coronary artery-specific fractional flow reserve using computational flow dynamics can improve upon the accuracy (especially specificity) of angiography (E-Fig. 44-6).

Coronary CT angiography is not recommended as a routine screening test in asymptomatic patients, even those with diabetes. However, it is especially useful in selected situations, such as in low- or low-intermediate-risk patients with chest pain, patients who present to the emergency department with chest pain but without ECG changes or elevations of cardiac biomarkers (Chapters 39 and 57), or patients with equivocal or nondiagnostic stress testing. Some guidelines recommend CT angiography as the initial test for diagnosing coronary diseases in symptomatic patients.[8,9] In patients who have acute non-ST elevation MI, CT angiography has a high positive and negative predictive value as compared with invasive angiography and may be an alternative in lower risk patients with this clinical presentation.[10]

In symptomatic patients with suspected coronary disease, the strategies of initial coronary CT angiography and functional testing using exercise electrocardiography, nuclear stress testing, or stress echocardiography provide equivalent clinical outcomes at an equivalent cost over a median follow-up of 2 years.[A3,A4] CT angiography is associated with similar outcomes and fewer complications or revascularizations compared with invasive angiography in patients who have intermediate-risk chest pain.[A5] However, CT angiography can improve outcomes compared with standard care in patients with stable chest pain by stimulating the use of more aggressive medical therapies without increasing rates of coronary angiography or coronary revascularization.[A6] The extent and severity of coronary disease found at CT angiography correlate with subsequent all-cause mortality in a similar fashion to catheter-based coronary angiography. Low-attenuation, noncalcified plaque is the most potent predictor of subsequent myocardial infarction,[11] whereas progression of calcification is associated with a mildly increased risk of subsequent events after adjusting for other risk factors.[12] In asymptomatic patients, however, CT angiography does not improve risk stratification over calcium scoring.

OTHER CARDIAC APPLICATIONS

The same data acquired by coronary CT angiography can be reformatted and used for functional cardiac imaging, including measurement of left ventricular volumes, ejection fraction, wall thickness, and global and segmental wall motion. CT angiography can complement echocardiography to evaluate cardiac anatomy in patients with congenital heart disease. CT can evaluate pericardial thickness and calcification in patients with suspected constrictive pericarditis (see Fig. 62-9) and can evaluate native and prosthetic valvular structures (E-Fig. 44-7) and cardiac masses when imaging with other modalities is inadequate.

CT angiography is often used to image the left atrium and pulmonary venous anatomy and to exclude left atrial thrombus prior to electrical cardioversion or pulmonary vein ablation for atrial fibrillation (Chapter 54). CT is an important

FIGURE 44-11. Contrast-enhanced computed tomographic coronary angiogram of the left anterior descending artery (LAD) in a 54-year-old man who presented to an emergency department with risk factors but atypical chest pain. The mid LAD demonstrates mixed obstructive plaque with calcified and noncalcified components.

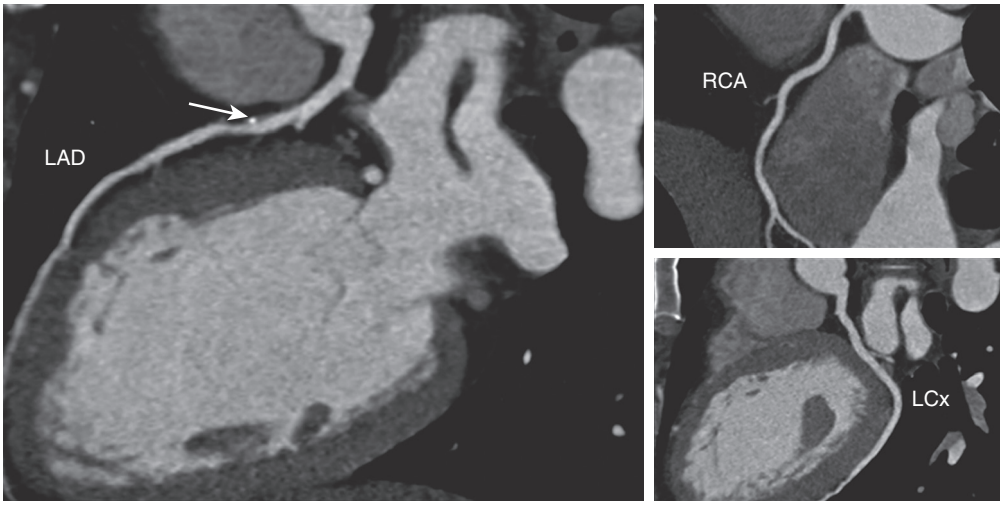

FIGURE 44-10. Contrast-enhanced computed tomographic coronary angiogram obtained on a dual-source 64-detector scanner in a patient with atypical chest pain. The left anterior descending (LAD) artery has a nonobstructive lesion (*arrow*) containing both noncalcified (soft) plaque, which appears dark, and a focal area of calcification. The right coronary artery (RCA) and left circumflex coronary artery (LCx) are normal.

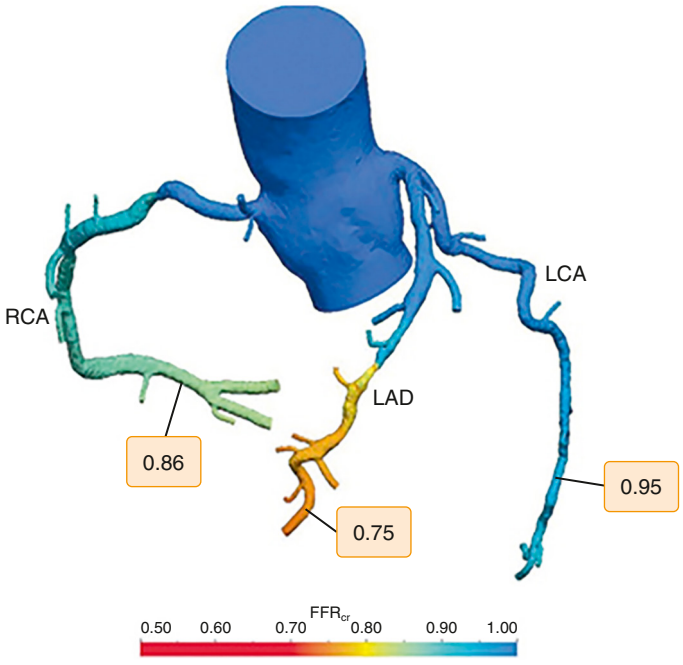
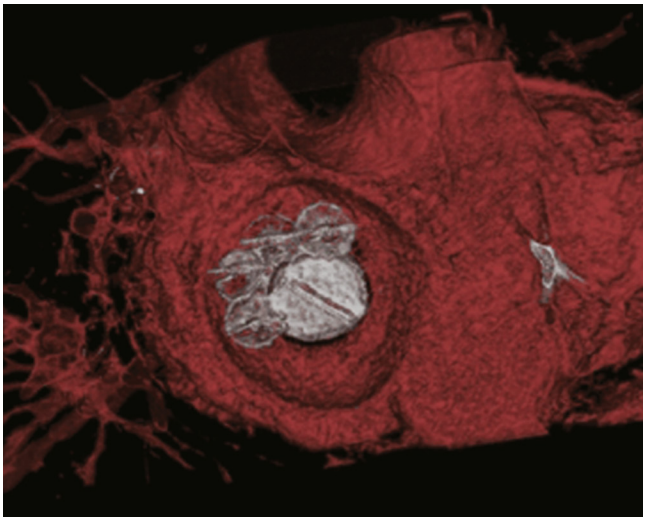


E-FIGURE 44-6. Fractional flow reserve (FFR) data computed from a typical computed tomographic coronary angiogram. A FFR value of 0.8 or higher is considered normal. Thus the left anterior descending (LAD) coronary artery demonstrates reduced FFR at 0.75 and therefore is considered to have a significant stenosis whereas the right coronary artery (RCA) and left circumflex coronary artery (LCA) do not.



E-FIGURE 44-7. Three-dimensional reconstruction of a computed tomographic angiogram in a patient with a St. Jude's mechanical mitral valve with a paravalvular leak that has been closed with four Amplatzer devices.

tool for peri-preprocedural planning in patients being considered for transcatheter valve replacement (Chapter 60).

CARDIOVASCULAR MAGNETIC RESONANCE IMAGING

INDICATIONS, CONTRAINDICATIONS, AND PULSE SEQUENCES

Cardiac MR is a versatile and flexible imaging modality that can be applied in diverse cardiovascular conditions using either 1.5- or 3-Tesla (T) scanners. Advantages of cardiac MR include the lack of ionizing radiation, the variety of tissues that can be characterized, and the ability to image the heart in any arbitrary plane. Images typically are obtained using ECG gating and breath-hold techniques.

Although some metallic devices are contraindications to cardiac MR, patients with newer pacemaker and defibrillator systems can be imaged by carefully following the manufacturer's instructions. In addition, some non-pacemaker-dependent patients with older pacemaker and defibrillator models can be scanned safely with close monitoring and testing, as well as reprogramming of the device after the procedure. Cardiac MR is safe for all prosthetic heart valves and intracoronary stents. Gadolinium-based contrast agents can be associated with nephrogenic systemic fibrosis in patients with a glomerular filtration rate of less than 30 mL/minute/1.83 m^2 (Chapter 246), but this risk is very low with current cyclic contrast agents.

A comprehensive cardiac MR study includes evaluation of cardiac structure, function, tissue characteristics (T1, T2, T2*, and extracellular volume [ECV]) mapping, perfusion, and scarring or fibrosis. Cardiac MR is highly accurate for the noninvasive quantitative assessment of ventricular volumes and ejection fraction. The components of the examination are tailored to the particular diagnostic question at hand.

SPECIFIC CLINICAL APPLICATIONS

CORONARY ARTERY DISEASE

For detection of myocardial ischemia, first-pass gadolinium perfusion imaging during vasodilator stress with adenosine or regadenoson shows defects, generally in the subendocardium, that persist for at least five heartbeats during the first pass of contrast in patients with CHD (Fig. 44-12). Imaging is often repeated at rest after approximately 10 minutes to be sure any defect seen with stress was not either artifactual or caused by an infarct (the latter is excluded in combination with late gadolinium enhancement). Cardiac MR stress testing is more accurate than SPECT, is a strong predictor of cardiac events and survival, and is cost-effective in the evaluation of patients with chest pain.[13] In patients with suspected angina, cardiac MR can reduce unnecessary angiography within 12 months compared with routine clinical care but not compared with myocardial perfusion scintigraphy.[A7] Cardiac MR perfusion can be used to assess coronary flow. In patients with stable angina, cardiac MR perfusion is as good as the measurement of fractional flow reserve by invasive angiography for predicting future coronary events and may reduce referral for coronary revascularization.[A8] Coronary CT angiography has superior spatial resolution and accuracy compared with cardiac MR for imaging of the coronary arteries, but cardiac MR coronary imaging is useful for the diagnosis of anomalous coronary arteries.

Cardiac MR with late gadolinium enhancement is the gold standard technique for assessment of myocardial scar caused by myocardial infarction, with a better accuracy than nuclear imaging approaches, especially for smaller non–Q wave infarctions (Fig. 44-13). In acute myocardial infarction, cardiac MR T2-weighted techniques can assess the myocardium at risk and estimate the amount of salvaged myocardium owing to reperfusion. Areas of low signal in the subendocardial core of the infarction represent regions of microvascular obstruction with severe capillary destruction and are a marker of subsequent adverse left ventricular remodeling and poorer outcome. To assess myocardial viability in patients with chronic coronary heart disease, cardiac MR with late gadolinium enhancement has the best sensitivity for recovery of function with revascularization, but low-dose dobutamine contractile reserve has better specificity.

CARDIOMYOPATHIES

Cardiac MR should not be routinely performed in all patients with new onset heart failure,[A9] but it is very helpful in identifying patterns of scar or fibrosis that typify specific causes of cardiomyopathy (Chapter 57). Cardiac MR measurements of left ventricular mass and left atrial volume can be used to estimate left ventricular filling pressures and to predict survival in patients who have heart failure.[14] In nonischemic dilated cardiomyopathy, late gadolinium enhancement is associated with an adverse prognosis,[15] regardless of the left ventricular ejection fraction. In patients who have chest pain, elevated

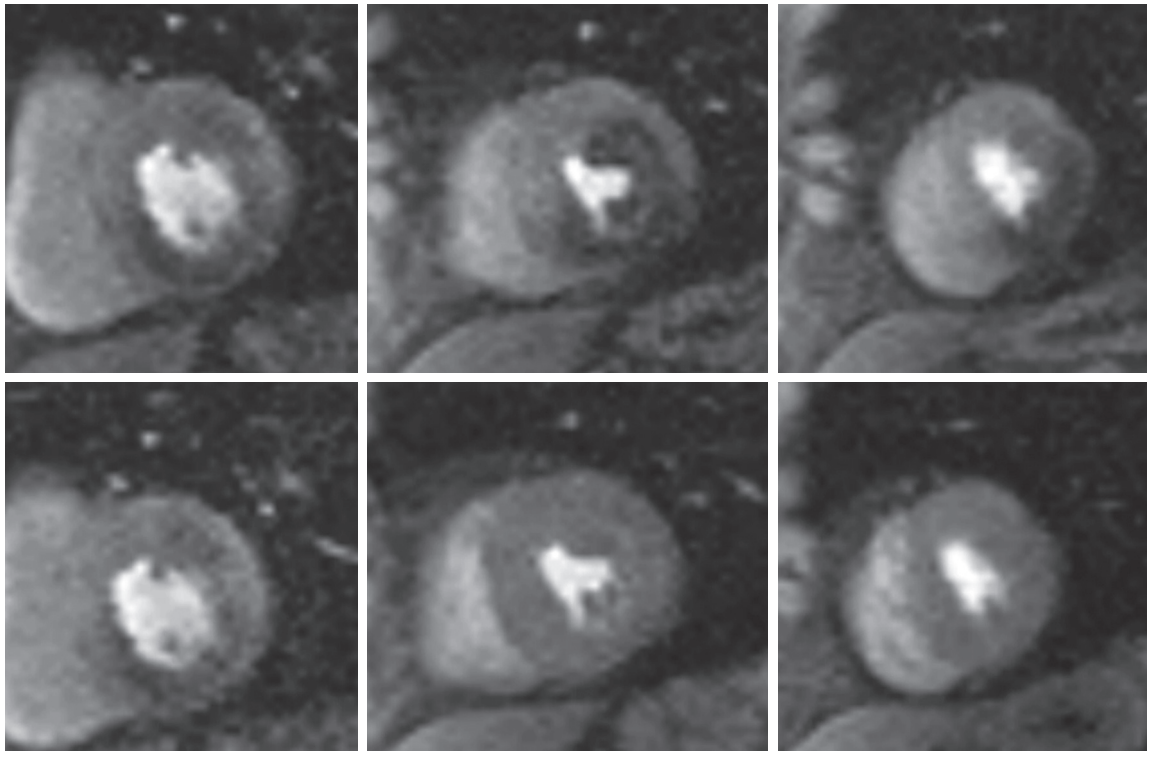


FIGURE 44-12. **Set of first-pass gadolinium-enhanced magnetic resonance perfusion images during adenosine stress (*top row*) and at rest (*bottom row*) at the base (*left*), mid-ventricle (*center*), and apex (*right*). The stress images demonstrate a large perfusion deficit in the anterolateral and inferolateral walls (from 1 o'clock to 7 o'clock), especially in the mid-ventricle and apex, whereas the same regions appear normal at rest.**

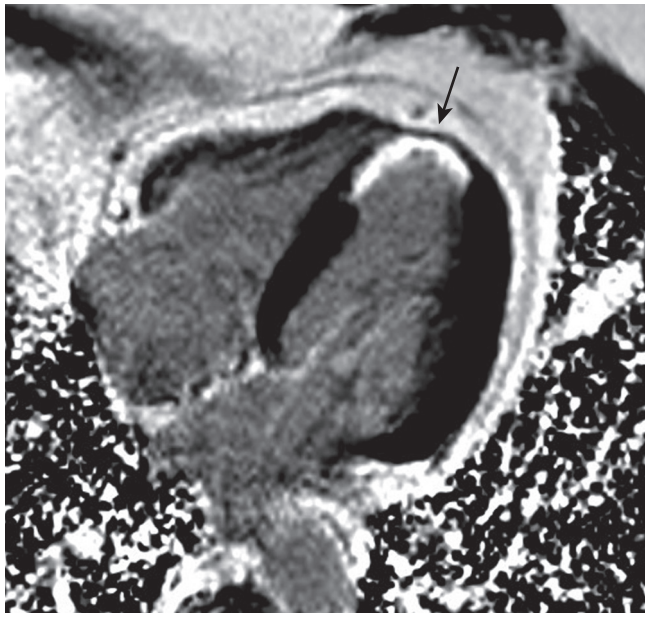

FIGURE 44-13. Late gadolinium-enhanced four-chamber long axis image in a patient with a scar (*arrow*) from a prior anterior myocardial infarction.

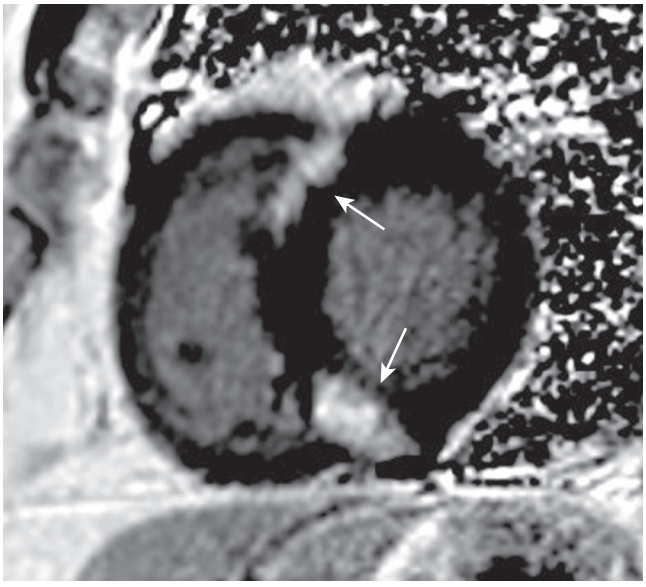

FIGURE 44-15. Late gadolinium-enhanced magnetic resonance short axis image of a 35-year-old man with hypertrophic cardiomyopathy demonstrates a classic pattern of enhancement, which identifies fibrosis (*arrows*) in the right ventricular insertion sites.

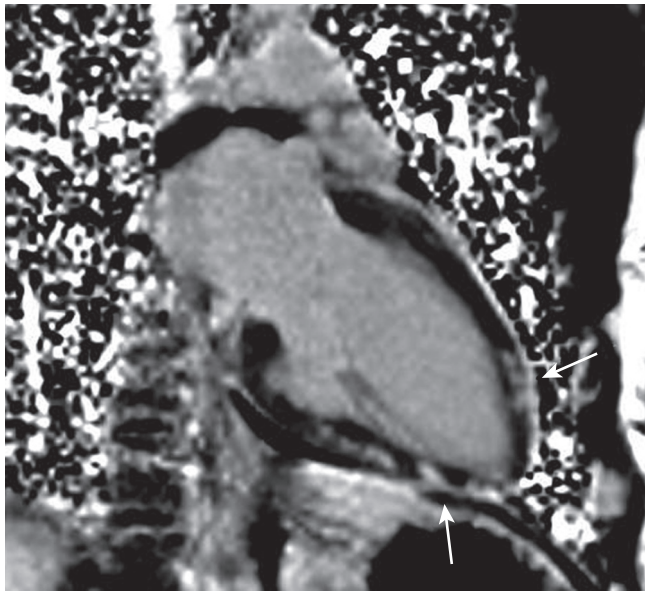

FIGURE 44-14. Gadolinium-enhanced image in a 22-year-old man shows patchy subepicardial enhancement (*arrows*) characteristic of acute myocarditis.

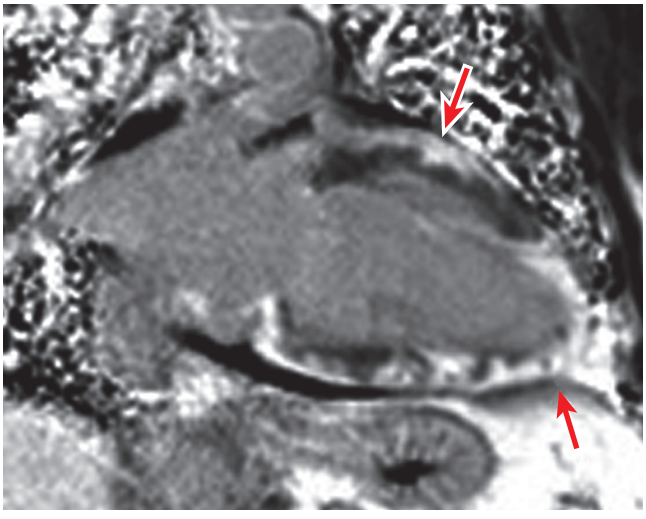

FIGURE 44-16. Late gadolinium-enhanced magnetic resonance image in a 47-year-old man with heart failure, heart block, and hilar lymphadenopathy shows patchy late gadolinium enhancement in a noncoronary distribution, including subepicardial anterior wall enhancement (*upper arrow*) and near transmural apical enhancement (*lower arrow*) consistent with myocardial sarcoidosis.

troponin levels, but a negative coronary arteriogram, cardiac MR is ideally suited to identify myocarditis or unusual causes of myocardial infarction,[16] (Fig. 44-14) (Chapter 47). In patients with hypertrophic cardiomyopathy (Chapter 47), cardiac MR is more sensitive than echocardiography for identifying increased regional wall thickness and can demonstrate late gadolinium enhancement (Fig. 44-15), the extent of which correlates with the risk of sudden death. Cardiac amyloidosis (Chapters 47 and 174) can be seen as diffuse subendocardial, transmural, or patchy late gadolinium enhancement. In cardiac sarcoidosis (Chapters 47 and 83; Fig. 44-16), patchy midwall and/or subepicardial fibrosis is readily identified, is complementary to PET (see earlier), and is more sensitive than endomyocardial biopsy. Cardiac MR is also useful for diagnosing the myocarditis associated with coronavirus disease 2019 (Chapter 336).[17]

Cardiac MR is often used to diagnose arrhythmogenic ventricular cardiomyopathy (Fig. 44-17; Chapters 47 and 53), which is characterized by global right ventricular dilation and regional akinesis or dyskinesis. In iron overload conditions such as thalassemia (Chapter 148), imaging of T2* can identify the extent of iron overload and can be used to follow the effects of chelation therapy. Rarer causes of cardiomyopathy, such as ventricular noncompaction and Chagas disease (Chapters 47 and 318), also have characteristic cardiac MR findings.

AORTIC DISEASE, PERICARDIAL DISEASE, AND MASSES

Cardiac MR is an excellent test to image aneurysms but is a second-line test to detect acute aortic dissection or intraluminal aortic hematoma (see Fig. 63-5) in stable patients. Cardiac MR is also an excellent test for the evaluation of chronic pericardial disease (Fig. 44-18) because it accurately identifies pericardial thickness as well as adherence of the pericardium to the epicardium in constrictive pericarditis. Real-time imaging can demonstrate ventricular interdependence, a hallmark of this disease. Cardiac MR is also an ideal tool to diagnose intracardiac (Fig. 44-19) and extracardiac masses such as myxomas, thrombus, and tumors (Chapter 47), owing to its high spatial resolution and ability to perform tissue characterization.

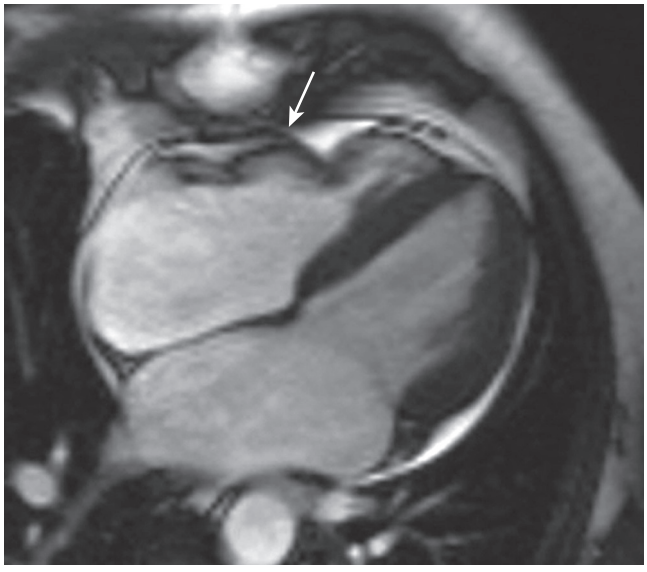

FIGURE 44-17. Magnetic resonance image in a 27-year-old woman with arrhythmogenic ventricular cardiomyopathy demonstrates regional right ventricular (RV) systolic dysfunction, which is the hallmark of the disease. The *arrow* points to a region of RV dyskinesis at end systole, and the RV appears like an accordion at end systole.

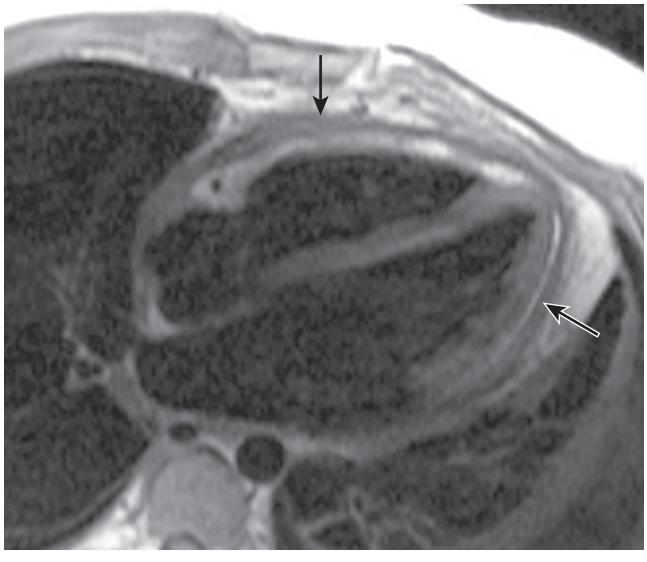

FIGURE 44-18. Magnetic resonance image of a 35-year-old man with dyspnea many years after mantle radiation for Hodgkin lymphoma shows a thickened pericardium (*arrows*) circumferentially around the left and right ventricles.

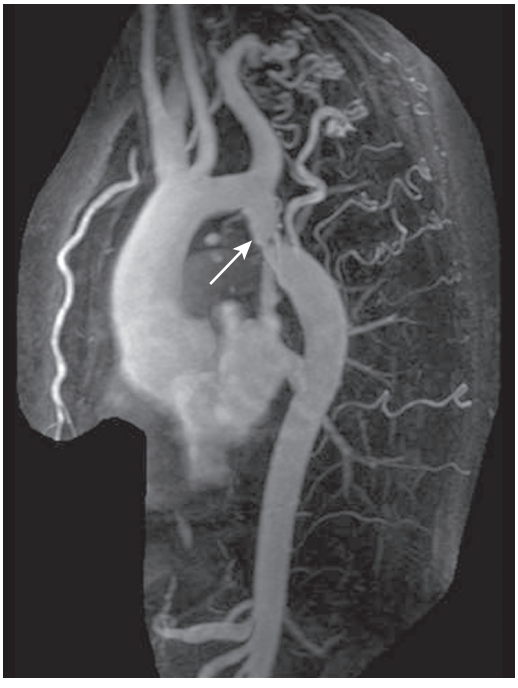

FIGURE 44-20. Three-dimensional contrast-enhanced magnetic resonance angiogram in a patient with an aortic coarctation (*arrow*).

CONGENITAL HEART DISEASE

Cardiac MR is useful for the assessment of both simple and complex congenital heart disease and is often used as an adjunct to echocardiography (Chapter 55). For example, phase velocity cardiac MR readily quantifies blood flow through the major blood vessels, thereby facilitating accurate assessment of the ratio of pulmonary to systemic blood flow in the presence of shunts. Cardiovascular MR is particularly valuable for assessing abnormalities of the great vessels, such as aortic coarctation (Fig. 44-20), extracardiac anatomy, or anomalous pulmonary venous drainage, and in patients with complex congenital heart disease who have undergone prior corrective or palliative shunt surgery, such as in tetralogy of Fallot or hypoplastic left heart syndrome. Cardiac MR is uniquely able to measure right ventricular volumes accurately, an often important determination in this setting.

45 HEART FAILURE: EPIDEMIOLOGY, PATHOBIOLOGY, AND DIAGNOSIS

JOSEPH G. ROGERS AND CHRISTOPHER M. O'CONNOR

DEFINITION

Heart failure is a clinical syndrome that results when abnormalities in myocardial structure and function impair cardiac output or decrease filling of the ventricles. Clinical characteristics of the heart failure syndrome include dyspnea, fatigue, impaired exercise performance, and edema. Congestion is a common but not universal feature, so the term *congestive heart failure* is no longer used.

EPIDEMIOLOGY

Current estimates are that more than 64 million people worldwide have heart failure.[1] Most studies estimate the prevalence of heart failure to be 1 to 2% of the total adult population, with a lifetime risk that ranges between 20 to 45% depending upon age, race, and geography. Although the overall prevalence of the disease appears to be stabilized or decreasing, it is increasing in younger and older individuals as well as individuals with a preserved ejection fraction. Heart failure is the leading cause of hospitalization in patients older than age 65 years, and once a patient is hospitalized for heart failure, the 30-day risk of rehospitalization is 25%, with a 10% risk of 30-day postdischarge mortality. Although survival has improved, the absolute mortality rates for heart failure remain approximately 50% within 5 years of diagnosis.

Nearly half of patients with heart failure have a preserved ejection fraction. Compared with patients who have heart failure with reduced ejection fraction, heart failure patients with a preserved ejection fraction tend to be older and are more likely to be women with a prior history of hypertension and diabetes. The mortality rate of patients who have heart failure with a preserved ejection fraction is similar to the rate for patients with reduced ejection fraction.[2] Hospitalization and rehospitalization rates are comparable for heart failure patients regardless of their ejection fractions.

Disparities

Black Americans are at increased risk for incident heart failure compared with White Americans and also have more frequent hospitalizations. Black patients with heart failure also have a higher mortality rate than White populations. The reasons for these disparities include racial differences in risk factors, the causes of heart failure, access to care, and response to therapies. However, there is a growing literature to support systemic racial inequities and even racism as an important underlying explanation.[3] Hispanics represent a growing population of heart failure patients in the United States with an incidence rate between those of Black and White Americans.

Classification

The classification of heart failure considers the disease state and progression, degree of exercise intolerance (Chapter 39), measurement of the left ventricular ejection fraction, and its underlying cause.[4] In the first approach, heart failure is classified by its progression through four stages from pre-disease to advanced symptoms (Fig. 45-1). The second approach evaluates functional states by standardized classification systems such as the New York Heart Association classification, the Canadian Cardiovascular Society system, or other validated measures of exercise tolerance (see Table 39-5). Functional status is the most appropriate way to understand a patient's limitations and the impact of heart failure on quality of life. It also correlates with prognosis and is commonly used as a secondary end point in clinical trials. A third approach is to describe heart failure based upon ejection fraction. This method stratifies patients into those with reduced (<40%), midrange (40 to 50%), and preserved (>50%) ejection fraction. This approach also helps in understanding the patient's underlying pathophysiologic process and in guiding therapeutic decisions. Classification based on etiology, usually ischemic versus nonischemic (Chapter 47), is useful in guiding the diagnostic evaluation and in tailoring treatment.

Causes of Heart Failure

Heart failure has numerous causes (Table 45-1). In developed countries, coronary artery disease, usually with a prior myocardial infarction, accounts for nearly 70% of heart failure cases (Chapter 58). Comorbid conditions such as hypertension (Chapter 64),[5] diabetes (Chapter 210),[6] and obesity (Chapter 201)[7] are commonly associated with heart failure. Diseases of the myocardium

45 HEART FAILURE: EPIDEMIOLOGY, PATHOBIOLOGY, AND DIAGNOSIS

JOSEPH G. ROGERS AND CHRISTOPHER M. O'CONNOR

DEFINITION

Heart failure is a clinical syndrome that results when abnormalities in myocardial structure and function impair cardiac output or decrease filling of the ventricles. Clinical characteristics of the heart failure syndrome include dyspnea, fatigue, impaired exercise performance, and edema. Congestion is a common but not universal feature, so the term *congestive heart failure* is no longer used.

EPIDEMIOLOGY

Current estimates are that more than 64 million people worldwide have heart failure.[1] Most studies estimate the prevalence of heart failure to be 1 to 2% of the total adult population, with a lifetime risk that ranges between 20 to 45% depending upon age, race, and geography. Although the overall prevalence of the disease appears to be stabilized or decreasing, it is increasing in younger and older individuals as well as individuals with a preserved ejection fraction. Heart failure is the leading cause of hospitalization in patients older than age 65 years, and once a patient is hospitalized for heart failure, the 30-day risk of rehospitalization is 25%, with a 10% risk of 30-day postdischarge mortality. Although survival has improved, the absolute mortality rates for heart failure remain approximately 50% within 5 years of diagnosis.

Nearly half of patients with heart failure have a preserved ejection fraction. Compared with patients who have heart failure with reduced ejection fraction, heart failure patients with a preserved ejection fraction tend to be older and are more likely to be women with a prior history of hypertension and diabetes. The mortality rate of patients who have heart failure with a preserved ejection fraction is similar to the rate for patients with reduced ejection fraction.[2] Hospitalization and rehospitalization rates are comparable for heart failure patients regardless of their ejection fractions.

Disparities

Black Americans are at increased risk for incident heart failure compared with White Americans and also have more frequent hospitalizations. Black patients with heart failure also have a higher mortality rate than White populations. The reasons for these disparities include racial differences in risk factors, the causes of heart failure, access to care, and response to therapies. However, there is a growing literature to support systemic racial inequities and even racism as an important underlying explanation.[3] Hispanics represent a growing population of heart failure patients in the United States with an incidence rate between those of Black and White Americans.

Classification

The classification of heart failure considers the disease state and progression, degree of exercise intolerance (Chapter 39), measurement of the left ventricular ejection fraction, and its underlying cause.[4] In the first approach, heart failure is classified by its progression through four stages from pre-disease to advanced symptoms (Fig. 45-1). The second approach evaluates functional states by standardized classification systems such as the New York Heart Association classification, the Canadian Cardiovascular Society system, or other validated measures of exercise tolerance (see Table 39-5). Functional status is the most appropriate way to understand a patient's limitations and the impact of heart failure on quality of life. It also correlates with prognosis and is commonly used as a secondary end point in clinical trials. A third approach is to describe heart failure based upon ejection fraction. This method stratifies patients into those with reduced (<40%), midrange (40 to 50%), and preserved (>50%) ejection fraction. This approach also helps in understanding the patient's underlying pathophysiologic process and in guiding therapeutic decisions. Classification based on etiology, usually ischemic versus nonischemic (Chapter 47), is useful in guiding the diagnostic evaluation and in tailoring treatment.

Causes of Heart Failure

Heart failure has numerous causes (Table 45-1). In developed countries, coronary artery disease, usually with a prior myocardial infarction, accounts for nearly 70% of heart failure cases (Chapter 58). Comorbid conditions such as hypertension (Chapter 64),[5] diabetes (Chapter 210),[6] and obesity (Chapter 201)[7] are commonly associated with heart failure. Diseases of the myocardium

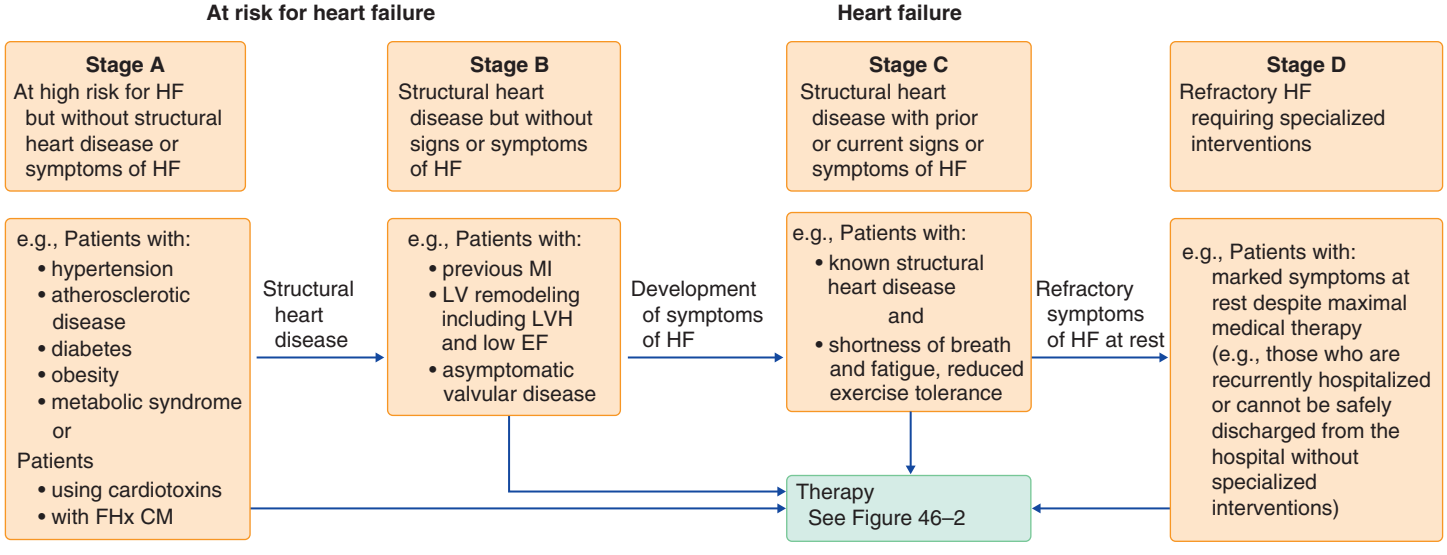

FIGURE 45-1. Stages of heart failure. EF = ejection fraction; FHx CM = family history of cardiomyopathy; HF = heart failure; LV = left ventricle; LVH = left ventricular hypertrophy; MI = myocardial infarction. (Modified from Heidenreich PA. 2022 AHA/ACC/HFSA guideline for the management of heart failure: a report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines. *Circulation*. 2022;145:e895-e1032.)

ABSTRACT

The prevalence of heart failure is increasing worldwide owing to the aging population and development of more effective treatments of many heart diseases that injure the myocardium. Heart failure is now classified by the presence or absence of left ventricular systolic dysfunction, with a growing appreciation for the complexity of patients who have heart failure with preserved left ventricular systolic function. The evaluation of heart failure integrates a carefully performed history and physical examination, a thorough knowledge of general medicine, and the appropriate use of diagnostic testing.

TABLE 45-1 CAUSES OF HEART FAILURE

Coronary artery disease or prior myocardial infarction or ischemic injury
Hypertension
Familial and genetic disorders, including dilated cardiomyopathies, hypertrophic cardiomyopathies, storage diseases, and muscular dystrophies
Valvular disease: valvular stenosis or regurgitation
Toxic/drug-induced damage, including prior chemotherapy
Infiltrative processes, such as sarcoid, amyloid, and hemochromatosis (i.e., restrictive cardiomyopathy)
Arrhythmia-related dysfunction, including premature ventricular contraction–induced cardiomyopathy and atrial tachyarrhythmia–related dysfunction
Arrhythmogenic right ventricular cardiomyopathy
Pulmonary heart disease, including cor pulmonale
Infectious agents, including viral infections and Chagas disease
Immunologically mediated myocardial injury
Intra- and extra-cardiac shunts
Constrictive pericarditis (i.e., nonmyocardial processes)
Nutritional disorders, such as beriberi
Inflammatory heart disease such as systemic lupus erythematosus
High-output states, such as chronic anemia, thyrotoxicosis

TABLE 45-2 FACTORS THAT MAY PRECIPITATE ACUTE DECOMPENSATION OF CHRONIC HEART FAILURE

Myocardial ischemia or infarction
Arrhythmias
Worsening hypertension
Worsening mitral or tricuspid regurgitation
Initiation of medications that worsen heart failure (calcium antagonists, β-blockers, nonsteroidal anti-inflammatory drugs, antiarrhythmic agents, chemotherapeutic drugs, antidiabetic drugs)
Failure to adhere to guideline-directed management
Dietary indiscretion
Iatrogenic volume overload (transfusion, fluid administration)
Alcohol consumption
Fever or infection
Anemia
Thyroid abnormalities
Exposure to environmental toxins
Exposure to high altitude
Pregnancy

(Chapter 47), valves (Chapter 60), and pericardium (Chapter 62), as well as endocrinopathies, metabolic abnormalities, and genetic conditions,[8] may cause heart failure. Chemotherapy (e.g., anthracyclines and trastuzumab; Chapter 164) and chest radiation (Chapter 18) may damage the myocardium. Reversible myocardial dysfunction from toxin exposure (e.g., cocaine [Chapter 365] and excessive alcohol intake [Chapter 364]), persistent tachycardia (Chapters 52 and 53), and severe mental/emotional stress (e.g., takotsubo cardiomyopathy [Chapter 47]) may cause ventricular dysfunction that typically resolves following withdrawal of the inciting etiology. Right-sided heart failure is most commonly caused by left-sided heart failure, but it also can result from pulmonary thromboembolic disease (Chapter 68), chronic lung disease (Chapters 76 and 80), and pulmonary arterial hypertension (Chapter 69).[9]

The underlying causes of heart failure vary by region. For instance, Chagas cardiomyopathy (Chapter 47) is prevalent in Central and South America. Rheumatic valvular disease is a common cause of heart failure in developing countries but is infrequent in developed countries.

Acute decompensation of heart failure may be related to worsening of the primary cause, a new cardiac or pulmonary condition, the influence of other disease states that require increased cardiac output, poor adherence to medical therapies, or the addition of medications used to treat other conditions (Table 45-2). As a result, a systematic approach to the clinical evaluation is critical. Some patients will have decompensated heart failure that requires hospitalization, whereas others will have heart failure as a comorbidity during hospitalization for another problem.

PATHOBIOLOGY

A number of factors contribute to the development and progression of heart failure (Table 45-3). The relative contribution of these mechanisms to the overall pathophysiologic manifestations of heart failure (E-Fig. 45-1) varies in individual patients.

Heart Failure with a Reduced Ejection Fraction

A central tenet of heart failure is that myocardial dysfunction limits the heart's ability to pump blood at a rate commensurate with the requirements of metabolizing tissues or that it can do so only in the setting of elevated cardiac filling pressures. The pathobiology of the failing heart results in maladaptive regulation of multiple neurohormonal pathways that reduce intrinsic cardiac contractility and cause prototypical ventricular remodeling (Chapter 41). Alterations in cardiac extracellular matrix and replacement fibrosis increase the connective tissue content and further impair systolic and diastolic function (Chapter 41). Several neurohormonal pathways regulate myocardial fibrosis, including aldosterone, matrix metalloproteinases, tissue inhibitors of metalloproteinases (TIMPS), TNF-alpha, and ST2.

Adrenergic nervous system activation plays a pivotal role in the development and progression of left ventricular dysfunction. Reduced pulse pressure

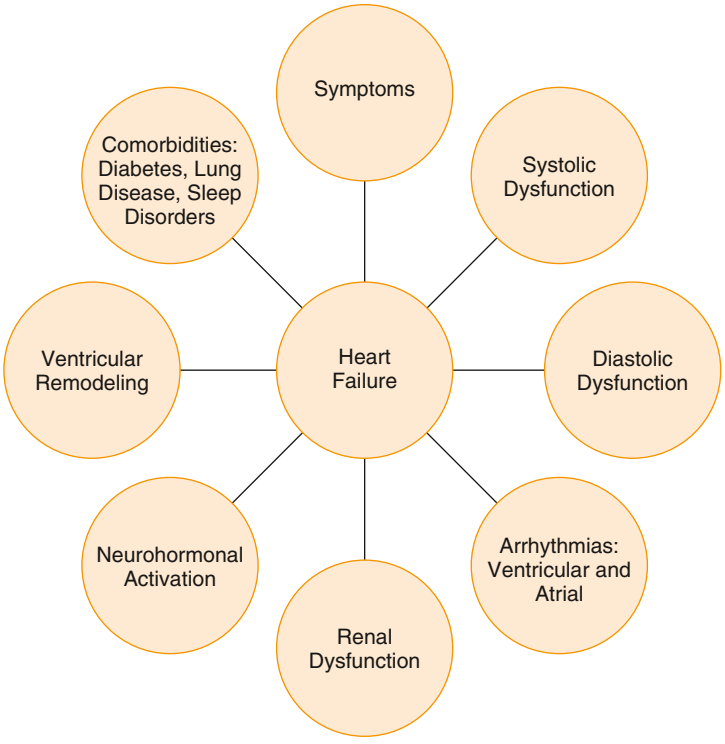
Myocardial genetics

activates arterial baroreceptors and stimulates sympathetic nervous system activity, elevated levels of circulating norepinephrine, and increased release of norepinephrine by several organs, including the heart. Exposure of cardiac myocytes to chronically elevated levels of norepinephrine reduces the density of their β-adrenergic receptors, downregulates signaling pathways, and is directly toxic to the cells. The renin-angiotensin-aldosterone system, which is also activated relatively early in heart failure, causes vasoconstriction and sodium retention. The presumptive mechanisms of induction include renal hypoperfusion, β-adrenergic system stimulation, and hyponatremia. Adrenergic and renin-angiotensin-aldosterone system activation stimulate the failing heart and support the circulation in the short term. Over time, however, the prolonged activation of these systems causes maladaptive remodeling and further ventricular dysfunction. In addition, the sympathetic nervous system and renin-angiotensin-aldosterone system are co-regulated, such that increased activity of each pathway stimulates a simultaneous increase in the other.

Natriuretic peptides counterbalance the vasoconstricting and sodium-retaining properties of the renin-angiotensin-aldosterone system and sympathetic nervous systems by causing both arterial and venous vasodilation, natriuresis, and diuresis. The extent of natriuretic pathway activation is a marker of the severity of heart failure and is associated with adverse outcomes, including the risk for hospitalization and death.

Many patients with heart failure have elevated levels of endothelin and arginine vasopressin. Arginine vasopressin induces vasoconstriction through a vascular (V_1) receptor and reduces free water clearance through a renal tubular (V_2) receptor. Endothelin causes prolonged vasoconstriction, reductions in glomerular filtration, and pulmonary arteriolar constriction.

Cardiorenal interactions highlight the integral role of kidney dysfunction in the worsening of heart failure, with both organs contributing to the retention of sodium and water. In most patients with chronic heart failure, the kidneys are anatomically and structurally normal, but passive venous congestion and reduced renal perfusion lead to worsening renal function and a vicious cycle of progressive dysfunction of both organ systems. Renal failure may limit the ability to use inhibitors of the renin-angiotensin-aldosterone system to treat heart failure.



E-FIGURE 45-1. Pathophysiology of heart failure. The contributing and exacerbating factors to the pathophysiologic process of heart failure.

Abnormal calcium cycling reduces the calcium content in the cardiac sarcoplasmic reticulum owing to diastolic leak through altered ryanodine receptors. The reduced calcium content of the sarcoplasmic reticulum alters the contraction interactions between cardiac myosin and actin myofilaments. In addition, a loss of function of cardiac SERCA2a (sarcoendoplasmic reticulum calcium transport ATPase 2a) pumps, which are responsible for removal of cytoplasmic calcium, affects ventricular relaxation and causes diastolic dysfunction.

In all forms of heart failure, a variety of stimuli (e.g., elevated neurohormone levels, adrenergic activation, inflammatory mechanisms, and toxin exposure) accelerate cell death. Elevated serum levels of proinflammatory cytokines (including tumor necrosis factor-α, interleukin-1β, and interleukin-6) induce contractile dysfunction, myocardial fibrosis, and myocyte necrosis, perhaps by mediating some of the deleterious responses to catecholamines and angiotensin II.

Persistent tachycardia (e.g., atrial fibrillation with rapid ventricular response) also can result in heart failure, presumably related to chronic hyperadrenergic stimulation.[10] In some patients, the tachycardic response to heart failure may itself contribute to worsening heart failure. These forms of heart failure may be reversible, depending on the relative contribution of the tachycardia to the underlying myocardial dysfunction.

Genetic mutations are increasingly identified as important mediators of the cardiac structural and functional abnormalities linked to symptomatic heart failure (see E-Table 47-1). The majority of familial cardiomyopathies (Chapter 47), most of which are inherited in an autosomal dominant fashion, are related to defects in cytoskeletal or nuclear proteins. Inherited cardiomyopathies are also associated with muscular dystrophies, infiltrative diseases such as hemochromatosis, and mitochondrial disorders. A low plasma transthyretin concentration is a marker of transthyretin tetramer instability associated with a higher risk of heart failure in the general population even in the absence of amyloidosis.[11]

Heart Failure with a Preserved Ejection Fraction

The pathophysiologic mechanism of heart failure with a preserved ejection fraction is complex and includes alterations in cardiac structure and function, vascular abnormalities, end-organ dysfunction, and interrelated comorbidities (Table 45-4).[12] In principle, diastolic dysfunction in heart failure with a preserved ejection fraction can result from increased ventricular stiffness due to hypertrophy and interstitial fibrosis as well as from abnormal ventricular relaxation due to dysfunctional calcium cycling. Although there are many potential causes of heart failure with preserved ejection fraction, most patients have current or prior hypertension; the resulting left ventricular hypertrophy and fibrosis are responsible for increased chamber stiffness. Ischemic heart disease also may contribute to heart failure with a preserved ejection fraction by virtue of subendocardial fibrosis or as a result of intermittent ischemic dysfunction. Age itself is a crucial predisposing factor because it causes loss of myocytes (apoptosis), increased fibrosis with shifts to more rigid forms of collagen, and loss of vascular compliance.

Myocardial relaxation is an energy-dependent process. Processes that interfere with myocardial energy metabolism, such as ischemia, compromise myocardial relaxation. These changes reduce ventricular compliance and increase filling pressures. Elevated filling pressures raise the pulmonary capillary wedge pressure and contribute to the sensation of dyspnea. Diastolic dysfunction may remain asymptomatic for years, but increasing age, renal dysfunction, hypertension, and progressive left ventricular dysfunction are associated with the development of symptomatic heart failure. The resting hemodynamic profile in heart failure with preserved ejection fraction is frequently normal, but physiologic perturbations such as tachycardia or exercise result in exaggerated increases in filling pressures. This phenomenon accounts for the exertional limitations seen in this syndrome.[13] Furthermore, because atrial contraction is responsible for a disproportionately large proportion of ventricular diastolic filling into a noncompliant ventricle, atrial fibrillation can exacerbate symptoms. Abnormalities in ventricular relaxation and myocardial stiffness limit ventricular filling, so patients may have a narrow window for optimal fluid volume. Modest volume overload can substantially exacerbate symptoms of dyspnea, and diuresis may precipitate symptomatic hypotension owing to ventricular underfilling. Although isolated diastolic dysfunction can occur, the majority of patients with ventricular dysfunction have both systolic and diastolic components. As a result, it is preferable to characterize patients as having heart failure with a preserved ejection fraction or heart failure with a reduced ejection fraction rather than as having systolic or diastolic heart failure.

High-output heart failure is seen in severe anemia and hyperthyroidism (Chapter 207). It is also seen in patients with vasodilative states such as obesity (Chapter 201), late-stage liver disease (Chapter 140), arteriovenous shunts, hypoxic-hypercapnic lung disease, and myeloproliferative/myelofibrotic disorders with extramedullary hematopoiesis (Chapter 152).

CLINICAL MANIFESTATIONS

The diagnosis of heart failure may be apparent when patients present with classic symptoms of shortness of breath in combination with a clinical examination consistent with volume overload. A previous history of a myocardial infarction or poorly controlled hypertension should increase the clinician's suspicion for the diagnosis. In contrast, the diagnosis may be missed or delayed in patients who experience a more insidious course with vague symptoms, such as fatigue and exercise intolerance. The use of biomarkers such as natriuretic peptides has significantly improved diagnostic accuracy in recent years.

The evaluation of a patient with suspected heart failure should proceed in an organized and focused manner (Fig. 45-2 and Table 45-5).

Symptoms

Shortness of Breath

Dyspnea (Chapter 71) is the most common but nonspecific symptom of heart failure, and patients with predominant lung disease or anemia may have similar symptoms. In most heart failure patients, dyspnea is present only with activity. It is the most common reason that patients seek care for heart failure, both during the chronic state and with acutely decompensated heart failure. The most important cause of dyspnea is pulmonary congestion that increases the accumulation of interstitial or intra-alveolar fluid, reduces lung compliance, and increases the work of breathing (E-Fig. 45-2). The relief of dyspnea is a primary treatment goal because of its effect on quality of life and its association with worse in-hospital and postdischarge outcomes.

When dyspnea occurs in the recumbent position, it is called *orthopnea*. Orthopnea results from the increase in venous return from the extremities and splanchnic circulation to the central circulation with changes in posture. The increase in ventricular preload raises pulmonary venous and pulmonary capillary hydrostatic pressures. Orthopnea is clinically characterized by the number of pillows a patient requires to sleep comfortably without shortness of breath. Patients with orthopnea may report an inability to sleep in a bed and instead may sleep sitting upright. Orthopnea is a specific symptom of heart failure, and it correlates well with the severity of pulmonary congestion.

Bendopnea is defined as dyspnea that occurs while bending over. The mechanism of bendopnea is poorly defined but appears to be related to increases in left ventricular filling pressures during bending in patients with a baseline elevation in pulmonary capillary wedge pressure. There appears to be an association between bendopnea and baseline mismatch of left- and right-sided filling pressures (i.e., elevated wedge pressure out of proportion to right atrial pressure). The clinical spectrum of this symptom and its relationship to outcomes are not well understood, but recent data suggest that this symptom may be more common than has previously been recognized.

Paroxysmal nocturnal dyspnea is acute, severe shortness of breath that awakens the patient from sleep. Paroxysmal nocturnal dyspnea usually occurs about 1 hour after the patient lies in a recumbent position and subsides with sitting or standing. Paroxysmal nocturnal dyspnea results from increased venous return and the mobilization of interstitial fluid from the splanchnic circulation and lower extremities, with accumulation of alveolar edema. Paroxysmal nocturnal dyspnea is relatively uncommon but almost always represents severe heart failure, and it appears to be associated with increased mortality.

Fatigue

Fatigue occurs in more than 90% of patients with heart failure. Although nonspecific and difficult to quantify, it can be an occult and troublesome manifestation of heart failure.

Chest Pain

Chest pain (Chapter 39) may be mediated by myocardial ischemia related to underlying coronary artery disease or increased wall stress that is proportional

TABLE 45-5 APPROACH TO THE DIAGNOSIS OF HEART FAILURE

Obtain a history and physical examination to identify disorders or behaviors that might cause or exacerbate heart failure.
Obtain a family history to aid in diagnosis of heritable causes of heart failure.
Assess volume status and vital signs at each encounter.
Patients with suspected new-onset or acute heart failure should undergo chest radiography to assess heart size and pulmonary congestion and to detect other diseases that may cause or contribute to the patient's symptoms.
A 12-lead electrocardiogram should be obtained for all patients presenting with heart failure.
Echocardiography should be performed during the initial evaluation of patients with heart failure to assess ventricular function and valve function.
Measurement of natriuretic peptides is recommended for the following indications: To support the diagnosis of heart failure in ambulatory patients with dyspnea as well as in those with possible acute heart failure, especially in the setting of an uncertain diagnosis. To establish prognosis or disease severity in heart failure.
The initial evaluation of patients presenting with heart failure should include a complete blood count, urinalysis and renal function, serum electrolytes, glucose and lipid profile, liver function tests, and thyroid-stimulating hormone.
Hemodynamic monitoring is recommended to guide therapy in patients who have respiratory distress or clinical evidence of impaired perfusion in whom the adequacy or excess of intracardiac filling pressures cannot be determined from clinical assessment.

Modified from Yancy CW, Jessup M, Bozkurt B, et al. 2013 ACCF/AHA guideline for the management of heart failure: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol.* 2013;62:e147-e239.

to the degree of left ventricular dilation. Left ventricular hypertrophy may cause chest pain from a mismatch between oxygen supply and demand. Patients with amyloid heart disease can have chest pain owing to transient ischemia caused by deposition of amyloid protein in the medial layer of myocardial arterioles.

Cardiac Cachexia

As heart failure progresses, patients may develop constitutional symptoms, including nausea, vomiting, anorexia, abdominal pain, and muscle wasting. The development of cardiac cachexia is associated with a poor prognosis.[14] In many patients, these symptoms arise from right-sided heart failure, with or without concomitant tricuspid regurgitation, and resulting passive venous congestion in the abdominal vasculature or liver. Patients with significant hepatic congestion may develop right upper quadrant abdominal pain and jaundice that can be difficult to distinguish clinically from gallbladder disease or other abdominal conditions (Chapter 141). In patients with advanced cardiogenic shock (Chapter 93), severe abdominal pain can be a particularly ominous sign of abdominal ischemia (Chapter 129).

Cognitive Dysfunction and Mood Disorders

Cognitive dysfunction (Chapter 371) is common, particularly in elderly heart failure patients. Confusion can be a manifestation of worsening heart failure related to relative hypotension or precipitated by medications used to treat heart failure. Although intrinsic brain function itself is not affected in most patients with heart failure, cerebral hypoperfusion in advanced heart failure can cause memory impairment, limited attention span, and altered mentation.

Depressive symptoms (Chapter 362) occur in up to 25% of patients with heart failure. Depressive symptoms can be detected by simple questions such as the Patient Health Questionnaire depression module (see Chapter 23), which has an 80% predictive value for depression and is associated with worse outcomes in heart failure patients.

Sleep Disorders

Sleep-disordered breathing is observed in upward of 70% of heart failure patients and is associated with increased morbidity and mortality. Patterns of sleep-disordered breathing include obstructive sleep apnea and central sleep apnea/Cheyne-Stokes respiration (Chapter 74). Patients may have both types, and the relative proportion of each type varies with the severity of heart failure and its treatment. Nocturnal rostral fluid movement from the lower extremities of heart failure patients may worsen obstructive sleep apnea. Central sleep apnea is due in part to the instability of the ventilatory control systems in heart failure.

Chronic sleep-disordered breathing also causes a series of derangements that may precipitate or exacerbate heart failure. Sleep-disordered breathing increases blood pressure and the risk of arrhythmias.

Symptoms of sleep-disordered breathing (Chapter 374) include hypersomnolence, choking or gasping during sleep, recurrent awakenings, unrefreshing sleep, daytime fatigue, and impaired concentration or memory. The symptoms may be difficult to distinguish from other symptoms of heart failure, including unrefreshing sleep due to orthopnea and paroxysmal nocturnal dyspnea. Treatment of sleep-disordered breathing with continuous positive airway pressure ventilation improves quality of life and left ventricular ejection fraction, but these effects are attenuated after 3 months.[A1] The use of adaptive servo-ventilation increases mortality and should be avoided in this patient population.[A2]

Physical Examination

A carefully performed physical examination is critical to make an accurate diagnosis, assess comorbid conditions, understand the patient's underlying hemodynamic state, and estimate prognosis.[15]

Global Observation and Vital Signs

The patient's general appearance may provide details related to the acuity and severity of the heart failure. Patients with severe symptoms may be pale or

diaphoretic and unable to speak in complete sentences. In extreme circumstances, they may be unable to lie recumbent in bed because of severe dyspnea. The heart rate may be elevated (>100 beats per minute), and premature ventricular beats or atrial arrhythmias are common. Approximately 30% of heart failure patients have atrial fibrillation (Chapter 52). Pulsus alternans (alternating amplitude of successive beats) is an uncommon sign but is virtually diagnostic for advanced heart failure. Blood pressure is most commonly normal or high, but it may be low (systolic blood pressure <90 mm Hg) in advanced low-output heart failure. Blood pressure has historically been identified as an important prognostic marker (i.e., higher blood pressure is associated with improved long-term outcomes), but these associated data may not be applicable to all subgroups of patients, especially the elderly. A narrow pulse pressure (e.g., <30 to 35 mm Hg) is indicative of more severe heart failure. Weight should be assessed and compared with the patient's known dry weight or recent weight trajectory. The assessment of weight not only helps the clinician to appreciate the severity of volume overload, but it may also assist with quantifying the degree of cardiac cachexia. The respiratory rate should be measured. Both low rates and high rates may be seen in heart failure. Likewise, both hypothermia and hyperthermia can be informative of impending shock or secondary causes of heart failure.

Jugular Veins

Examination of the jugular veins assesses right atrial pressure (see Fig. 39-2). Right atrial pressure can be estimated by measuring the height of the jugular pulse in centimeters above the sternal angle and adding 5 cm H_2O (normal = 8 cm H_2O; see Fig. 39-3). An alternative is to assess the height of the veins in relationship to the clavicle. Jugular pulsations can be distinguished from carotid pulsations by their more lateral location, lack of palpability, and a visible double waveform. It may also be useful to compare the timing to the contralateral carotid or radial pulse. If the jugular pulsation is not seen in the neck, the right atrial pressure may be either very high or low. The presence of abdominal-jugular reflux, which is a sign of abnormally elevated right-sided filling pressures, should be assessed by putting sustained pressure on the right upper quadrant of the abdomen for 30 seconds; a positive finding is at least a 1-cm rise in the jugular pressure, which then slowly declines when abdominal pressure is removed. Either an elevated jugular venous pressure or an abnormal abdominal jugular reflux has been reported in 80% of patients with advanced heart failure.

An additional important finding in the neck is evidence of tricuspid regurgitation, which is visualized as a large *cv* wave (see Fig. 39-3). This finding is often corroborated by hepatic pulsations, which can be detected during the abdominal examination. Difficulty palpating the carotid pulses may suggest low cardiac output from heart failure, aortic stenosis, or carotid artery disease (see Fig. 39-4).

Pulmonary Examination

Despite elevated left ventricular filling pressures that are transmitted back into the left atrium and pulmonary circulation, most patients with heart failure do not have evidence of pulmonary congestion on physical examination. The lungs of chronic heart failure patients undergo adaptive changes and have robust lymphatic drainage to compensate for elevated filling pressures. However, a subset of patients may develop alveolar fluid accumulation, which is appreciated as rales (Chapter 71) and which are an independent predictor of prognosis among patients with heart failure and a reduced ejection fraction.[16] These findings are more common in patients with acute pulmonary edema due to sudden decompensation from an inciting event.

Fluid may also accumulate in the pleural space related to the increased transudation of fluid and impaired lymphatic drainage in the setting of elevated systemic venous pressures (Chapter 86). The clinician should listen and percuss for the possible presence of pleural effusions (Chapter 86), which tend to lateralize to the right side owing to the greater surface area of the lungs and the position of the diaphragm.[17] The diagnosis of a moderate or large pleural effusion is critical because draining the effusion may improve dyspnea.

Cardiac Examination

The cardiac examination is the cornerstone of the evaluation of the patient with heart failure. Visual inspection and palpation may reveal a right ventricular heave, suggestive of right ventricular dysfunction and underlying pulmonary hypertension. The location, size, and duration of the point of maximal impulse against the chest wall may provide details related to the degree of left ventricular dilation; the impulse is typically laterally displaced in the setting of left ventricular enlargement and may be sustained in the setting of left ventricular hypertrophy.

Auscultation of the heart sounds provides important information related to the underlying rhythm and frequency of ectopic beats. Auscultation of a loud P2 or the ability to hear a P2 beyond the pulmonic listening area suggests pulmonary hypertension. The presence (or worsening) of valvular disorders (Chapter 60) can be characterized for their potential contribution to cardiac dysfunction. An apical S_3 gallop (see Fig. 39-5 in Chapter 39) is common in severe LV dysfunction, and its presence is correlated with an elevated left ventricular end-diastolic pressure and a poor prognosis. An S_4 gallop is common in patients who have ischemic heart disease and hypertension, and it is more likely indicative of diastolic dysfunction. Pericardial effusions (Chapter 62) may also occasionally occur in the setting of heart failure, particularly in inflammatory cardiomyopathies.

Abdomen

The physical examination should estimate the size of the liver and spleen and elicit the presence of ascites (Chapter 132). Abdominal venous congestion may cause renal venous hypertension and subsequent renal dysfunction. An enlarged and pulsatile liver is seen in individuals with markedly elevated right heart pressures and in patients with significant tricuspid insufficiency. In the setting of irreversible liver disease (i.e., cardiac cirrhosis), patients with heart failure are at a substantially increased risk during surgical interventions. Thus, a thorough abdominal examination represents a critical component of the evaluation of heart failure patients.

Extremities

Edema (Chapter 39) results from the retention of sodium due to low cardiac output and reduced renal perfusion pressures, which ultimately result in elevated right-sided filling pressures, increased hydrostatic pressures in the venous circulation, and transudation of fluid into dependent interstitial spaces, especially in the ankles or lower extremities. Edema is commonly measured on a scale of 0 to 3+, but this system has marked interobserver variation. Peripheral edema is a nonspecific finding, and edema due to heart failure must be distinguished from edema related to medication use (e.g., calcium-channel blockers, thiazolidinediones, or nonsteroidal anti-inflammatory drugs), venous insufficiency, or hypoproteinemia.

The temperature of the extremities should also be assessed. Cool extremities suggest low cardiac output or concomitant peripheral arterial disease (Chapter 65).

DIAGNOSIS

Patterns of Presentation

The initial presentation ranges from subtle outpatient findings to acute decompensation that requires hospitalization (see Figs. 45-3 and 45-4). In critically ill patients with respiratory compromise, the distinction between cardiac pulmonary edema compared with acute respiratory distress syndrome (Chapter 90) can be challenging.[18]

An initial presentation of heart failure may represent the gradual progression of known but previously asymptomatic (stage A or B) heart failure or be the first indication of altered cardiac function. In patients without an antecedent history of heart failure, precipitating factors, such as acute myocardial infarction (Chapter 58), tachyarrhythmias (Chapters 52 and 53), previously unrecognized or new valvular abnormalities (Chapter 60), toxic injury (including alcohol excess), or acute myocarditis (Chapter 47), should be considered.

When patients with stage C or D heart failure present with worsening symptoms, precipitating factors may also include myocardial ischemia, arrhythmias, or worsening of valvular function (see Table 45-2). Other conditions can include anemia, infection, thyroid abnormalities, and any disease process that may accompany or require a higher cardiac output. In many patients, however, the worsening may be gradual, augured by subtle signs and symptoms (Fig. 45-5).

Electrocardiography

A 12-lead electrocardiogram (Chapter 42) should be obtained for all patients who present with possible heart failure to evaluate the cardiac rhythm, identify current ischemia or prior myocardial infarction, and detect evidence of left ventricular hypertrophy. Rhythm abnormalities may be responsible for the development or exacerbation of underlying cardiac dysfunction. For example, an underlying tachyarrhythmia can lead to the development of left ventricular systolic dysfunction that is reversible with appropriate intervention. Q waves suggest coronary artery disease as a likely contributor to ventricular dysfunction. Voltage criteria for left ventricular hypertrophy support a diagnosis of hypertensive heart disease, including heart failure with a preserved ejection fraction. Underlying conduction abnormalities, such as delayed ventricular conduction (i.e., bundle branch morphology), determine eligibility criteria for cardiac resynchronization therapy in appropriate patients (Chapters 46 and 54) and have important prognostic implications. Holter monitoring sometimes may be helpful to determine the burden of ventricular arrhythmias or ectopic beats because tachycardia-mediated cardiomyopathies may be reversible with medical or ablation therapy.

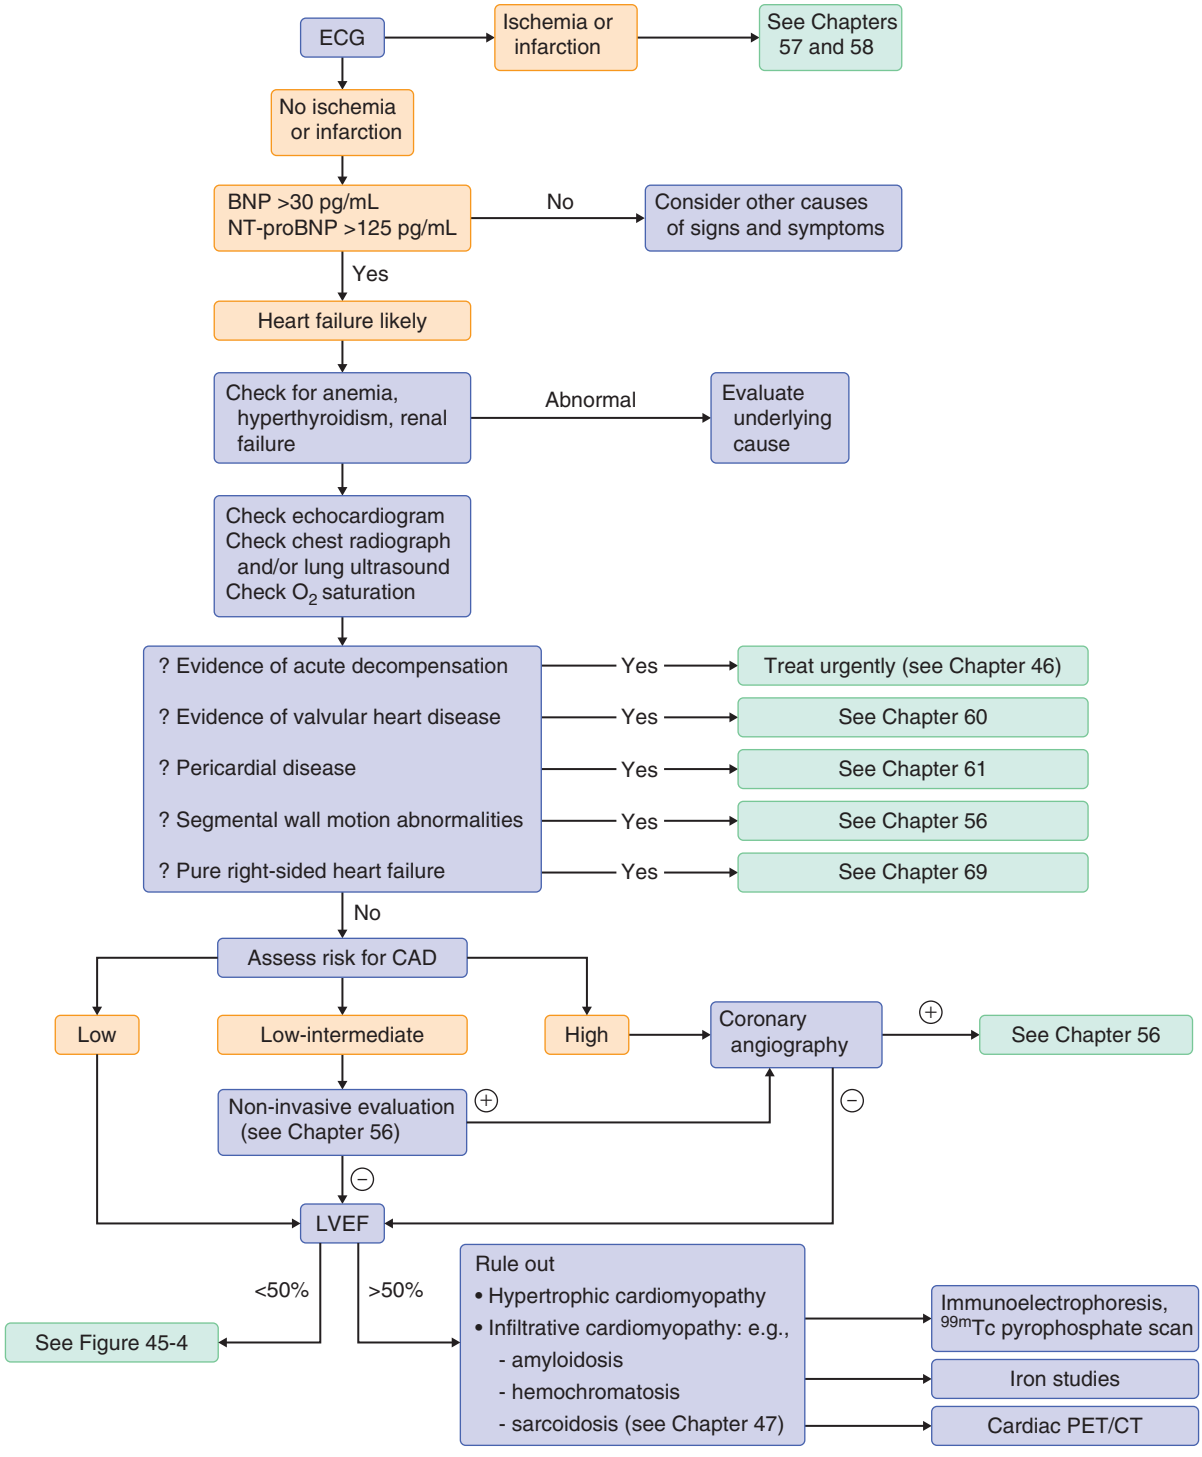

FIGURE 45-3. **Diagnostic approach to the patient with suspected heart failure.** BNP = brain natriuretic peptide; CAD = coronary artery disease; CT = computed tomographic scan; ECG = electrocardiogram; LVEF = left ventricular ejection fraction; NT-proBNP = N-terminal pro-B-type natriuretic peptide; PET = positron emission tomography.

Chest Radiography

Patients with suspected new-onset or worsening heart failure should undergo chest radiography to assess heart size and pulmonary congestion as well as to detect other diseases that may cause or contribute to the patient's symptoms. Many patients with acute heart failure but only a minority of those with chronic heart failure have clear evidence of pulmonary venous hypertension (upper lobe vascular redistribution, enlarged pulmonary veins) or pulmonary edema (perihilar or patchy peripheral infiltrates; see Fig. 44-2). Pleural effusions, usually on the right if unilateral but often bilateral, are also identified on the chest radiograph (see Fig. 86-3). Chest radiography may also play a role in identifying the location of the lead placement of intracardiac devices, such as biventricular pacemakers. Inappropriate lead placement may be observed in patients with worsening heart failure symptoms.

Laboratory Testing

The initial evaluation of patients presenting with heart failure should include a complete blood count to detect anemia and systemic diseases with hematologic manifestations; urinalysis and tests of renal function to assess underlying renal disease; serum electrolyte values to identify abnormalities needing treatment and to provide a baseline for subsequent therapy; glucose level and lipid profile to diagnose diabetes and dyslipidemia, which should be carefully managed in patients with heart failure; and thyroid-stimulating hormone level. Markers of hepatic congestion, such as elevated serum aminotransferase and bilirubin levels (Chapter 133), also should be measured because they have prognostic importance. Screening for hemochromatosis (Chapter 196) or human immunodeficiency virus (HIV) infection is reasonable in selected patients with heart failure. Diagnostic tests for rheumatologic diseases (Chapter 236), amyloidosis (Chapter 174), or pheochromocytoma (Chapter 209) are

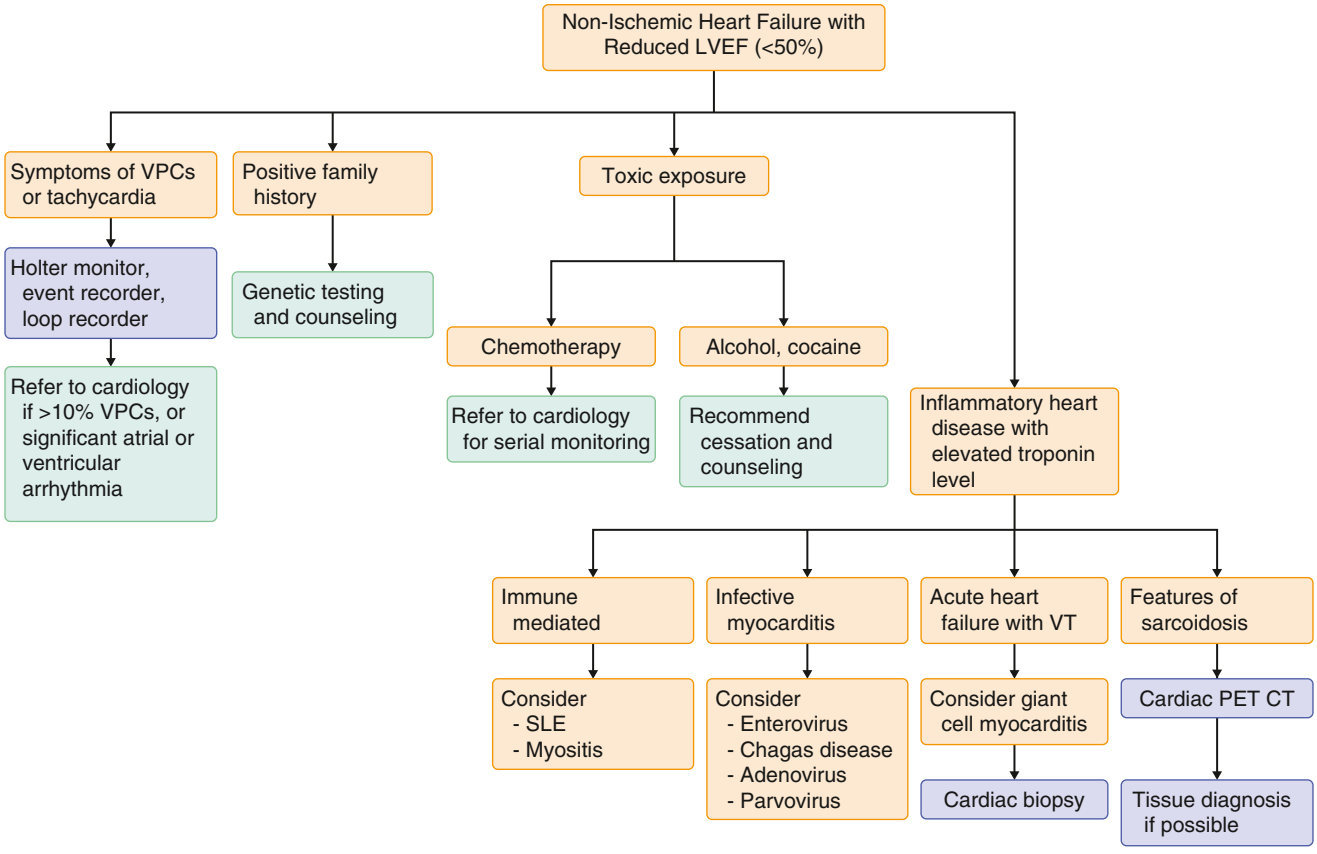

FIGURE 45-4. **Diagnostic approach to the patient with nonischemic heart failure and a reduced left ventricular ejection fraction.** CT = computed tomographic scan; LVEF = left ventricular ejection fraction; PET = positron emission tomography; SLE = systemic lupus erythematosus; VPC = ventricular premature contraction; VT = ventricular tachycardia.

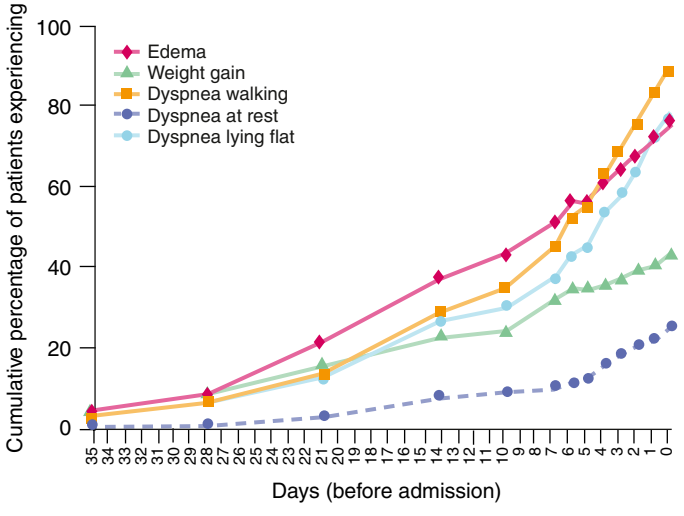

FIGURE 45-5. **Number of days from onset of worsening of selected symptoms of heart failure to admission to the hospital: cumulative percentage of patients.** (From Schiff GD, Fung S, Speroff T, et al. Decompensated heart failure: symptoms, patterns of onset, and contributing factors. *Am J Med*. 2003;114:625-630.)

not routinely indicated but rather should be targeted to patients with other ancillary findings suggestive of these conditions. Viral antibody titers yield relatively little incremental information and are rarely indicated in the evaluation of heart failure.

Natriuretic Peptides

Brain natriuretic peptide (BNP) and its amino-terminal fragment (NT-proBNP) provide incremental diagnostic and prognostic information above and beyond the history and physical examination in patients with heart failure. A natriuretic peptide level should be measured to support the diagnosis of heart failure in ambulatory patients with dyspnea, as well as in patients with possible acute heart failure, especially in the setting of an uncertain diagnosis. It also is useful to estimate the severity of heart failure and its prognosis.

BNP levels are relatively sensitive (about 95 to 99%) but less specific (about 50 to 60%) markers for diagnosing clinically confirmed heart failure. Circulating levels are influenced by comorbid processes. For example, obesity reduces BNP levels, whereas advancing age and renal dysfunction are associated with higher levels. Most heart failure therapies reduce BNP levels, but the usefulness of BNP-guided heart failure therapy is not well established.[A3,A4]

Troponin

Owing to the increased sensitivity of currently available troponin assays, the majority of patients admitted with acute heart failure have elevations in circulating troponin even without any obvious myocardial ischemia. These elevations, which suggest ongoing myocyte injury or necrosis, are associated with worse clinical outcomes and mortality.[19]

Other Biomarkers: Galectin-3 and ST2

A number of additional biomarkers characterize inflammation, myocyte injury, neurohormonal upregulation, and extracellular matrix turnover in patients with heart failure (E-Table 45-1). In the future, strategies that combine multiple biomarkers into a risk stratification model may prove additive to clinical judgment.

Echocardiography

An echocardiogram should be obtained during the initial evaluation of patients with heart failure to assess ventricular and valvular function. Repeated echocardiograms are also indicated when patients have a significant change in their clinical status or receive treatment that may have had a significant effect on cardiac function. In contrast, routine repeated measurements of left ventricular function in the absence of a change in clinical status or treatment should not be performed.

Echocardiography (Chapter 43) allows the assessment of systolic and diastolic ventricular function (see Figs. 43-2 and 43-3). Wall thickness, chamber size, and regional wall motion abnormalities provide evidence of the underlying etiology of heart failure with a diminished or preserved ejection fraction.[20] Echocardiography also evaluates valvular dysfunction (Chapter 60), which may be the result of or cause worsening ventricular

E-TABLE 45-1 EMERGING BIOMARKERS IN CHRONIC HEART FAILURE

BIOMARKER	PROPOSED PATHOPHYSIOLOGY	POTENTIAL ROLE IN PATIENTS WITH CHRONIC HF
Copeptin	Stable plasma surrogate for vasopressin, which is released from the hypothalamus in response to changes in plasma osmolarity and reduced cardiac output Elevated levels of vasopressin contribute to development of hyponatremia, vasoconstriction, and adverse cardiac remodeling	Independent role as a prognostic marker in patients with chronic HF Potential role of molecular marker for tailored therapies with vasopressin antagonism
Cystatin C	Cysteine protease inhibitor that is more sensitive and specific to changes in GFR than creatinine Produced at a constant rate by all nucleated cells of the body	Independent predictor of mortality in patients with chronic HF Identifies poor prognosis even in patients with a normal creatinine level, pointing to a role as a marker of the CRS
Endothelin 1	Produced by the endothelium in response to ATII, inflammation, and vascular shear stress Causes vasoconstriction and adverse cardiac remodeling	Independent predictor of mortality in patients with chronic HF Clinical application requires measurement of the more stable precursor (CT-proET-1) Whether patients with elevated levels of CT-proET-1 would benefit from endothelin 1 antagonism is unclear
Galectin-3	β-Galactoside–binding lectin produced by several tissues Promotes cardiac fibroblast proliferation and collagen synthesis (maladaptive remodeling)	Predicts mortality independent of natriuretic peptides in patients with chronic HF Does not appear to be modified by treatment Potential role as a target for therapy
GDF-15	Member of the TGF-β cytokine family Expressed in most tissues Expression in myocytes is triggered by ischemia, stretch, inflammation, and neurohormonal activation May protect myocytes against apoptosis and hypertrophy	Predictive of mortality in patients with chronic HF independent of established biomarker Serial changes are associated with prognosis Could lead to the development of unique treatments for patients with chronic HF
hs-cTn	Proteins involved in the regulation of cardiac and skeletal muscle contraction Released after loss of myocytes from necrosis, apoptosis, or reversible injury with increased membrane permeability	Predictive of chronic HF mortality in patients with no known CHD Independently predictive of mortality in patients with chronic HF The effect of serial changes in hs-cTn levels on prognosis, and how therapy should be modified on the basis of increased levels of hs-cTn, is unknown
MR-proADM	Produced by various tissues within the cardiovascular system in response to hemodynamic stress Favorable effects on the vasculature—positive inotropy and vasodilation	May add prognostic value to predictive models for patients with chronic HF beyond that provided by natriuretic peptides and traditional clinical risk factors
Neuregulin 1	Belongs to a family of growth factors with an important role in cardiac development and the pathogenesis of chronic HF Has an important role in promoting cardiomyocyte growth in function and regulation of the stress response	Preliminary studies show independent associations with disease severity and risk of adverse outcomes in patients with chronic HF A promising target for drug therapy Trials with recombinant neuregulin are already under way, with a phase II trial showing improvement in cardiac structure and function
NGAL	Small glycoprotein released by multiple cell types during inflammation and injury Involved in cell survival, inflammation, and matrix degradation Early marker of renal tubular damage Increased levels found in patients with chronic HF	Early detection of renal injury in patients with chronic HF A more effective marker of CRS than creatinine Independent predictor of mortality in patients with chronic HF
sST2	Member of the IL-1 receptor family that is secreted from myocytes during biomechanical strain Possible mediator of myocardial hypertrophy and fibrosis by compromising the favorable effects of IL-33/ST2 signaling	Independent predictor of morbidity and mortality in patients with chronic HF Possible role as a novel therapeutic target

ATII = angiotensin II; CHD = coronary heart disease; CRS = cardiac-renal syndrome; CT-proET-1 = C-terminal pro-endothelin 1; GDF = growth differentiation factor; GFR = glomerular filtration rate; HF = heart failure; hs-cTn = cardiac troponins measured by a highly sensitive assay; IL = interleukin; MR-proADM = mid-regional pro-adrenomedullin; NGAL = neutrophil gelatinase–associated lipocalin; TGF = transforming growth factor.

function or symptoms. Quantitative measurements of pulmonary artery pressure and central venous pressure help characterize the degree of pulmonary hypertension and may guide diuretic therapies in circumstances in which the jugular veins are difficult to visualize. Detection of atrial or ventricular thrombi requires anticoagulation. Novel methods using ventricular strain analysis and three-dimensional echocardiography can provide additional insights about myocardial performance.

Point-of-Care Ultrasound

Point-of-care ultrasonography has gained increasing acceptance as a noninvasive tool for the detection and quantification of jugular venous distention[21] and pulmonary congestion[22] in both ambulatory and hospitalized patients with potential heart failure. However, adding ultrasound to the standard clinical evaluation has not been shown to reduce admission rates or mortality, although it may reduce future urgent visits for worsening symptoms.[A5]

Nuclear Cardiology and Coronary Angiography

Significant coronary artery disease is common in adults with heart failure and should prompt careful evaluation for ischemia, which is common not only in patients who have heart failure with a reduced ejection fraction but is also found (either as epicardial stenosis or microvascular dysfunction) in about 90% of patients who have heart failure with a preserved ejection fraction[23] (Chapters 39, 43, 44, and 56). When myocardial ischemia may be contributing to heart failure, coronary arteriography (Chapter 59) is reasonable to assess eligibility for revascularization.

The most powerful predictors of prognosis for patients with ischemic cardiomyopathy are a history of prior myocardial infarction, stenosis of 75% or greater of the left main or proximal left anterior descending artery, stenosis of 75% or greater of two or more epicardial vessels, and the severity of ventricular dysfunction. Coronary computed tomographic angiography (Chapter 44) may represent a noninvasive modality for assessing coronary disease in appropriately selected patients.

Noninvasive imaging (Chapter 44) to detect myocardial ischemia and viability is reasonable in patients who present with de novo heart failure and in patients who have known coronary artery disease and no angina, unless they are not eligible for revascularization. Viability assessment is reasonable in select situations in planning revascularization for patients who have heart failure and coronary artery disease.[24] However, stress testing to assess myocardial viability so far has not been able to identify patients who will benefit from revascularization compared with medical therapy alone.

For suspected cardiac transthyretin amyloidosis (Chapters 47 and 174), which is responsible for about 6% of cases of heart failure with a preserved ejection fraction,[25] a ^{99m}Tc-pyrophosphate scan is highly sensitive and specific. Typical findings avoid the need for a confirmatory biopsy.[26]

The single-photon emission computed tomography tracer *m*-iodobenzylguanidine (mIBG) has been widely used for studying causes and effects of cardiac sympathetic hyperactivity. Cardiac sympathetic imaging with mIBG is a noninvasive tool that may assist with the risk stratification of patients with heart failure. With mIBG imaging, the myocardial uptake and distribution can be visually assessed and quantified by calculating a heart-to-mediastinum ratio. This approach provides a highly reproducible index of cardiac sympathetic activity. Further study is required to determine the role of this imaging modality in heart failure risk stratification and clinical care.

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (Chapter 44) provides accurate measurements of left ventricular volume and ejection fraction, and it is useful when echocardiography is inadequate. It is also helpful to assess for potential infiltrative cardiomyopathies when the cause of heart failure, especially heart failure with a preserved ejection fraction, is unclear. Late gadolinium enhancement (see Fig. 44-16) adds important prognostic information related to the risks of ventricular arrhythmias and mortality.

Myocardial Biopsy

Guidelines indicate that endomyocardial biopsy should not be performed in the routine evaluation of patients with heart failure. However, endomyocardial biopsy may be useful in patients who present with heart failure when a specific suspected diagnosis would influence therapy. For example, in patients with acute myocarditis or giant cell myocarditis and in patients with sarcoid or amyloid cardiomyopathy (Chapter 47), the appropriate pathologic diagnosis may inform treatment recommendations and prognosis. In certain circumstances, biopsy may be performed along with genetic testing (e.g., transthyretin gene mutation) to inform decisions on management and counseling of family members.

Assessment of Exercise Capacity

A heart failure patient's exercise capacity can be quantified by several testing modalities, including 6-minute walk distance and cardiopulmonary exercise testing (Chapter 73). Although these tests are not routinely recommended, they are helpful for determining the relative contribution of cardiac compared with pulmonary causes of functional limitation. The results of cardiopulmonary exercise testing are critical to determine candidacy for heart transplantation or placement of a ventricular assist device (Chapter 46). A maximal oxygen consumption of less than 14 mL/kg/minute is associated with a sufficiently poor prognosis that transplantation or implantation of a left ventricular assist device is warranted. Serial cardiopulmonary exercise testing, the 6-minute walk test, or the 60-foot walk test also can be useful to follow the disease course of specific patients objectively.

Invasive Diagnostics and Hemodynamic Monitoring

Invasive monitoring may be useful in selected patients who have acute heart failure, who have persistent symptoms despite adjustment of standard therapies, and whose fluid status or perfusion is uncertain. However, the routine use of pulmonary artery catheters should be discouraged.

Up to 30% of patients with heart failure with a reduced ejection fraction have an implantable device that detects arrhythmias and can provide hemodynamic assessment. Indirect measures, such as changes in impedance or heart rate variability, are precursors to worsening heart failure symptoms. Chronic hemodynamic monitors (i.e., direct measures of pulmonary pressures and right ventricular pressures) have been approved by the U.S. Food and Drug Administration and are now available for the serial measurement of left ventricular filling pressure surrogates. Interrogation of these devices may become part of the routine diagnostic follow-up to guide therapy[27] in patients who have respiratory distress or clinical evidence of impaired perfusion in whom the adequacy or excess of intracardiac filling pressures cannot be determined by clinical assessment.

CONSEQUENCES OF MISDIAGNOSIS

The diagnosis of heart failure may be straightforward in a patient with dyspnea, signs of congestion, and an elevated BNP level. Conversely, many patients have multiple comorbid conditions that make the assessment of shortness of breath a diagnostic dilemma. Pulmonary conditions such as chronic obstructive pulmonary disease (Chapter 76) represent the most common reason for misdiagnosis. The BNP level and echocardiogram provide useful information to make this distinction. Other potential causes of edema or volume overload include renal failure (Chapter 117), venous thrombosis (Chapter 68), and venous insufficiency. If left ventricular systolic function is normal, it may be difficult to make a conclusive determination of the relative role of heart failure with preserved ejection fraction compared with other concomitant conditions, such as pericardial constriction, severe obesity, deconditioning, chronic anemia, or other systemic illnesses. BNP levels may be helpful in some circumstances. In other situations, exercise testing or invasive hemodynamic testing may be necessary to establish the appropriate diagnosis. Misdiagnosis can result in excessive and unnecessary diagnostic testing, higher costs, and increased morbidity and mortality because of the inappropriate use or nonuse of heart failure therapies.

46 HEART FAILURE: TREATMENT AND PROGNOSIS

JOHN J.V. MCMURRAY AND MARC A. PFEFFER

EVALUATION AND MANAGEMENT OF HEART FAILURE

Heart failure is an overarching term for a syndrome (i.e., a constellation of signs and symptoms) that encompasses a vast spectrum of cardiovascular disorders and is associated with a greatly heightened risk for death and nonfatal adverse cardiovascular events (Chapter 45). Treatment is initially directed toward prevention of cardiac injury (e.g., due to hypertension or myocardial infarction) or toward limiting structural progression if cardiac damage has already occurred (e.g., left ventricular remodeling with declining left ventricular ejection fraction) and delaying the development of symptomatic heart failure. When symptoms develop, treatments are also directed at improving functional status as well as prognosis.

At least one in five adults will develop heart failure. In the United States, 6.5 million people have heart failure, and 1.25 million patients are discharged from U.S. hospitals annually with a primary diagnosis of heart failure.[1] The estimated cost of heart failure in the United States exceeds $30 billion per year. Randomized controlled clinical trials (RCTs) supply the framework for quantifying what different therapeutic approaches can offer. Even when they are definitive, RCTs generate data only about average risks and benefits of the tested therapeutic option in a selected cohort. Because an individual patient's responses can only be inferred from the overall estimated group responses, RCTs cannot definitively direct the approach of every patient or answer the myriad questions that confront the practitioner regarding the specific circumstances of the patient. Another major limitation of RCTs is the relatively narrow time frame of observation, generally only months to several years, compared with epidemiologic experiences during decades. Despite these limitations, RCTs are the premier tool of evidence-based medicine, and the field of heart failure has fortunately been the focus of relatively high-quality RCTs that have provided robust evidence to improve clinical care and prognosis (Table 46-1). Indeed, the implementation of evidence from RCTs into clinical practice has resulted in impressive temporal improvements in survival after discharge from a first hospital admission for heart failure. Moreover, the age at which symptomatic heart failure first becomes evident has increased. Despite these tangible advances, heart failure continues to be a leading cause of morbidity and mortality in elderly people.

STAGES OF HEART FAILURE

Guidelines for the evaluation and management of chronic heart failure use a staging classification to underscore the evolution and progression of heart failure severity (Fig. 46-1).[2,3] This classification emphasizes the use of different strategies and therapeutic options across the full spectrum of the syndrome, from prevention of heart failure to palliation of patients with end-stage disease.

Cardioverter-defibrillator
Ventricular assist device
Heart transplantation
Exercise training

INDIVIDUALS AT RISK FOR DEVELOPMENT OF HEART FAILURE (STAGE A)

Stage A designates patients at risk for development of heart failure based on concomitant cardiovascular diseases such as hypertension, coronary artery disease, and diabetes mellitus. Also included in stage A are individuals with prior exposure to cardiotoxic agents such as doxorubicin (Chapter 164) and those with a family history of a cardiomyopathy (Chapter 47). Although these predisposing factors do not by themselves technically constitute the syndrome of heart failure, the guidelines stress the importance of identifying individuals with modifiable factors because this represents an important opportunity to reduce the reservoir of patients at risk.

Population-based preventive approaches can reduce the incidence of heart failure. For example, public health programs targeting the eradication of the insect vector for *Trypanosoma cruzi* (Chapter 318) have reduced the incidence of Chagas cardiomyopathy (Chapter 47) in endemic regions of South and Central America.

Other population-based approaches to reduce the incidence of heart failure require specific screening efforts to identify individuals with modifiable risk factors. The most important, although unfortunately nonmodifiable, risk factor for the development of heart failure is advanced age; the incidence of heart failure rises sharply per decade after the age of 45 years (Chapter 45). For each decade of age after 45 years, the incidence of heart failure doubles, and heart failure is the leading hospital diagnosis for patients older than 65 years in the United States.

HYPERTENSION

Of the modifiable factors, hypertension (Chapter 64) undoubtedly contributes the greatest population-attributable risk for heart failure. In other words, even though the increased risk for heart failure in an individual with hypertension is modest, the high prevalence of hypertension in the general population means that at a population level, hypertension is the major cause of heart failure.

The contribution of hypertension to the risk for heart failure was a consistent finding from all major cardiovascular epidemiologic studies, and the earliest RCTs of antihypertensive therapy showed unambiguous reductions in the risk for heart failure. Of the components of blood pressure, elevated systolic pressure has a greater influence on the incidence of heart failure than does diastolic pressure. In fact, aging is associated with a progressive rise in systolic blood pressure and fall in diastolic pressure as the compliance of the arterial tree diminishes (Chapter 64). In community-based studies, isolated systolic hypertension and elevated pulse pressure have been the most predictive blood pressure measurements for development of heart failure. Antihypertensive treatment to a systolic blood pressure goal of 130 mm Hg appears to reduce the risk of developing heart failure.[A1] Reduction to lower than 120 mm Hg systolic provides additional benefit for reducing nonfatal cardiovascular events and all-cause mortality in patients without diabetes or prior heart failure,[A2] but at the cost of more hypotension, electrolyte abnormalities, and renal impairment. The current blood pressure goal is lower than 120 mm Hg for selected patients at high cardiovascular risk without diabetes or prior heart failure and lower than 130 mm Hg otherwise (Chapter 64).

DIABETES

Individuals with diabetes (Chapter 210) are also at heightened risk for premature cardiovascular mortality and morbidity, including heart failure. Type 2 diabetes frequently clusters with hypertension, obesity, and a sedentary lifestyle, thereby exacerbating the risks associated with each condition. However, the glucose level is an independent risk factor for cardiovascular events, including heart failure. Unlike hypertension, where pharmacologic therapy has had a generally favorable impact on reducing the risk of heart failure, historically, glucose-lowering therapy has not been shown to reduce this risk. However, sodium-glucose cotransporter 2 (SGLT2) inhibitors (e.g., dapagliflozin 10 mg daily; Chapter 210) reduce the risk of heart failure hospitalization in patients with type 2 diabetes and cardiovascular risk factors, preexisting cardiovascular disease, or chronic kidney disease (Chapter 116) with or without type 2 diabetes.[A3] The glucagon-like peptide-1 (GLP-1) receptor agonists may also reduce the risk of developing heart failure,[A4] but not to the extent seen with SGLT2 inhibitors.[A5] The α-glucosidase inhibitor acarbose, insulin, and the meglitinide nateglinide do not increase the risk of developing heart failure in patients with impaired glucose tolerance, diabetes, or both.[A6] An increase in risk of heart failure was reported with saxagliptin, although this increased risk has not been seen with other dipeptidyl peptidase-4 (DPP-4) inhibitors.[4]

By comparison, thiazolidinediones cause retention of sodium and water and should not be used in patients at risk for developing heart failure.

ABSTRACT

The treatment of heart failure is guided by its stage: patients at risk of heart failure (stage A), asymptomatic structural or functional heart disease (stage B; pre-heart failure), structural heart disease with prior or current symptoms of heart failure (stage C), and advanced heart failure requiring specialized interventions (stage D). Treatment of hypertension and lipid disorders, smoking cessation, regular exercise, discouraging alcohol intake, and control of weight and hyperglycemia are cornerstones of therapy for all stages. An ACE inhibitor or an angiotensin receptor blocker and often an SGLT2 inhibitor are indicated for stages A and B. β-Blockers are added in stages B and C, implantable defibrillators oftentimes in stages B and C, and sacubitril/valsartan, mineralocorticoid antagonists, cardiac resynchronization therapy, and sometimes other medications in stage C. For stage D, left ventricular mechanical support, heart transplantation, and compassionate and often palliative care are indicated.

Stage A High risk for HF without structural heart disease or symptoms of HF	**Stage B** Structural heart disease but without signs or symptoms of HF	**Stage C** Structural heart disease with prior or current symptoms of HF	**Stage D** Refractory HF requiring specialized interventions
Patients with • Hypertension • Atherosclerotic disease • Diabetes • Obesity • Metabolic syndrome or • Patients using cardiotoxins with family history of cardiomyopathy (FHx CM)	Patients with • Previous MI • LV remodeling including LVH and low EF • Asymptomatic valvular disease	Patients with • Known structural heart disease • Shortness of breath and fatigue, reduced exercise tolerance	Patients with marked symptoms at rest despite maximal medical therapy (e.g., those who are recurrently hospitalized or cannot be safely discharged from the hospital without specialized interventions)
THERAPY **Goals** • Treat hypertension • Encourage smoking cessation • Treat lipid disorders • Encourage regular exercise • Discourage alcohol intake, illicit drug use • Control metabolic syndrome **Drugs** • ACE inhibitor or ARB as appropriate for patients with vascular disease or diabetes • SGLT2i in patients with type 2 diabetes	**THERAPY** **Goals** • Treat hypertension • Encourage smoking cessation • Treat lipid disorders • Encourage regular exercise • Discourage alcohol intake, illicit drug use • Control metabolic syndrome **Drugs** • ACE inhibitor or ARB as appropriate for patients with vascular disease or diabetes • β-blockers in appropriate patients • SGLT2i in patients with type 2 diabetes **Devices in selected patients** • Implantable defibrillators	**THERAPY** **Goals** • Treat hypertension • Encourage smoking cessation • Treat lipid disorders • Encourage regular exercise • Discourage alcohol intake, illicit drug use • Control metabolic syndrome • Dietary salt restriction **Drugs for routine use** • Diuretics for fluid retention • ACE inhibitor or ARNI • β-blockers • Mineralocorticoid antagonists • SGLT2i **Drugs in selected patients** • ARBs • Digitalis • Hydralazine/nitrates • Ivabradine **Device in selected patients** • Biventricular pacing (CRT) • Implantable defibrillators	**THERAPY** **Goals** • Appropriate measures under stages A,B,C • Decision re: appropriate level of care **Options** • Compassionate end-of-life care/hospice • Extraordinary measures • Heart transplantation • Chronic inotropes • Permanent mechanical support • Experimental surgery or drugs

FIGURE 46-1. Stages of heart failure and therapies at various stages of heart failure (HF). Check marks indicate therapies proved by randomized trials to be beneficial; check marks in brackets indicate benefits uncertain. ACEI = angiotensin converting enzyme inhibitor; ARB = angiotensin receptor blocker; ARNI = angiotensin receptor/neprilysin inhibitor; CRT = cardiac resynchronization therapy; EF = ejection fraction; FHx CM = family history of cardiomyopathy; HF = heart failure; LV = left ventricle; LVH = left ventricular hypertrophy; MI = myocardial infarction; SGLT2i = sodium glucose cotransporter 2 inhibitors.

OTHER RISK FACTORS

Treatment of atherosclerotic risk factors, such as hypercholesterolemia (Chapter 190), and promotion of measures that encourage healthier lifestyles, such as smoking cessation (Chapter 363), weight control (Chapter 201), adoption of a Mediterranean diet (Chapter 13), and aerobic exercise (Chapter 14), should also reduce the number of individuals who progress from stage A to stage B (structural heart disease but without symptoms of heart failure). ACE inhibitors and SGLT2 inhibitors protect against the development of heart failure in patients with diabetes mellitus or with evidence of atherosclerosis. Elevated natriuretic peptide levels and elevated troponin levels may help identify patients with an elevated risk of developing heart failure.

Many anticancer drugs can cause myocardial damage and heart failure, as can mediastinal radiotherapy. Pericardial constriction can be a result of previous radiotherapy, and malignant pericardial involvement can cause effusion and tamponade (Chapter 62).

PRE–HEART FAILURE (STAGE B): ASYMPTOMATIC STRUCTURAL OR FUNCTIONAL HEART DISEASE

Stage B identifies asymptomatic (New York Heart Association or Canadian Cardiovascular Society class I; Chapter 45) patients who have a structural or functional cardiac disorder (e.g., left ventricular hypertrophy, enlargement, or dysfunction and valvar abnormalities) but do not have the signs and symptoms, such as dyspnea and fatigue, of the heart failure syndrome. In addition to history, physical examination, and electrocardiography (Chapter 42), more extensive screening with echocardiography (Chapter 43) or other imaging modalities (Chapter 44) is often required to detect patients with asymptomatic cardiac structural abnormalities.

A patient who has an acute myocardial infarction not complicated by early heart failure is an obvious example of someone who transitions from stage A to stage B. Rapid mechanical or pharmacologic coronary reperfusion is one of the immediate goals of therapy, with the aim of limiting the extent of myocardial injury and reducing the risk for death and future development of heart failure (Chapters 57 and 58). Survivors of the acute phase of myocardial infarction, a well-studied stage B cohort, are at particularly high risk for the future development of heart failure, with an overall annual incidence of 2% per year—but higher in patients who are older, have a lower left ventricular ejection fraction, do not routinely perform at least moderate exercise, or have concomitant hypertension or diabetes mellitus. For example, a clinically stable asymptomatic patient who has recovered from a myocardial infarction but who is older than 60 years with a left ventricular ejection fraction of less than 50% and a history of diabetes and hypertension has an estimated 30% 5-year likelihood of experiencing death or heart failure; without diabetes or hypertension, the 5-year estimated rate becomes 12%. By comparison, a younger myocardial infarction survivor who has a left ventricular ejection fraction over 50% and does not have hypertension or diabetes would be anticipated to have a 5-year rate for heart failure or death of only 3%. Measures of right ventricular function and biomarkers such as natriuretic peptides and troponin provide further independent incremental prediction for the risk for developing heart failure. With the continued improvements in care of patients with acute myocardial infarction (Chapters 57 and 58) and the use of implantable cardioverter-defibrillators (ICDs) after myocardial infarction in patients with reduced left ventricular ejection fraction, this pool of stage B patients, who represent a reservoir for new-onset heart failure, has been expanding. An ICD is recommended in patients who have a left ventricular ejection fraction of 30% or less and who survive at least 40 days after an acute myocardial infarction to reduce the risk for death (Chapter 58).

The impaired left ventricle, often due to a prior myocardial infarction, can undergo progressive chamber enlargement. This process, also termed left ventricular remodeling, describes the time-dependent and often insidious structural alterations of the impaired left ventricle, whereby the relationship of the left ventricular cavity volume increases out of proportion to mass, so the overall ventricular geometry becomes more distorted, usually more spherical. This distortion of left ventricular geometry often leads to mitral regurgitation. These structural changes produce regional and global increases in myocardial wall stress, which can promote further remodeling and contribute to the progressive deterioration of cardiac function and structure often associated with the later stages of symptomatic heart failure.

TREATMENT

The treatment of heart failure is guided by the stage of symptoms and signs (see Fig. 46-1) as well as a robust literature on therapies proved to be beneficial by randomized trials (Fig. 46-2).[5]

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Mechanistic studies confirm that ACE inhibitors inhibit progressive left ventricular enlargement by reducing wall stress during the entire cardiac cycle as well as by more direct inhibition of the intracellular signaling pathways involved in myocardial hypertrophy and interstitial fibrosis. This attenuation of ventricular remodeling by ACE inhibitors reduces the development of symptomatic heart failure or death, including sudden and unexpected deaths, in stage B asymptomatic patients with left ventricular dysfunction by about 20%.

Several ACE inhibitors are effective as prophylactic therapy for high-risk stage B patients, and the target dose of each agent is established (Table 46-2). Therefore, patients with left ventricular systolic dysfunction, heart failure, or both complicating acute myocardial infarction should receive an ACE inhibitor to reduce the risk for chronic heart failure, reinfarction, stroke, and death. The angiotensin receptor blocker (ARB) valsartan is as effective as captopril in reducing risk for cardiovascular death and other nonfatal cardiovascular outcomes, thereby providing an alternative pharmacologic class of agents for patients who cannot tolerate an ACE inhibitor because of cough or angioedema. Importantly, in patients with left ventricular dysfunction or acute heart failure in the context of a myocardial infarction, the combination of an ACE inhibitor and ARB is not better than either alone, so combination therapy is not recommended in this setting. Unlike in stage C heart failure, sacubitril/valsartan is not clearly superior to an ACE inhibitor.[A7]

β-Blockers

β-Adrenergic receptor blockers (β-blockers) have long been known to reduce death and recurrent myocardial infarction when they are administered during the acute phase of myocardial infarction in patients without pulmonary congestion (Chapter 58). However, carvedilol (Table 46-3) also improves survival, reduces subsequent nonfatal myocardial infarctions, and has a favorable trend for reduced hospitalizations for heart failure in patients with a recent myocardial infarction and reduced left ventricular ejection fraction (≤40%) when it is added to an ACE inhibitor and should be considered in such patients. For stage B patients whose left ventricular dysfunction does not have an ischemic etiology, the evidence for β-blockers is less firm.

Treatment of Arrhythmias

Functional as well as structural problems may lead to the development of heart failure. For example, a persistently rapid ventricular rate in patients with atrial fibrillation can cause a rate-related (tachycardia-induced) cardiomyopathy (Chapter 52). Adequate pharmacologic control of the ventricular rate or interventions to restore sinus rhythm or to ablate re-entry pathways (Chapter 54) may reduce the risk for heart failure.

Other Therapies

Any treatments that control hypertension or reduce the risk for myocardial infarction will benefit stage B patients. Examples include statins, antiplatelet agents, and smoking cessation. Sodium glucose cotransporter 2 (SGLT2) inhibitors also reduce the risk that patients with type 2 diabetes, established cardiovascular disease, or chronic kidney disease will develop heart failure.

SYMPTOMATIC HEART FAILURE (STAGES C AND D)

The development of symptoms and signs of the heart failure syndrome defines the transition from patients in the asymptomatic "at-risk" stages (A and B) to those who fulfill the clinical diagnosis of symptomatic heart failure (Chapter 45). This transition to the symptomatic phase underscores the progressive nature of heart failure and heralds a marked decline in prognosis. In one study, for example, the 2-year mortality rate was 27% in symptomatic patients compared with 10% in asymptomatic patients despite similarly reduced left ventricular ejection fractions and comorbidities.

HEART FAILURE PHENOTYPES BASED ON LEFT VENTRICULAR EJECTION FRACTION

Patients with heart failure are divided into three main categories defined by their left ventricular ejection fraction: heart failure with a reduced ejection fraction (HFrEF, ≤40%),[6] mildly reduced ejection fraction (HFmrEF, 41% to 49%),[7] or preserved ejection fraction (HFpEF, ≥50%).[8] Some patients with an ejection fraction ≤40% have a follow-up measurement >40%, often as a result of treatment. This fourth group of patients are said to have heart failure with improved ejection fraction (HFimpEF). Strong evidence helps guide the treatment of patients who have heart failure with a reduced ejection fraction, but less robust evidence is available for the other subtypes of heart failure.

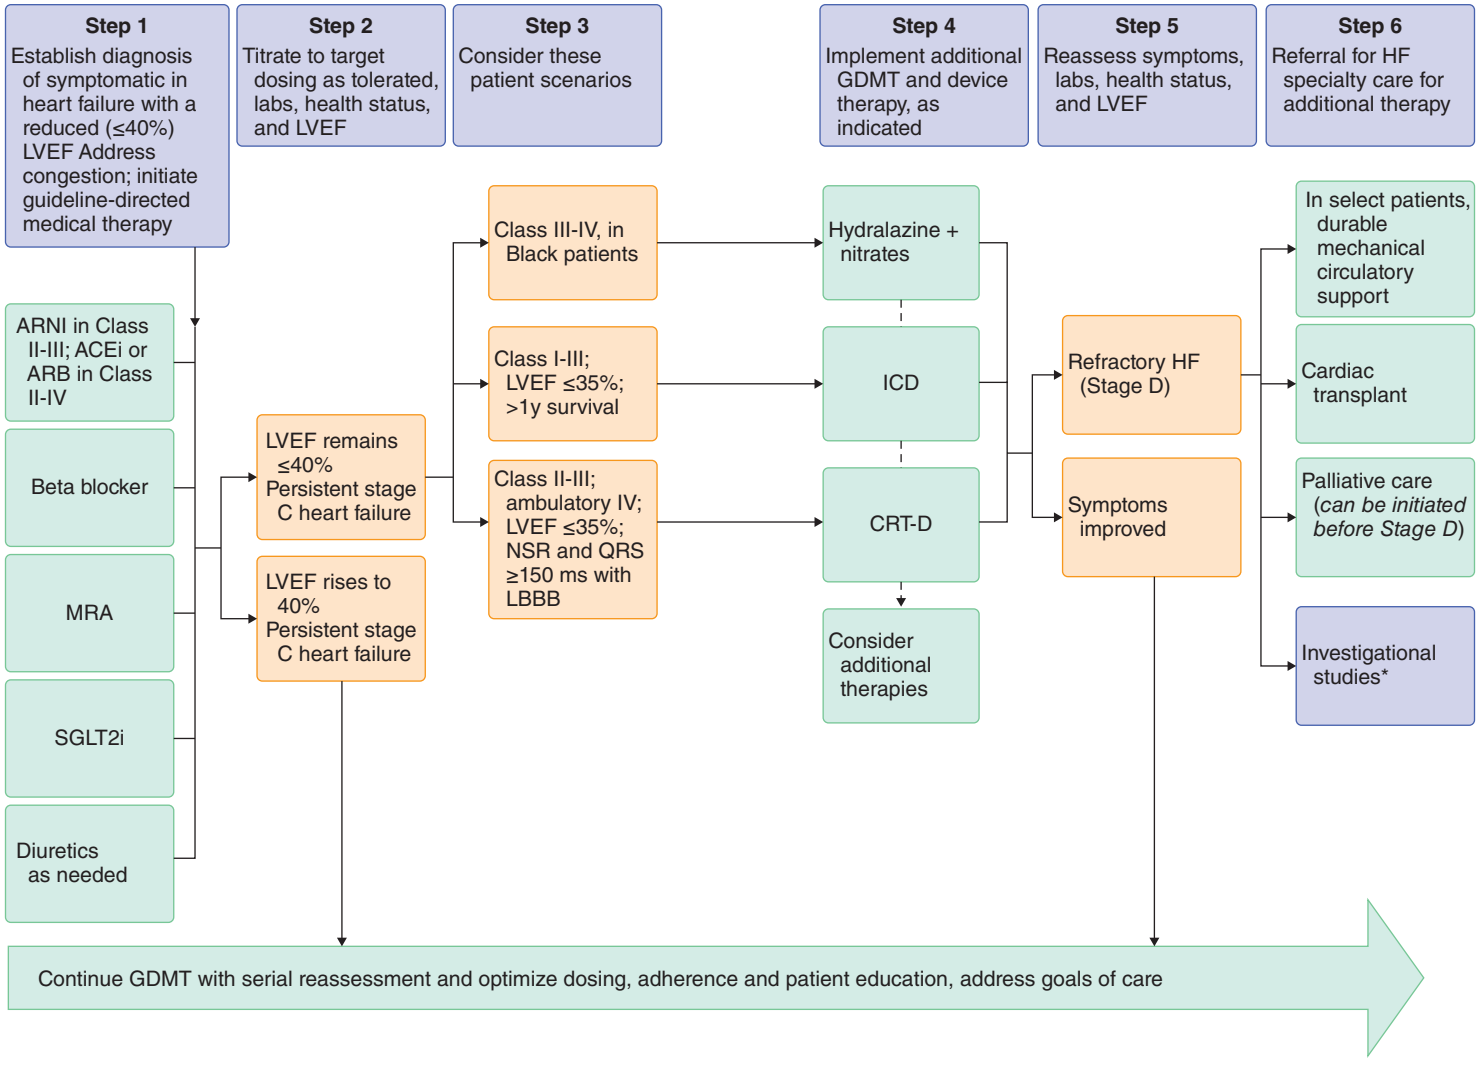

FIGURE 46-2. General approach to stage C heart failure with a reduced ejection fraction. *Participation in investigational studies is appropriate for stage C, NYHA class II and III heart failure (HF). ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin-receptor blocker; ARNI = angiotensin receptor-neprilysin inhibitor; CRT-D = cardiac resynchronization therapy with defibrillator; eGFR = estimated glomerular filtration rate; GDMT = guideline-directed medical therapy; HR = heart rate; ICD = implantable cardiovascular-defibrillator; LBBB = left bundle branch block; LVEF = left ventricular ejection fraction; MRA = mineralocorticoid receptor antagonist; NSR = normal sinus rhythm; SGLT2i = sodium glucose cotransporter 2 inhibitor. (From Heidenreich PA, Bozkurt B, Aguilar D, et al. 2022 AHA/ACC/HFSA guideline for the management of heart failure: a report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines. *Circulation*. 2022;145:e895-e1032.)

TREATMENT

The goals of treatment for patients with stage C and stage D heart failure are relief of symptoms, avoidance of hospital admission or other manifestations of worsening heart failure, and prevention of premature death. In general, the preventive measures that are of value during stages A and B should be sustained in patients with stages C and D heart failure.

Heart Failure with Reduced Left Ventricular Ejection Fraction

Pharmacologic Treatment

Drugs are the mainstay of the treatment of patients with symptomatic heart failure on the basis of the cumulative experiences from RCTs, particularly for patients with reduced left ventricular ejection fraction.[9] However, devices and surgery have an important and increasing role in patients with advanced symptomatic heart failure (stages C and D; see Fig. 46-1). Exercise clearly improves well-being and clinical outcomes, but the evidence base for other lifestyle interventions is less robust. The organization and delivery of care can also have a substantial impact on outcomes.

Although diuretics are required to control fluid retention in most patients who have symptomatic heart failure with a reduced ejection fraction, four other life-saving foundational therapies should be prescribed in any order for all patients, wherever possible: an angiotensin receptor neprilysin inhibitor, a β-blocker, a mineralocorticoid receptor antagonist, and a sodium-glucose cotransporter 2 (SGLT2) inhibitor. The key principles guiding the use of these therapies are that all should be initiated as quickly as possible, usually starting at low doses, and up-titrated to the evidence-based target (see later).

Diuretics

MECHANISM OF ACTION. Conventional diuretics (see Table 102-4 in Chapter 102) act by blocking sodium reabsorption in the loop of Henle and distal renal tubule, thereby enhancing urinary excretion of sodium and water.

CLINICAL BENEFITS. Although not proven to improve mortality and morbidity in large trials, diuretics are required in nearly all patients with symptomatic heart failure (stages C and D) to relieve dyspnea and the signs of sodium and water retention ("congestion"), that is, peripheral and pulmonary edema.[10] No other treatment relieves symptoms and the signs of sodium and water overload as rapidly and effectively. Once a patient needs a diuretic, treatment is usually necessary for the rest of the patient's life, although the dose and type of diuretic may vary.

PRACTICAL USE. The key principle is to prescribe the minimum dose of diuretic needed to maintain an edema-free state ("dry weight"). Excessive use can lead to electrolyte imbalances, such as hyponatremia, hypokalemia (and risk for digitalis toxicity), hyperuricemia (and risk for gout), and uremia. The risk for renal dysfunction is increased by concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs). Diuretic-induced hypovolemia may also cause symptomatic hypotension and prerenal azotemia. Restriction of dietary sodium intake may help reduce, but does not eliminate, the requirement for diuretics. Diuretic dosing should be flexible, with temporary increases for evidence of fluid retention (e.g., increasing symptoms, weight gain, edema) and decreases for evidence of hypovolemia (e.g., as a consequence of increased electrolyte loss due to gastroenteritis, decreased fluid intake, or both).

In some patients with milder symptoms of heart failure and preserved renal function (stage C), a thiazide diuretic such as chlorthalidone may suffice. In

TABLE 46-2 PRACTICAL GUIDANCE ON THE USE OF ANGIOTENSIN-CONVERTING ENZYME INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS IN PATIENTS WITH HEART FAILURE DUE TO LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

WHY?

Randomized trials have conclusively shown that angiotensin-converting enzyme (ACE) inhibitors increase survival, reduce hospital admissions, and improve New York Heart Association (NYHA) class and quality of life in patients with *all* grades of symptomatic heart failure. Other randomized trials in patients with systolic dysfunction after acute myocardial infarction show that ACE inhibitors increase survival. In patients with heart failure, the composite end point of death or hospital admission is reduced by higher doses of an ACE inhibitor compared with lower doses. ACE inhibitors also delay or prevent the development of symptomatic heart failure in patients with *asymptomatic* left ventricular systolic dysfunction.

In patients who are intolerant of an ACE inhibitor, an angiotensin receptor blocker (ARB) is indicated. For example, candesartan reduces the risk for the composite outcome of cardiovascular death or heart failure hospitalization, reduces the risk of hospital admission for heart failure, and improves functional class. Valsartan is as effective as the ACE inhibitor captopril in reducing mortality and cardiovascular morbidity in patients with left ventricular systolic dysfunction, heart failure, or both complicating acute myocardial infarction.

IN WHOM AND WHEN?

ACE Inhibitors/ARBs

Indications
- Potentially all patients with heart failure and a low ejection fraction, although usually an angiotensin receptor-neprilysin inhibitor (ARNI) is the preferred treatment (see later).
- First-line treatment (along with a β-blocker, mineralocorticoid receptor antagonist [MRA], and sodium glucose cotransporter 2 [SGLT2] inhibitor) in patients with NYHA class II to IV heart failure; start as early as possible in course of disease.
- ACE inhibitors (and probably ARBs) are also of benefit in patients with asymptomatic left ventricular systolic dysfunction (NYHA class I).

Contraindications
- ACE inhibitors only—history of angioedema
- Known bilateral renal artery stenosis
- Combination with an angiotensin receptor blocker-neprilysin inhibitor (valsartan/sacubitril)—risk of angioedema if combined with an ACE inhibitor (and renal dysfunction and hyperkalemia when combined with an ACE inhibitor or an ARB)

Cautions/seek specialist advice
- Significant hyperkalemia ($K^+ > 5.0$ mmol/L)
- Significant renal dysfunction (creatinine 221 μmol/L or >2.5 mg/dL)
- Symptomatic or severe asymptomatic hypotension (systolic blood pressure <90 mm Hg)

Potential drug interactions of particular concern
- K^+ supplements/K^+-sparing diuretics (e.g., amiloride and triamterene [beware combination preparations with furosemide])
- Mineralocorticoid receptor antagonists (spironolactone, eplerenone), ARBs, NSAIDs*
- "Low-salt" substitutes with a high K^+ content
- Angiotensin receptor blocker-neprilysin inhibitor (sacubitril/valsartan)—see earlier (contraindicated)

WHERE?

In the community for most patients
Exceptions—see Cautions/seek specialist advice

WHICH ACE INHIBITOR AND WHAT ORAL DOSE?

	STARTING DOSE	TARGET DOSE
Captopril	6.25 mg three times daily	50 mg three times daily
Enalapril	2.5 mg twice daily	10-20 mg twice daily
Lisinopril	2.5-5.0 mg once daily	20-35 mg once daily
Ramipril	2.5 mg once daily	5 mg twice daily or 10 mg once daily
Trandolapril	0.5 mg once daily	4 mg once daily

WHICH ARB AND WHAT ORAL DOSE?

	STARTING DOSE	TARGET DOSE
Candesartan	4 or 8 mg once daily	32 mg once daily
Valsartan	40 mg twice daily	160 mg twice daily
Losartan	50 mg once daily	150 mg daily

HOW TO USE?

Start with a low dose (see doses in previous column).
Double dose typically at 2-week intervals.
Aim for target dose (see doses in previous column) or, failing that, the highest tolerated dose.
Remember: *some* ACE inhibitor/ARB is better than *no* ACE inhibitor/ARB.
Monitor blood pressure and blood chemistry (urea/blood urea nitrogen, creatinine, K^+).
Check blood chemistry 1 to 2 weeks after initiation and 1 to 2 weeks after final dose titration.
When to stop up-titration, reduce dose, stop treatment—see Problem Solving.
A specialist heart failure nurse or pharmacist may assist with education of the patient, follow-up (in person or by telephone), biochemical monitoring, and dose up-titration.

ADVICE TO PATIENT

Explain expected benefits (see Why?).
Treatment is given to improve symptoms, to prevent worsening of heart failure leading to hospital admission, and to increase survival.
Symptoms improve within a few weeks to a few months of starting treatment.
Advise patients to report principal adverse effects, (i.e., dizziness/symptomatic hypotension, cough)—see Problem Solving.
Advise patients to avoid NSAIDs* not prescribed by a physician (self-purchased over-the-counter) and salt substitutes high in K^+—see Problem Solving.

PROBLEM SOLVING

Asymptomatic low blood pressure
- Does not usually require any change in therapy

Symptomatic hypotension
- If dizziness, lightheadedness, or confusion and a low blood pressure, reconsider need for nitrates, calcium-channel blockers,† and other vasodilators.
- If no signs or symptoms of congestion, consider reducing diuretic dose.
- If these measures do not solve problem, seek specialist advice.

Cough
- Cough is common in patients with heart failure, many of whom have smoking-related lung disease.
- Cough is also a symptom of pulmonary edema, which should be excluded when a new or worsening cough develops.
- ACE inhibitor–induced cough rarely may not require treatment discontinuation.
- When a troublesome cough does develop (e.g., one stopping the patient from sleeping) and can be proved to be due to ACE inhibition (i.e., recurs after ACE inhibitor withdrawal and rechallenge), substitution of an ARB should be considered.

Worsening renal function
- Some rise in urea (blood urea nitrogen), creatinine, and potassium is to be expected after initiation of an ACE inhibitor/ARB; if an increase is small and asymptomatic, no action is necessary.
- An increase in creatinine of up to 50% above baseline, or 266 μmol/L (3 mg/dL), whichever is the smaller, is acceptable.
- An increase in potassium to ≤5.5 mmol/L is acceptable but must be rechecked.
- If urea, creatinine, or potassium does rise excessively, consider stopping concomitant nephrotoxic drugs (e.g., NSAIDs*) and other potassium supplements or retaining agents (triamterene, amiloride, spironolactone-eplerenone) and, if no signs of congestion, reducing the dose of diuretic.
- If greater rises in creatinine or potassium than those outlined earlier persist despite adjustment of concomitant medications, the dose of the ACE inhibitor should be halved and blood chemistry rechecked within 1 to 2 weeks; if there is still an unsatisfactory response, specialist advice should be sought.
- If potassium rises to >5.5 mmol/L or creatinine increases by >100% or to above 310 μmol/L (3.5 mg/dL), the ACE inhibitor/ARB should be stopped and specialist advice sought. Concomitant use of a K^+ binder (e.g., patiromer; see Chapter 103) may allow an ACE inhibitor/ARB (or ARNI) to be continued in patients developing hyperkalemia.
- Blood chemistry should be monitored frequently and serially until potassium and creatinine have plateaued.

*Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) unless essential.
†Calcium-channel blockers should be discontinued unless absolutely essential (e.g., for angina or hypertension).
Note: It is rarely necessary to stop an ACE inhibitor/ARB, and clinical deterioration is likely if treatment is withdrawn. Ideally, specialist advice should be sought before treatment discontinuation.
Modified from McMurray J, Cohen-Solal A, Dietz R, et al. Practical recommendations for the use of ACE inhibitors, β-blockers, mineralocorticoid receptor antagonists and angiotensin receptor blockers in heart failure: putting guidelines into practice. *Eur J Heart Fail*. 2005;7:710-721.

TABLE 46-3 PRACTICAL GUIDANCE ON THE USE OF B-BLOCKERS IN PATIENTS WITH HEART FAILURE DUE TO LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

WHY?

Several major randomized controlled trials have shown conclusively that certain β-blockers increase survival, reduce hospital admissions, and improve New York Heart Association (NYHA) class and quality of life when added to standard therapy (diuretics, digoxin, and angiotensin-converting enzyme [ACE] inhibitors) in patients with heart failure. Carvedilol is substantially more effective than a low dose of short-acting metoprolol.*

IN WHOM AND WHEN?

Indications
- Potentially *all* patients with *euvolemic* heart failure with mild to moderate symptoms; patients with severe heart failure should be referred for specialist advice.
- First-line treatment (along with an angiotensin receptor-neprilysin inhibitor [ARNI] or ACE inhibitor or angiotensin receptor blocker [ARB], mineralocorticoid receptor antagonists [MRA], and sodium-glucose cotransporter 2 [SGLT2] inhibitor) in patients with *euvolemic* NYHA class II to III heart failure; start as early as possible in course of disease.

Contraindications
- Asthma
- Second- or third-degree atrioventricular block

Cautions/seek specialist advice
- Severe (NYHA class IV) heart failure
- Current or recent (<4 weeks) exacerbation of heart failure (e.g., hospital admission with worsening heart failure, heart block, or heart rate <60 beats/minute).
- Persisting signs of congestion, hypotension/low blood pressure (systolic < 90 mm Hg), raised jugular venous pressure, ascites, marked peripheral edema

Potential drug interactions of particular concern
- Verapamil, diltiazem (should be discontinued)†
- Digoxin, amiodarone

WHERE?

In the community in stable patients (NYHA class IV/severe heart failure patients should be referred for specialist advice)
Not in unstable patients hospitalized with worsening heart failure
Other exceptions—see Cautions/seek specialist advice

WHICH β-BLOCKER AND WHAT ORAL DOSE?

	STARTING DOSE	TARGET DOSE
Bisoprolol	1.25 mg once daily	10 mg once daily
Carvedilol	3.125 mg twice daily	25-50 mg twice daily
Metoprolol CR/XL	12.5-25 mg once daily	200 mg once daily*
Nebivolol	1.25 mg once daily	10 mg once daily

HOW TO USE?

Start with a low dose (see dose shown in previous column).
Double dose at *not less than* 2-week intervals.
Aim for target dose (see dose shown in previous column) or, failing that, the highest tolerated dose.
Remember: *some* β-blocker is better than *no* β-blocker.
Monitor heart rate, blood pressure, and clinical status (symptoms, signs—especially signs of congestion, increased body weight).
Check blood chemistry 1 to 2 weeks after initiation and 1 to 2 weeks after final dose titration.
When to stop up-titration, reduce dose, stop treatment—see Problem Solving.
A specialist heart failure nurse may assist with education of the patient, follow-up (in person or by telephone), and dose up-titration.

ADVICE TO PATIENT

Explain expected benefits (see Why?).
Treatment is given to improve symptoms, to prevent worsening of heart failure leading to hospital admission, and to increase survival.
Symptomatic improvement may develop slowly after starting treatment, and treatment for 3 to 6 months or longer may be required before the full effects on left ventricular size and function are observed.
Temporary symptomatic deterioration *may* occur during initiation or up-titration phase; in the long term, β-blockers improve well-being.
Advise patient to report deterioration (see Problem Solving) and that deterioration (tiredness, fatigue, breathlessness) can usually be easily managed by adjustment of other medication; patients should be advised not to stop β-blocker therapy without consulting the physician.
To detect and to treat deterioration early, patients should be encouraged to weigh themselves daily (after waking, before dressing, after voiding, before eating) and to increase their diuretic dose should their weight increase persistently (>2 days) by >1.5-2.0 kg.‡

PROBLEM SOLVING

Worsening symptoms or signs (e.g., increasing dyspnea, fatigue, edema, weight gain)
- If increasing congestion, increase dose of diuretic or halve dose of β-blocker (if increasing diuretic does not work).
- If marked fatigue (or bradycardia—see later), halve dose of β-blocker (rarely necessary); review patient in 1 to 2 weeks; if not improved, seek specialist advice.
- If serious deterioration, halve dose of β-blocker or stop this treatment (rarely necessary); seek specialist advice.

Low heart rate
- If <50 beats/minute and worsening symptoms, halve dose of β-blocker or, if severe deterioration, stop β-blocker (rarely necessary).
- Review need for other heart rate–slowing drugs (e.g., digoxin, amiodarone, diltiazem, or verapamil†).
- Arrange electrocardiogram to exclude heart block.
- Seek specialist advice.

Asymptomatic low blood pressure
- Does not usually require any change in therapy.

Symptomatic hypotension
- If dizziness, lightheadedness, or confusion and a low blood pressure, reconsider need for nitrates, calcium-channel blockers,† and other vasodilators.
- If no signs or symptoms of congestion, consider reducing diuretic dose.
- If these measures do not solve problem, seek specialist advice.

*Metoprolol tartrate should not be used in preference to an evidence-based β-blocker in heart failure.
†Calcium-channel blockers should be discontinued unless absolutely necessary, and diltiazem and verapamil are generally contraindicated in heart failure.
‡This is generally good advice for all patients with heart failure.
Note: β-Blockers should not be stopped suddenly unless absolutely necessary (there is a risk for a "rebound" increase in myocardial ischemia or infarction and arrhythmias). Ideally, specialist advice should be sought before treatment discontinuation.
Modified from McMurray J, Cohen-Solal A, Dietz R, et al. Practical recommendations for the use of ACE inhibitors, β-blockers, mineralocorticoid receptor antagonists and angiotensin receptor blockers in heart failure: putting guidelines into practice. *Eur J Heart Fail*. 2005;7:710-721.

more advanced heart failure (stage D) or in patients with concomitant renal dysfunction, a loop diuretic such as furosemide is often needed. Loop diuretics cause a rapid onset of an intense but relatively short-lived diuresis compared with the longer lasting but gentler effect of a thiazide diuretic. The timing of administration of a loop diuretic, which need not be taken first thing every morning, can be adjusted according to the patient's social activities. The dose may be postponed or even temporarily omitted if the patient has to travel or has another activity that might be compromised by the prompt action of the diuretic. In severe heart failure (stage D), the effects of long-term administration of a loop diuretic may be diminished by increased sodium reabsorption at the distal tubule. This problem can be offset by use of the combination of a loop diuretic and a thiazide or thiazide-like diuretic (e.g., hydrochlorothiazide or metolazone), which act in synergy with a loop diuretic by blocking sodium reabsorption in different segments of the nephron.[A8] This combination requires more frequent monitoring of electrolytes and renal function for diuretic-induced hyponatremia, abnormalities of the serum potassium level, and prerenal azotemia. The combination of a loop diuretic with the proximally acting carbonic anhydrase inhibitor acetazolamide can augment decongestion in the acute setting.[A9]

A period of intravenous loop diuretic, given either as bolus injections or by continuous infusion, may be required either in the ambulatory setting or as an in-patient in patients who become resistant to the action of oral diuretics. Why this resistance develops is uncertain, but factors thought to be important include impaired absorption of oral diuretics due to gut edema, hypotension,

reduced renal blood flow, renal venous congestion, and adaptive changes in the nephron. In cases of severe resistant volume overload, mechanical removal of fluid by ultrafiltration may be considered.

Patients receiving a combination of diuretics require careful monitoring of blood chemistry and clinical status.

Although they are highly effective in relieving symptoms and signs, diuretics alone are not sufficient for treatment of heart failure. The addition of other disease-modifying treatments will slow structural progression, better maintain clinical stability, and reduce the risk for hospital admission and premature death.

ACE Inhibitors and Angiotensin Receptor Blockers (ARBs)

MECHANISM OF ACTION. ACE inhibitors inhibit the enzyme that converts the inactive decapeptide angiotensin I to the active octapeptide angiotensin II (and that also breaks down bradykinin). In patients with heart failure, excessive angiotensin II is thought to exert myriad harmful actions mediated through stimulation of the angiotensin II type 1 receptor subtype (AT1R), including vasoconstriction (which increases ventricular afterload), excessive growth of myocytes and the extracellular matrix (contributing to maladaptive left ventricular remodeling), activation of the sympathetic nervous system, prothrombotic actions, and augmentation of the release of arginine vasopressin and the retention of sodium (both directly and through stimulation of secretion of aldosterone, which activates the mineralocorticoid receptor). ARBs selectively block the action of angiotensin II at the AT1 receptor. Although pharmacologically distinct from ACE inhibitors, their clinical effects are similar.

ACE inhibitors also reduce the breakdown of bradykinin, and the resultant accumulation of bradykinin is directly or indirectly responsible for two of the specific adverse effects of ACE inhibitors: cough and angioedema. ARBs do not inhibit kininase II or the breakdown of bradykinin, so they do not cause cough and are associated with lower rates of angioedema than are ACE inhibitors. This difference between ARBs and ACE inhibitors explains why the combination of neprilysin (which also breaks down bradykinin and may itself cause angioedema) and an ARB is safe (and why the combination of an ACE inhibitor and a neprilysin inhibitor poses a significant risk of angioedema and is not recommended).

CLINICAL BENEFITS. Clinical trials have shown that treatment with an ACE inhibitor, when it is used alone or added to diuretics and digoxin, decreases left ventricular size, improves ejection fraction, reduces symptoms and hospital admissions, and prolongs survival. These agents also reduce the risk of developing myocardial infarction and possibly diabetes and atrial fibrillation. Consequently, treatment with an ACE inhibitor is recommended for all patients with left ventricular systolic dysfunction, irrespective of symptoms or etiology. ACE inhibitors are not a substitute for a diuretic but mitigate diuretic-induced hypokalemia.

When used as the sole agent in heart failure, ARBs produce benefits similar to those of ACE inhibitors. An ARB may be used as a substitute in patients who have cough or angioedema with an ACE inhibitor. When they are used in clinically effective doses, other adverse effects such as hypotension, renal dysfunction, and hyperkalemia are encountered as frequently as with an ACE inhibitor.

PRACTICAL USE. As early as possible in a patient's treatment, the combination of an ARB with a neprilysin inhibitor (i.e., sacubitril/valsartan) is preferred because of the additional benefit of neprilysin inhibition. If the combination is not tolerated, an ACE inhibitor or an ARB can be used. The only contraindications are a history of angioedema (for an ACE inhibitor), current symptomatic hypotension, and bilateral renal artery stenosis (Chapter 110); the latter is often associated with a prompt and marked increase in serum levels of blood urea nitrogen and creatinine when renal perfusion is reduced precipitously by inhibiting the production and actions of angiotensin II. Combined use of an ACE inhibitor and an ARB is contraindicated because it results in increased side effects without an increase in efficacy.

Treatment should be started in a low dose (see Table 46-2), with the dose gradually increased toward a target dose of proven benefit in a clinical trial. The patient should be evaluated for symptomatic hypotension, uremia, and hyperkalemia after each dose increment; these adverse effects are uncommon and can usually be resolved by reduction in the dose of diuretic (if the patient is edema free) or concomitant hypotensive or nephrotoxic medications (e.g., nitrates, calcium-channel blockers, or NSAIDs). A dry, nonproductive cough occurs in approximately 5% of patients treated with an ACE inhibitor, and if it is troublesome, substitution of an ARB is recommended. In the rare cases of angioedema (Chapter 232), the ACE inhibitor should be stopped and not used again; an ARB can be cautiously substituted (see later).

Neprilysin Inhibition

Neprilysin is an enzyme that breaks down natriuretic peptides and other vasoactive substances, including adrenomedullin and bradykinin. Inhibiting neprilysin augments the concentrations of these substances, which have vasodilator and natriuretic actions, and also inhibits pathologic growth, including hypertrophy and fibrosis. Because neprilysin also degrades angiotensin II, a neprilysin inhibitor must be combined with an agent that blocks the renin-angiotensin system. Because ACE and neprilysin each degrade bradykinin, inhibiting both enzymes leads to a significant increase in the risk of angioedema. Consequently, an ARB (valsartan) combined with a neprilysin inhibitor (sacubitril), termed an angiotensin receptor neprilysin inhibitor (ARNI), is preferred. When added to a β-blocker and a mineralocorticoid receptor antagonist, sacubitril/valsartan (97/103 mg twice daily) reduces heart failure hospitalization, cardiovascular mortality, death from all causes, and other measures of progressive worsening of heart failure compared with adding enalapril (10 mg twice daily).[A10] Compared with enalapril, sacubitril/valsartan causes more hypotension and slightly more angioedema but less renal dysfunction and hyperkalemia. Neprilysin inhibition increases levels of B-type natriuretic peptide but not NT pro-B-type natriuretic peptide.

PRACTICAL USE. Sacubitril/valsartan, which is recommended as first-line starting therapy instead of an ACE inhibitor or an ARB, can be initiated in patients hospitalized with decompensated heart failure.[A11] Switching to sacubitril/valsartan should be considered in patients who have persisting symptoms despite tolerating treatment with an ACE inhibitor or ARB (Table 46-4). Because neprilysin inhibition with sacubitril increases bradykinin, a history of angioedema is a contraindication to sacubitril/valsartan. Sacubitril/valsartan should never be combined with an ACE inhibitor, and a "wash-out" period of 36 hours is required between stopping an ACE inhibitor and starting the ARNI. Because neprilysin inhibition increases a number of vasodilator peptides, hypotension is more common with sacubitril/valsartan than with an ACE inhibitor or ARB, and switching is not recommended in a patient with a systolic blood pressure lower than 95 mm Hg.

β-Blockers

MECHANISM OF ACTION. Heart failure is characterized by excessive activation of the sympathetic nervous system, which causes vasoconstriction and sodium retention, thereby increasing cardiac preload and afterload and often inducing myocardial ischemia or arrhythmias. In addition, norepinephrine can cause hypertrophy of myocytes and augment their apoptosis. β-Blockers counteract many of these harmful effects of the hyperactivity of the sympathetic nervous system. A rapid heart rate is an important prognostic factor in heart failure among patients in sinus rhythm, and β-blockers reduce heart rate.

CLINICAL BENEFITS. The long-term addition of a β-blocker to an ARNI, an SGLT2 inhibitor, a diuretic, and a mineralocorticoid receptor antagonist further improves left ventricular systolic function and symptoms, reduces hospital admissions, and strikingly improves survival. Consequently, a β-blocker is recommended for all patients with symptomatic systolic dysfunction, irrespective of etiology and severity, and the combination of a β-blocker with an ARNI (or an ACE inhibitor or ARB) is a cornerstone of the treatment of symptomatic heart failure (see Fig. 46-1). Treatment with a β-blocker, added to an ARNI (or ACE inhibitor or ARB), a mineralocorticoid receptor antagonist, and an SGLT2 inhibitor is generally recommended for all patients with symptoms (functional classes II to IV) and left ventricular systolic dysfunction, irrespective of etiology.

In a retrospective analysis of pooled data from 11 randomized trials in patients with heart failure, β-blockers improved the left ventricular ejection fraction but did not appear to reduce all-cause mortality in patients with atrial fibrillation, whereas they reduced mortality by 27% in patients who were in sinus rhythm.[A12] Although the interpretation of these results is controversial, β-blockers remain the preferred treatment for control of the ventricular rate in patients who have both atrial fibrillation and heart failure with a reduced ejection fraction because of their excellent safety profile.

PRACTICAL USE. The major contraindications to use of a β-blocker are asthma (although it is important to note that the dyspnea caused by pulmonary congestion can be confused with reactive airway disease) and second- or third-degree atrioventricular block. Initiation of treatment during an episode of acute decompensated heart failure should also be avoided until the patient is stabilized. In addition, caution is advised in patients with a heart rate below 60 beats per minute or a systolic blood pressure below 90 mm Hg. It is recommended that a β-blocker shown to produce benefits in a randomized trial be used.

As with an ARNI (or an ACE inhibitor or ARB), mineralocorticoid receptor antagonist, and SGLT2 inhibitor, β-blockers should be introduced as early as possible in a patient's treatment, started in a low dose (see Table 46-3), and increased gradually toward a target dose used in a clinical trial (the "start low–go slow" approach). The patient should be checked for symptomatic hypotension and excessive bradycardia after each dose increment, but both of these side effects are uncommon, and hypotension can often be resolved by reduction in the dose of other nonessential blood pressure–lowering medications (e.g., nitrates and calcium-channel blockers). Bradycardia is more likely in patients who are also taking digoxin or amiodarone, and the simultaneous use of these agents should be reviewed if excessive bradycardia occurs. On occasion, symptomatic worsening and fluid retention (e.g., weight gain or edema) may occur after initiation of a β-blocker or during dose up-titration; these side effects usually can be resolved by a temporary increase in the diuretic dose without necessitating discontinuation of the β-blocker.

Treatment with a β-blocker should be given for life, although the dose may need to be decreased (or, rarely, treatment discontinued) temporarily during

TABLE 46-4 PRACTICAL GUIDANCE ON THE USE OF A COMBINED ANGIOTENSIN RECEPTOR BLOCKER-NEPRILYSIN INHIBITOR (SACUBITRIL/VALSARTAN) IN PATIENTS WITH HEART FAILURE DUE TO LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

WHY?

In one major randomized trial, patients who had symptomatic heart failure and who were previously treated with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) were randomized to an ARB plus a neprilysin inhibitor (ARNI) sacubitril/valsartan or the ACE inhibitor enalapril, added to standard pharmacologic therapy (diuretics, β-blockers, mineralocorticoid receptor antagonists [MRAs], and digoxin). Patients treated with sacubitril/valsartan had a better survival, fewer hospital admissions, and improved New York Heart Association (NYHA) class and quality of life compared with patients who were treated with enalapril.

IN WHOM AND WHEN?

Indications
- Potentially all patients with heart failure and a low ejection fraction
- First-line treatment (along with a β-blocker, MRA, and SGLT2 inhibitor) in patients with functional class II to IV heart failure as the preferred alternative to an ACE inhibitor or ARB.

Contraindications
- History of angioedema
- Known bilateral renal artery stenosis
- Combination with an ACE inhibitor or ARB—risk of angioedema if combined with an ACE inhibitor (and renal dysfunction and hyperkalemia when combined with ACE inhibitor or an ARB)

Cautions/seek specialist advice
- Significant hyperkalemia ($K^+ > 5.0$ mmol/L)
- Significant renal dysfunction (creatinine 221 μmol/L or >2.5 mg/dL)
- Symptomatic or asymptomatic hypotension (systolic blood pressure < 95 mm Hg)

Potential drug interactions of particular concern
- K+ supplements/K+-sparing diuretics (e.g., amiloride and triamterene [beware combination preparations with furosemide])
- Mineralocorticoid receptor antagonists (spironolactone, eplerenone), NSAIDs*
- "Low-salt" substitutes with a high K+ content
- ACE inhibitor/ARB—see earlier (contraindicated)

WHERE?

In the community for most patients
Exceptions—see Cautions/seek specialist advice

WHAT ORAL DOSE?

STARTING DOSE usually sacubitril/valsartan 49 mg/51 mg twice daily if switching from ACE inhibitor/ARB (24 mg/26 mg twice daily if starting de novo)
TARGET DOSE sacubitril/valsartan 97/103 mg twice daily

HOW TO USE?

As for ACE inhibitors/ARBs
ACE inhibitor treatment must be stopped for 36 hours before starting sacubitril/valsartan (to minimize risk of angioedema)

ADVICE TO PATIENT

As for ACE inhibitors/ARBs

PROBLEM SOLVING

As for ACE inhibitors/ARBs (manage cough related to neprilysin inhibition in same way as ACE inhibitor–induced cough)

*Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) unless essential.
SGLT2 = sodium glucose cotransporter 2.

episodes of acute decompensation if the patient shows signs of circulatory underperfusion or refractory congestion.

Mineralocorticoid Receptor (Aldosterone) Antagonists (MRAs)

MECHANISM OF ACTION. Aldosterone, which is the second effector hormone in the renin-angiotensin-aldosterone cascade, has detrimental vascular, renal, autonomic, and cardiac actions when it is produced in excess in patients with heart failure. Excessive aldosterone promotes sodium retention and hypokalemia, and it is believed to contribute to myocardial fibrosis, all of which predispose to arrhythmias. Aldosterone mediates its effects by activating the mineralocorticoid receptor, which is also stimulated by other endogenous corticosteroids. Mineralocorticoid receptor antagonists block these undesirable actions and, at high doses, also act as potassium-sparing diuretics.

CLINICAL BENEFITS. The mineralocorticoid receptor antagonist spironolactone improves symptoms, reduces hospital admissions, and increases survival when it is added to an ACE inhibitor (and diuretics and digoxin) in patients with a reduced left ventricular ejection fraction and severely symptomatic heart failure. Eplerenone, another mineralocorticoid receptor antagonist, reduces mortality and morbidity when it is added to both an ACE inhibitor and β-blocker in patients with a reduced left ventricular ejection fraction and heart failure with mild symptoms (NYHA class II). Consequently, a mineralocorticoid receptor antagonist should be considered in all patients with symptomatic (class II to IV) heart failure and reduced ejection fraction in addition to an ARNI (or ACE inhibitor or ARB), β-blocker, and an SGLT2 inhibitor.[A13] When begun, a mineralocorticoid receptor antagonist should be given indefinitely.

PRACTICAL USE. Treatment with a mineralocorticoid receptor antagonist should be initiated with a low dose (Table 46-5) with careful monitoring of serum electrolytes and renal function. Hyperkalemia and uremia are the adverse effects of greatest concern (as with ACE inhibitors, ARBs, or an ARNI), and a mineralocorticoid receptor antagonist should not be given to patients with a serum potassium concentration of more than 5.0 mmol/L, serum creatinine concentration above 2.5 mg/dL (>221 μmol/L), or other evidence of markedly impaired renal function. The importance of selection of patients and dose is underscored by reports of a worrisome incidence of serious hyperkalemia in community practice settings. Spironolactone can have antiandrogenic effects, especially painful gynecomastia, in men; because eplerenone has less of an action on the androgen receptor, it is a reasonable substitute in patients who experience this adverse effect.

Sodium Glucose Cotransporter 2 (SGLT2) Inhibitors

MECHANISM OF ACTION. The SGLT2 is found in the renal proximal tubule, where it is responsible for the reabsorption of glucose filtered at the glomerulus. Inhibition of SGLT2 results in increased urinary excretion of glucose and sodium, along with an osmotic diuresis. Whether this action completely or partly explains the benefit of these drugs in patients with heart failure (and chronic kidney disease) is unknown. In addition to increased glycosuria and a resultant reduction in blood glucose, the other consistent effects of SGLT2 inhibitors are an increase in hematocrit, reduced rate of long-term decline in glomerular filtration rate (after an initial dip in this measure), and a modest decrease in blood pressure.[11] Many other actions of SGLT2 have been speculated, but not confirmed, in humans.

CLINICAL BENEFITS. Clinical trials have shown that adding an SGLT2 inhibitor to a renin-angiotensin system blocker (or ARNI), β-blocker, and a mineralocorticoid receptor antagonist decreases left ventricular size, improves ejection fraction, reduces symptoms and hospital admissions, and prolongs survival in men and women, regardless of whether or not they have type 2 diabetes, chronic renal disease, or a recent worsening of their heart failure.[A14–A17] These agents also reduce the risk of worsening kidney function[A18] and possibly of developing diabetes. Consequently, treatment with an SGLT2 inhibitor is recommended for all patients with symptomatic heart failure and a reduced ejection fraction, irrespective of diabetes status. SGLT2 inhibitors mitigate MRA-induced hyperkalemia.

PRACTICAL USE. As with an ARNI (or an ACE inhibitor or ARB), β-blocker, and mineralocorticoid receptor antagonist, an SGLT2 inhibitor should be introduced as early as possible in a patient's treatment. The only contraindications are type 1 diabetes, a history of diabetic ketoacidosis, and severe renal dysfunction (estimated glomerular filtration rate <20 mL/min/1.73 m^2). In patients with type 2 diabetes (Chapter 210), other glucose-lowering therapy may need to be adjusted, especially if there is a recent history of hypoglycemia. The dose of insulin should not be decreased by more than 25%, and it is prudent to discuss changes in insulin dosage with an endocrinologist before commencing an SGLT2 inhibitor.

Unlike other treatments for heart failure, SGLT2 inhibitors are prescribed as a single dose, and no up-titration is required (Table 46-6). Treatment may lead to a modest initial, but short-lived, diuresis and small decline in estimated glomerular filtration rate, although neither of these is usually a clinical problem. It is advisable to check kidney function within a month of starting treatment, especially in patients with a very low baseline estimated glomerular filtration rate. A clinically meaningful change in blood pressure is rare. Genital skin fungal infections may occur in 5 to 10% of patients, are rarely troublesome, and can usually be treated with an antifungal cream. In the rare cases of ketoacidosis (Chapter 210), the SGLT2 inhibitor should be discontinued immediately. Patients at greatest risk of ketoacidosis are those who are concurrently taking insulin or who may be insulin-deficient (e.g., as a result of previous pancreatitis). SGLT2 inhibitors should be temporary withheld in situations that might trigger ketoacidosis (i.e., illness leading to decreased food and fluid intake or stopping or reducing the dose of insulin), including elective surgery, for which SGLT2 inhibitors should be discontinued 3 days preoperatively.

Second-Line Treatments for Heart Failure with Reduced Left Ventricular Ejection Fraction

Several secondary agents are available for selected patients with heart failure (Fig. 46-3).

TABLE 46-5 PRACTICAL GUIDANCE ON THE USE OF MINERALOCORTICOID RECEPTOR ANTAGONISTS (MRAS) IN PATIENTS WITH HEART FAILURE DUE TO LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

WHY?

Treatment with an MRA (spironolactone or eplerenone) increases survival, reduces hospital admissions, and improves New York Heart Association (NYHA) class when added to standard therapy (diuretic, digoxin, ACE inhibitor/ARB, and β-blocker) in patients with symptomatic (NYHA class II to IV) heart failure. Eplerenone also increases survival and reduces hospital admission for cardiac causes in patients with left ventricular systolic dysfunction and heart failure (or diabetes) complicating *acute* myocardial infarction.

IN WHOM AND WHEN?

Indications
- Potentially all patients with symptomatic heart failure (NYHA class II to IV)
- First-line therapy (along with an angiotensin receptor-neprilysin inhibitor [ARNI], an ACE inhibitor, or an ARB], plus a β-blocker and an SGLT2 inhibitor) in patients with symptomatic heart failure (NYHA class II to IV) and an LVEF ≤40%

Cautions/seek specialist advice
- Significant hyperkalemia ($K^+ > 5.0$ mmol/L)†
- Significant renal dysfunction (creatinine >221 μmol/L or 2.5 mg/dL)†

Potential drug interactions of particular concern
- K^+ supplements/K^+-sparing diuretics (e.g., amiloride and triamterene; beware combination preparations with furosemide)
- ACE inhibitor, ARBs, ARNIs, NSAIDs‡
- "Low-salt" substitutes with a high K^+ content

WHERE?

In the community or in the hospital
Exceptions—see Cautions/seek specialist advice

WHICH ORAL DOSE?†

	STARTING DOSE	TARGET DOSE
Spironolactone	25 mg once daily or on alternate days	25-50 mg once daily
Eplerenone	25 mg once daily	50 mg once daily

HOW TO USE?

Start with a low dose (see dose shown in previous column).
Check blood chemistry at 1, 4, 8, and 12 weeks; 6, 9, and 12 months; 6-monthly thereafter.
If K^+ rises above 5.5 mmol/L or creatinine rises to 221 μmol/L (2.5 mg/dL), reduce dose to 25 mg on alternate days and monitor blood chemistry closely.
If K^+ rises to >6.0 mmol/L or creatinine to >310 μmol/L (3.5 mg/dL), stop MRA immediately and seek specialist advice.
A specialist heart failure nurse may assist with education of the patient, follow-up (in person or by telephone), biochemical monitoring, and dose up-titration.

ADVICE TO PATIENT

Explain expected benefits (see Why?).
Treatment is given to improve symptoms, to prevent worsening of heart failure leading to hospital admission, and to increase survival.
Symptom improvement occurs within a few weeks to a few months of starting treatment.
Avoid NSAIDs‡ not prescribed by a physician (self-purchased over-the-counter agent) and salt substitutes high in K^+.
If diarrhea or vomiting occurs, patients should stop the MRA and contact the physician.

PROBLEM SOLVING

Worsening renal function/hyperkalemia
- See How to Use? section.
- Major concern is hyperkalemia (>6.0 mmol/L)
- Conversely, a high-normal potassium level may be desirable in patients with heart failure, especially if they are taking digoxin.
- It is important to avoid other K^+-retaining drugs (e.g., K^+-sparing diuretics such as amiloride and triamterene) and nephrotoxic agents (e.g., NSAIDs‡)

Concomitant use of a K^+ binder (e.g., patiromer [Chapter 103] may allow an MRA to be continued in patients who develop hyperkalemia with an MRA.
Some "low-salt" substitutes have a high K^+ content.
Male patients treated with spironolactone may develop breast discomfort or gynecomastia (these problems are significantly less common with eplerenone).

†It is extremely important to adhere to these cautions and doses in light of recent evidence of serious hyperkalemia with spironolactone in usual clinical practice in Ontario.
‡Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) unless essential.
ACE = angiotensin converting enzyme; ARB = angiotensin receptor blocker; ARNI = angiotensin receptor/neprilysin inhibitor; MRA = mineralocorticoid receptor antagonist; NSAID = nonsteroidal anti-inflammatory drug; SGLT2 = sodium-glucose cotransporter 2.
Modified from McMurray J, Cohen-Solal A, Dietz R, et al. Practical recommendations for the use of ACE inhibitors, β-blockers, aldosterone antagonists and angiotensin receptor blockers in heart failure: putting guidelines into practice. *Eur J Heart Fail*. 2005;7:710-721.

Sinus Node Inhibitors: Ivabradine

MECHANISM OF ACTION. Ivabradine is the first of a new class of drugs developed to inhibit the mixed sodium-potassium channel or current (also known as the funny channel, abbreviated as I_f or I_{kf}) in the sinoatrial node and, in so doing, reduce heart rate. Reduction in heart rate is the only known cardiac action of ivabradine, which has this effect only in patients in sinus rhythm.

CLINICAL BENEFITS. In patients with symptomatic heart failure (NYHA class II to IV), a reduced ejection fraction (≤35%), and sinus rhythm with a rate of 70 beats per minute or higher, ivabradine improves symptoms and ejection fraction and reduces the risk for hospitalization for heart failure (but not mortality) when added to an ACE inhibitor (or ARB or, presumably, ARNI), a β-blocker, and a mineralocorticoid receptor antagonist.[A19]

PRACTICAL USE. Ivabradine should be considered in patients who have persistent symptoms (NYHA class II to IV) despite treatment with a diuretic and other disease-modifying therapies (i.e., an ARNI [or ACE inhibitor or ARB], β-blocker, and a mineralocorticoid receptor antagonist) and who are in sinus rhythm with a heart rate of 70 beats per minute or greater. Ivabradine is not a substitute for a β-blocker and is not effective in atrial fibrillation. Treatment should be started at 5 mg twice daily, increased to 7.5 mg twice daily after 14 days unless the heart rate is 60 beats per minute or less, and reduced usually to 2.5 mg twice daily if the rate is less than 50 beats per minute. Symptomatic bradycardia and visual disturbance (phosphenes) are uncommon but require the dose be reduced or ivabradine be discontinued. Ivabradine also may increase the risk of developing atrial fibrillation, which should prompt discontinuation of the drug. Ivabradine should not be used in combination with agents that prolong the QT interval (e.g., amiodarone) and must be used cautiously with inhibitors (including grapefruit juice) or inducers of CYP3A4.

Soluble Guanylate Cyclase Stimulator: Vericiguat

MECHANISM OF ACTION. Vericiguat stimulates soluble guanylate cyclase, thereby converting guanosine triphosphate to cyclic guanosine monophosphate and increasing phosphokinase G levels. Phosphokinase G levels cause relaxation of vascular and cardiac muscle. Stimulation of this pathway may also prevent pathologic fibrosis and muscle hypertrophy, which contribute to adverse vascular and cardiac remodeling.

CLINICAL BENEFITS. In patients with symptomatic heart failure, a reduced ejection fraction (<45%), and a recent hospital admission (or intravenous diuretic) for worsening heart failure, vericiguat reduces the risk for hospitalization for heart failure (but not mortality) when added to an ACE inhibitor (or ARB or ARNI), a β-blocker, and a mineralocorticoid receptor antagonist.[A20]

PRACTICAL USE. Vericiguat may be considered in patients who have persistent symptoms (functional class II to IV) despite treatment with a diuretic and other disease-modifying therapies (i.e., an ARNI [or ACE inhibitor or ARB], β-blocker, a mineralocorticoid receptor antagonist and an SGLT2 inhibitor) following a hospitalization for heart failure or need for outpatient intravenous diuretics. Treatment should be started at 2.5 mg orally once daily with food, and the dose should be doubled approximately every 2 weeks as tolerated to reach the target maintenance dose of 10 mg once daily. Hypotension is the most common side effect. Vericiguat also increases the risk of anemia. Concomitant use of vericiguat with a phosphodiesterase type 5 inhibitor is not recommended because of the potential for hypotension.

Digoxin

MECHANISM OF ACTION. Digitalis glycosides inhibit the cell membrane Na^+, K^+-ATPase pump, thereby increasing intracellular calcium and myocardial contractility. In addition, digoxin is thought to enhance parasympathetic and reduce sympathetic nervous activity as well as to inhibit renin release.

CLINICAL BENEFITS. In the only large RCT that examined the effects of starting (as opposed to withdrawing) digoxin, digoxin did not reduce mortality but did decrease the risk for admission to hospital for worsening heart failure and improve quality of life when it was added to a diuretic and an ACE inhibitor. In patients in sinus rhythm, the addition of digoxin can be considered if heart failure remains symptomatic despite standard treatment with a diuretic

TABLE 46-6 PRACTICAL GUIDANCE ON THE USE OF SODIUM GLUCOSE COTRANSPORTER 2 (SGLT2) INHIBITORS IN PATIENTS WITH HEART FAILURE DUE TO LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

WHY?

Treatment with SGLT2 inhibitors (dapagliflozin or empagliflozin) increases survival, reduces hospital admissions, and improves symptoms/quality of life class when added to standard therapy (diuretic, an angiotensin receptor blocker-neprilysin inhibitor [ARNI] or ACE inhibitor/ARB], a β-blocker, and an MRA) in patients with symptomatic (NYHA class II to IV) heart failure. SGLT2 inhibitors also slow the rate of decline in estimated glomerular filtration rate over time.

IN WHOM AND WHEN?

Indications
- Potentially all patients with symptomatic heart failure (NYHA class II to IV)
- First-line therapy (along with ARNI [or ACE inhibitor/ARB], β-blocker and MRA) in patients with symptomatic heart failure (NYHA class II to IV) and an LVEF ≤40%

Contraindications
- Previous diabetic ketoacidosis
- Estimated glomerular filtration rate <20 mL/min/1.73 m^2

Cautions/seek specialist advice
- Significant renal dysfunction (estimated glomerular filtration rate <30 mL/min/1.73 m^2)
- Recurrent hypoglycemia
- Insulin treatment if hypoglycemia or if "tight" glycemic control (i.e., glycated hemoglobin <7%)
- Possible pancreatic insufficiency (e.g., due to previous pancreatitis)
- History of genital fungal infection
- Possibility that excessive alcohol consumption and ketogenic low-carbohydrate diets may increase the risk of ketoacidosis (or cause diagnostic confusion)

Potential drug interactions of particular concern
- Glucose-lowering therapy, especially insulin or insulin secretagogues (such as sulfonylureas) because of small risk of hypoglycemia if "tight" glycemic control (i.e., glycated hemoglobin <7%)

WHERE?

In the community or in the hospital
Exceptions—see Cautions/seek specialist advice

WHICH ORAL DOSE?

	STARTING DOSE	TARGET DOSE
Dapagliflozin	10 mg once daily	10 mg once daily
Empagliflozin	10 mg once daily	10 mg once daily

HOW TO USE?

Start with dose shown earlier
Check kidney function at 4-8 weeks; earlier if baseline estimated glomerular filtration rate <30 mL/min/1.73 m^2. Regular monitoring not needed unless concerning initial decline in kidney function (rare).
A specialist heart failure nurse may assist with education of the patient, follow-up (in person or by telephone), and biochemical monitoring.

ADVICE TO PATIENT

Explain expected benefits (see Why?).
Treatment is given to improve symptoms, to prevent worsening of heart failure leading to hospital admission, and to increase survival.
Symptomatic improvement occurs within a few weeks to a few months after starting treatment.
Advise of small (5-10%) risk of genital fungal skin infection—more common in women and in noncircumcised men. Probably less common in people without diabetes. Genital skin hygiene important.
Advise of small (<5%) risk of hypoglycemia—only in patients with type 2 diabetes and probably only in those treated with insulin or insulin secretagogues. More likely in individuals with "tight" glycemic control (i.e., glycated hemoglobin <7%).
Advise temporary withholding of SGLT2 inhibitor and/or stopping/reducing insulin dose in situations that might trigger diabetic ketoacidosis (e.g., illness leading to decreased food and fluid intake). For example, stop SGLT2 inhibitors 3 days preoperatively. Ketoacidosis has not been observed in patients without type 2 diabetes, and the greatest risk is in patients treated with insulin or insulin secretagogues.

PROBLEM SOLVING

Most common problem is genital fungal skin infection
- Can usually be treated with an antifungal cream and does not usually require treatment interruption; oral antifungal therapy is an alternative.

Major concern is ketoacidosis, which is rare but serious
- Diagnosis may be delayed because blood glucose may not be elevated (or greatly elevated).
- Symptoms and signs that should raise concern are abdominal pain, vomiting, confusion, "pear drop/fruity" breath
- Other typical problems (e.g., breathlessness, thirst) are not helpful in patients with heart failure
- Some increase in ketones with SGLT inhibitors is common (up to 1 mmol/L)

ACE = angiotensin converting enzyme; ARB = angiotensin receptor blocker; ARNI = angiotensin receptor/neprilysin inhibitor; LVEF = left ventricular ejection fraction; MRA = mineralocorticoid receptor antagonist; SGLT2 = sodium glucose cotransporter 2.

and key disease-modifying drugs (i.e., an ARNI [or ACE inhibitor or ARB], a β-blocker, a mineralocorticoid receptor antagonist, and an SGLT2 inhibitor). However, digoxin has not been as well studied and may not be as safe as ivabradine when used in conjunction with contemporary therapies. In patients with atrial fibrillation, digoxin may be used at an earlier stage if a β-blocker fails to control the ventricular rate during exercise (Chapter 52). Digoxin can also be used to control the ventricular rate when β-blocker treatment is being initiated or up-titrated.

If the effect of digoxin is needed urgently, loading with 10 to 15 μg/kg lean body weight, given in three divided doses 6 hours apart, may be used. The maintenance dose should be one third of the loading dose. Smaller maintenance doses (e.g., one fourth of the loading dose and not more than 62.5 μg/day) should be used in elderly patients and in patients with reduced renal function as well as in patients with a low body mass. Monitoring of the serum digoxin concentration is recommended because of the narrow therapeutic window. A steady state is reached 7 to 10 days after treatment is started; blood should be collected at least 6 hours (and ideally 8 to 24 hours) after the last dose. The currently recommended therapeutic range is 0.5 to 1.0 ng/mL.

Digoxin can cause anorexia, nausea, arrhythmias, confusion, and visual disturbances, especially if the serum concentration is above 2.0 ng/mL. Hypokalemia increases susceptibility to the adverse effects. The dose of digoxin should be reduced in elderly patients and in patients with renal dysfunction. Certain drugs increase serum digoxin concentration, including amiodarone.

Hydralazine and Isosorbide Dinitrate

MECHANISM OF ACTION. Hydralazine is a powerful direct-acting arterial vasodilator. Its mechanism of action is not understood, although it may inhibit enzymatic production of superoxide, which neutralizes nitric oxide and may induce nitrate tolerance. Nitrates dilate both veins and arteries, thereby reducing preload and afterload by stimulating the nitric oxide pathway and increasing cyclic guanosine monophosphate in vascular smooth muscle. Neither drug on its own, nor any other direct-acting vasodilator, has been demonstrated to be beneficial in heart failure.

CLINICAL BENEFITS. The addition of hydralazine and isosorbide dinitrate reduces mortality, hospital admissions for heart failure, and heart failure symptoms when added to standard disease-modifying drugs (i.e., an ACE inhibitor [or presumably an ARB or ARNI, a β-blocker, mineralocorticoid receptor antagonist, and an SGLT2 inhibitor) in Black patients with functional class III or IV symptoms and an ejection fraction of 45% or less. The dose is a fixed combination of 37.5 mg of hydralazine and 20 mg of isosorbide dinitrate; if one tablet is tolerated, a second is given 12 hours later. Then the tablet is given three times daily for 3 to 5 days, at which point the dose is increased to the target maintenance of two tablets three times daily (i.e., a daily dose of 225 mg hydralazine and 120 mg isosorbide dinitrate). It is uncertain whether hydralazine/isosorbide dinitrate is an effective addition to standard therapy in non–African American patients.

PRACTICAL USE. Other than for Black patients, the main indication for hydralazine and isosorbide dinitrate is as a substitute in patients who are intolerant to an ARNI (or ACE inhibitor or ARB), primarily because of renal dysfunction. However, many patients who cannot tolerate these three drugs because of hypotension also do not tolerate hydralazine and isosorbide dinitrate. Hydralazine and isosorbide dinitrate can also be used as additional treatment in non–African Americans who remain symptomatic with other proven therapies. The main dose-limiting adverse effects of hydralazine and isosorbide dinitrate are headache and dizziness. A rare adverse effect of higher doses of hydralazine, especially in slow acetylators, is a systemic lupus erythematosus–like syndrome (Chapter 245).

Omega-3 Polyunsaturated Fatty Acids

In one trial, 1 gram of n-3 PUFA (850 to 852 mg eicosapentaenoic acid and docosahexaenoic acid as ethyl esters in the average ratio of 1 : 1.2) per day led to a

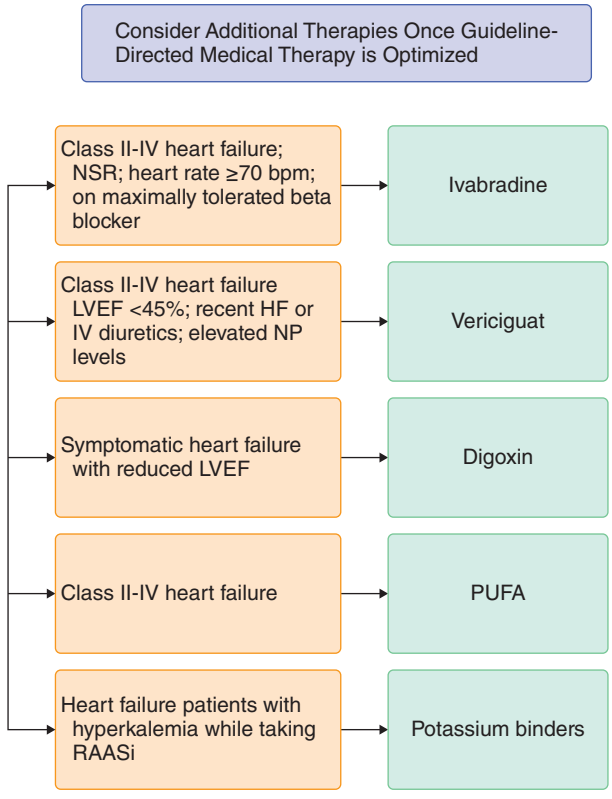

FIGURE 46-3. Second-line treatments for heart failure with reduced left ventricular ejection fraction. bpm = beats per minute; HR = heart rate; IV = intravenous; LVEF = left ventricular ejection fraction; NP = natriuretic peptide; NSR = normal sinus rhythm; PUFA = polyunsaturated fatty acids; RAASi = renin-angiotensin-aldosterone system inhibitor. (Reprinted with permission *Circulation*. 2022;145:e895-e1032 ©2022 American Heart Association, Inc.)

small reduction in cardiovascular morbidity and mortality in patients with heart failure. Although this agent may have beneficial anti-inflammatory and antiarrhythmic effects, its current role in the treatment of heart failure is uncertain, especially because trials in survivors of acute myocardial infarction have not shown benefit (Chapter 58).

Other Agents

The selective cardiac myosin activator omecamtiv mecarbil has shown inconsistent effects and is not approved by the U.S. Food and Drug Administration to treat heart failure. Other treatments have been tested in randomized trials and have been shown to have a neutral (e.g., amlodipine) or uncertain (e.g., bosentan and etanercept) effect on mortality and morbidity or to increase mortality (e.g., dronedarone, milrinone, flosequinan, vesnarinone, and moxonidine). The direct renin inhibitor aliskiren is inferior to an ACE inhibitor and is not recommended as an alternative to an ACE inhibitor (or ARB or ARNI) in patients with heart failure and a reduced ejection fraction. The potential role of cardiac stem cell therapy remains uncertain.[12]

Other Pharmacologic Issues

Some therapies that are of proven value for cardiovascular conditions that underlie or are associated with heart failure are of uncertain benefit (antiplatelet treatment, Chapter 70) or do not improve outcomes (statins, Chapter 190) in patients with persistent, symptomatic heart failure. Newer direct-acting oral anticoagulants or warfarin is indicated in patients with atrial fibrillation to reduce the risk for thromboembolism, unless patients have contraindications to their use (Chapter 52). Anticoagulants may also be used in patients with evidence of intracardiac thrombus (e.g., detected during echocardiographic examination) or systemic thromboembolism but otherwise are not indicated in patients who are not in atrial fibrillation.[A21] The many interactions of warfarin with other drugs, including some statins and amiodarone (Chapter 70), must always be considered. Heparin prophylaxis (Chapter 70) against deep vein thrombosis is indicated when patients with heart failure are bed bound, such as during hospital admission. Vaccination against influenza,[A22] pneumococcal infection, and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is advised (Chapter 15) in all patients with heart failure because these infections can lead to severe clinical deterioration.

Refractory Heart Failure and Pulmonary Edema

Patients presenting with acute heart failure include those who develop heart failure de novo as a consequence of another cardiac event, usually a myocardial infarction,[13] and those who present for the first time with decompensation of previously asymptomatic and often unrecognized cardiac dysfunction (patients previously with pre–heart failure [stage B], a transition with profound prognostic implications). However, because of frequent recurrences, most episodes of decompensation occur in patients with established, chronic heart failure that has worsened as a result of the unavoidable natural progression of the syndrome, with an intercurrent cardiac (e.g., arrhythmia) or noncardiac (e.g., pneumonia) event, or as a consequence of an avoidable reason, such as nonadherence with treatment or use of an agent that can alter renal function. Although it is not always identified, searching for a reversible precipitant is an important aspect of the initial therapy plan (Table 46-7). Many patients with decompensated heart failure experience worsening over a period of days or weeks before presenting to their doctor, during which time rising pulmonary artery pressure may be detected by an implantable pressure sensor.

TABLE 46-7 SOME COMMON PRECIPITATING CAUSES OF HEART FAILURE

Myocardial ischemia or infarction
Atrial fibrillation or other supraventricular tachycardias
Uncontrolled hypertension
Valvular disease
Ventricular tachycardia
Pulmonary embolism
Pericardial disease
Sepsis
Anemia
Poor dietary or medical adherence
Adverse drug effects
Hyperthyroidism or hypothyroidism
Unknown/unexplained*

*Commonly, no clear precipitant is identified.

Adapted from Kimmelstiel CD, DeNofrio D, Konstam MA. Heart failure. In: Wachter RM, Goldman L, Hollander H, eds. *Hospital Medicine,* 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2005:360.

Most patients with decompensated heart failure require admission to the hospital, especially if pulmonary edema is present. In contrast to the ambulatory setting, data from RCTs generally are not available to guide effective therapy for worsening of chronic heart failure or new-onset acute heart failure.[14] The principal goals of management of this heterogeneous group of patients are to relieve symptoms, the most important of which is extreme dyspnea, and to maintain or to restore vital organ perfusion. Importantly, using the acute admission period as an opportunity to commence evidence-based therapy and to titrate it rapidly after discharge results in a significant reduction in the risk of readmission and death.[A23]

The early administration of an intravenous bolus or infusion of a loop diuretic and, in hypoxemic patients, oxygen are the key first-line treatments. A small RCT suggested that high-dose diuretic (more than 2.5 times the previous oral dose) resulted in greater relief of dyspnea and congestion compared with low-dose diuretic (same intravenous dose as prior oral dose), but at the expense of more, albeit transient, renal dysfunction. Torsemide and furosemide are equally effective.[A24] A continuous infusion of furosemide may increase urine output compared with intermittent boluses but has not been shown to reduce mortality. An intravenous opiate may also be used cautiously in selected patients to relieve anxiety and distress, but at the risk of reducing ventilatory drive.

Noninvasive ventilation using a tight-fitting mask to provide positive-pressure ventilation reduces respiratory distress and metabolic disturbances more rapidly than standard oxygen therapy but has not reduced short-term mortality. Intravenous infusion of a nitrate (e.g., continuous intravenous infusion of 20 to 200 μg/mm of nitroglycerin, titrated according to the symptomatic response and hemodynamic measurements, particularly arterial blood pressure) may also be valuable in patients with hypertension or myocardial ischemia (Fig. 46-4).

Intravenous nesiritide can reduce the pulmonary capillary wedge pressure more promptly than intravenous nitroglycerin but has minimal effect on dyspnea and does not improve other clinical outcomes, and early intensive ventilator therapy is no better than usual care. In volume-overloaded patients with severe heart failure unresponsive to diuretics, ultrafiltration is an option at specialized centers, although it was not superior to intensified pharmacologic therapy in a recent trial.

In patients with marked hypotension or other evidence of organ hypoperfusion, an inotropic agent such as dobutamine (continuous intravenous infusion of 2.5 to 25 μg/kg/min, titrated according to hemodynamic and heart rate response and induction of arrhythmias or myocardial ischemia) or a phosphodiesterase inhibitor (e.g., milrinone) should be considered, although neither treatment has ever been shown to reduce in-hospital deaths. In some countries, the calcium

sensitizer levosimendan is also available for use in these patients. In general, potent inotropic agents should be used in a cardiac-monitored setting at the lowest clinically effective dose and for the shortest duration possible (Chapter 93). Although low-dose dopamine (intravenous infusion of 2.5 μg/kg/mm) is often administered in an attempt to improve diuresis and renal function, such benefits have not been confirmed in RCTs.

Devices and Surgery

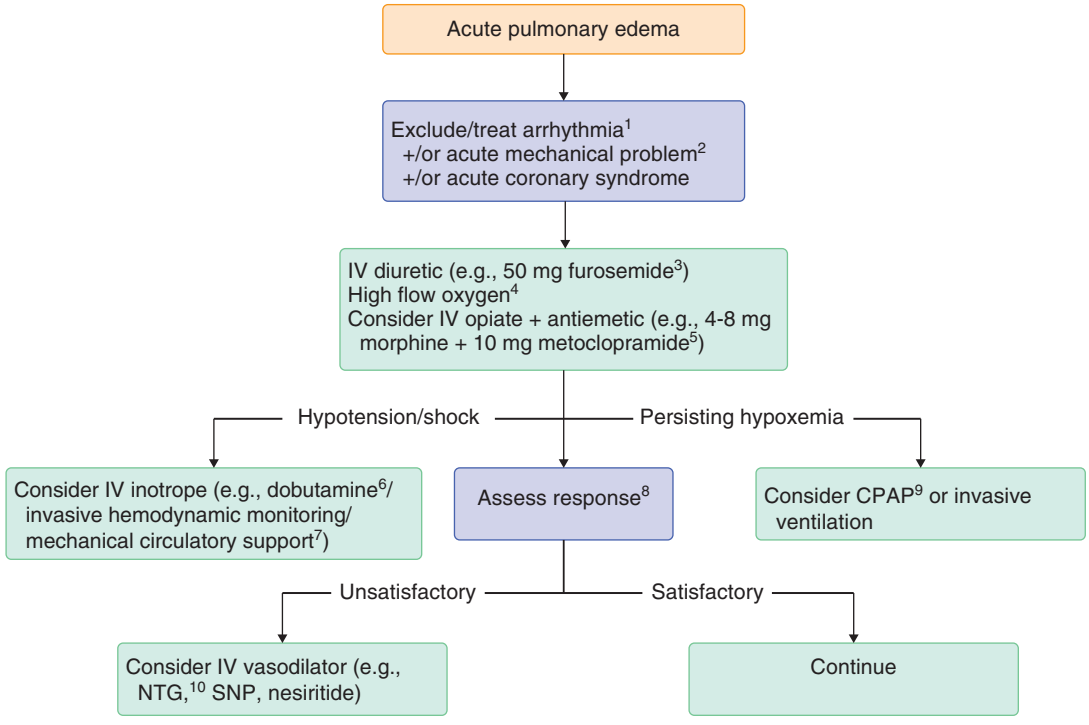
In critically ill patients (Chapter 93), temporary percutaneous mechanical circulatory support guided by invasive hemodynamic measurements may also be considered. The aim of treatment is to support the patient's circulation and vital organ function until either the patient's own heart recovers or a definitive operative procedure can be performed (e.g., percutaneous coronary intervention, implantation of a ventricular assist device, or cardiac transplantation).

Implantable Cardioverter-Defibrillators

About half of patients with heart failure die suddenly, mainly as the result of a ventricular arrhythmia. The relative risk for sudden death, as opposed to death from progressive heart failure, is greatest in patients with milder symptoms. In patients with more advanced heart failure, progressive pump failure deaths are relatively more common. Antiarrhythmic drugs do not improve survival in heart failure. ICDs (Chapter 54), however, reduce the risk for death in selected patients after myocardial infarction (Chapter 58) and, in one large RCT, improved survival in patients with class II to III heart failure and systolic dysfunction who were otherwise treated with what was considered optimal medical therapy at the time. However, a large RCT with longer follow-up found no reduction in all-cause mortality when an ICD was added to excellent contemporary pharmacologic and device therapy in older patients with nonischemic heart failure.[A25] Currently, in addition to their role in patients with an ischemic etiology, the balance of evidence also favors use of an ICD in patients who have nonischemic heart failure,[A26] limited comorbidity (i.e., a low risk of noncardiovascular death), an anticipated survival of at least a year, and a left ventricular ejection fraction remaining at 35% or less despite at least 3 months of treatment with disease-modifying therapy (i.e., an ARNI [or ACE inhibitor or ARB], β-blocker, mineralocorticoid receptor antagonist, and an SGLT2 inhibitor).

Cardiac Resynchronization Therapy

About 30% of patients with heart failure and a reduced ejection fraction have substantial prolongation of the QRS duration on the surface electrocardiogram, which is a marker of abnormal electrical activation of the left ventricle



[1] Casual arrhythmia (e.g., ventricular tachycardia). It can be difficult to determine whether atrial fibrillation is a primary cause of acute pulmonary edema or secondary to it. An ECG is an essential investigation.

[2] Acute mechanical problems include ventricular septal rupture and mitral valve papillary muscle rupture. Mechanical support (e.g., an intra-aortic balloon pump) and urgent surgery should be considered. An echocardiogram should be performed as soon as possible, especially in a patient without a prior diagnosis of heart failure/other relevant heart disease (e.g., prior myocardial infarction or valve disease).

[3] Dose of diuretic depends on prior diuretic use and renal function—a lower dose may suffice if preserved renal function and no prior diuretic use.

[4] Oxygen causes an increase in systemic vascular resistance and a reduction in heart rate and cardiac output and should only be administered to patients with hypoxemia.

[5] Consider if patient is agitated/distressed/in pain; may cause respiratory depression and dose should be reduced in very elderly.

[6] An intravenous infusion of dobutamine may be started at a dose of 2.5 μg/kg/min, doubling every 15 minutes according to response and tolerability (dose titration usually limited by excessive tachycardia, arrhythmias, or ischemia). A dose above 20 μg/kg/min is rarely needed.

[7] For example, an intra-aortic balloon pump

[8] Improvement in symptoms and peripheral perfusion and adequate urine output—patient should be monitored closely, and usually a response will occur within 30 minutes. Bladder catheterization may help in monitoring urine output.

[9] Continuous positive airways pressure (CPAP) is valuable in severe pulmonary edema, especially if associated with hypoxemia. Endotracheal intubation and invasive mechanical ventilation should be considered in patients with persisting hypoxemia and physical ventilatory exhaustion.

[10] If systolic blood pressure is adequate (>100 mm Hg), an intravenous infusion of nitroglycerin (NTG) can be considered. Start at a dose of 10 μg/min and double every 10 minutes according to response and tolerability (usually dose up-titration is limited by hypotension). A dose of more than 100 μg/min is rarely needed.

Approach to the patient with acute pulmonary edema. IV = intravenous; NTG = nitroglycerin; SNP = sodium nitroprusside.

causing dyssynchronous contraction, less efficient ventricular emptying, and, often, mitral regurgitation. Atrioventricular coupling may also be abnormal, as reflected by a prolonged PR interval, as may interventricular synchrony. Cardiac resynchronization therapy (CRT) with atrial-biventricular or multisite pacing optimizes atrioventricular timing and improves synchronization of cardiac contraction. In symptomatic patients (NYHA class II to IV) who are in sinus rhythm, have marked systolic dysfunction (left ventricular ejection fraction ≤35%), and have a wide QRS, the addition of CRT to optimal medical therapy and an ICD improves pump function, reduces mitral regurgitation, relieves symptoms, and significantly prolongs exercise capacity. CRT also substantially reduces the risk for death and for hospital admission for worsening heart failure in such patients.[15] Many other outcome measures, including quality of life, are also improved. Whether CRT is beneficial in patients in atrial fibrillation or with non–left bundle branch block (LBBB) QRS widening is uncertain. All patients in sinus rhythm with persistent symptoms (NYHA class II to IV) and an ejection fraction of 35% or less despite optimal disease-modifying medical therapy (ARNI [or ACE inhibitor or ARB], β-blocker, mineralocorticoid receptor antagonist, and an SGLT2 inhibitor) should be considered for CRT if they have a QRS duration 130 msec or longer, especially if they have LBBB morphology, with the greatest benefit seen in patients with a QRS duration 150 msec or longer. Conversely, patients with a QRS duration less than 130 msec may be harmed by CRT. The value of new pacing modes, such as left bundle branch or[A27] His-bundle pacing,[A28] is also being explored in heart failure.

Surgery

With the exception of cardiac transplantation and ventricular assist devices, there are no generally accepted criteria for surgical intervention. Use of operative procedures is variable among centers and greatly dependent on local experience and expertise. Expert imaging and detailed hemodynamic and functional assessments are usually required when any patient with heart failure is considered for surgery, and close liaison between the relevant experts in these fields is essential. The collective expertise in surgical centers is often used to make highly individualized decisions about whether to operate and what procedures will be attempted. "Established" operative treatments for patients with heart failure include coronary artery bypass grafting, surgery, surgical or percutaneous interventions for aortic valve stenosis and mitral valve incompetence (Chapter 60), implantation of ventricular assist devices,[16] and heart transplantation.

PERCUTANEOUS CORONARY INTERVENTION OR CORONARY ARTERY BYPASS GRAFTING. Percutaneous coronary intervention or coronary artery bypass grafting (Chapter 59), as appropriate, is indicated for relief of angina. The extent of ischemia and residual myocardial viability can be determined by noninvasive assessments such as dobutamine echocardiography (Chapter 43), magnetic resonance imaging (Chapter 44), and positron emission tomographic scanning (Chapter 44) in patients with impaired left ventricular ejection fraction. Coronary artery bypass grafting reduces the risk for cardiovascular death and cardiovascular hospitalization (including heart failure hospitalization) in patients with ischemic cardiomyopathy, an ejection fraction of 35% or less, and coronary artery disease amenable to coronary-artery bypass grafting.[A29] The net benefit is not apparent until approximately 2 years after randomization because of the perioperative mortality related to surgery. Coronary artery bypass grafting is therefore recommended in such patients who are otherwise fit for surgery and have an anticipated life expectancy of 2 years or more. Percutaneous coronary revascularization has not been proven to have similar benefits in this situation.[A30]

CARDIAC TRANSPLANTATION. Cardiac transplantation remains the most accepted (Table 46-8) surgical intervention in end-stage heart failure.[17] Selection criteria usually focus on patients with refractory heart failure, that is, those with severe symptoms and functional limitations (peak oxygen consumption of less than 12 mL/kg per minute), as well as a particularly worrisome clinical course and prognosis attributed to their cardiac condition. These patients are often dependent on intravenous inotropic agents and mechanical support.

Over 3800 heart transplants are performed annually in the United States. The major limitation is the scarcity of donor organs, although increasing acceptance of heart donation after circulatory death has helped ease this problem. Cardiac xenotransplantation is experimental but a potentially promising additional way to address this shortage.[18] Absolute and relative exclusion criteria for heart transplantation (Table 46-9) include advanced age, serious comorbid conditions, and nonreversible pulmonary vascular resistance of more than 6 Wood units.

To diagnose allograft rejection, which can be antibody-mediated or cell-mediated, transjugular endomyocardial biopsies are usually performed weekly for 1 month, every other week for 2 months, and then every 1 to 2 months for the first year. In patients who are asymptomatic on low doses of corticosteroids, a gene expression profile of peripheral blood[19] can provide equivalent clinical outcomes despite fewer biopsies.[A31] Cellular rejection is usually easily treated with high-dose corticosteroids, but humoral rejection may require more aggressive immunosuppression (Chapter 38).

Another form of chronic rejection is transplant vasculopathy, which occurs at an annual rate of 5 to 10%. Patients are more likely to present with fatigue, heart failure, myocardial infarction, ventricular arrhythmia, or sudden death than with exertional angina. Patients are typically screened with annual coronary angiography, stress echocardiography, or positron emission tomography. Treatment emphasizes high-dose statins (see Table 190-2 in Chapter 190) and mTOR inhibitors (e.g., sirolimus or everolimus), but repeat transplantation may be required.

The survival rate after heart transplantation is currently about 85 to 90% at 1 year, 70 to 75% at 5 years, and 20% at 20 years. Transplant vasculopathy and malignancies account for about one third of deaths among patients who survive for 10 or more years.

MECHANICAL CIRCULATORY SUPPORT. Given the scarcity of organ donors, durable mechanical circulatory support using a left ventricular (or biventricular) assist device (LVAD) may be used as a "bridge to transplantation" or, in some centers, as a permanent and definitive alternative to transplantation ("destination therapy").[20] Mechanical circulatory support may also be used as

TABLE 46-8 INDICATIONS FOR HEART TRANSPLANTATION

Indications for referral of ambulatory patients with chronic heart failure

1. Patients who have limiting symptoms on exertion despite optimal medical therapy
2. Patients who require frequent hospital admission (two or more in 12 months) despite adequate therapy and adherence
3. Deteriorating renal function or inability to clear congestion without adversely affecting renal function
4. The need to decrease the dose or discontinue prognostically beneficial medication due to symptoms (often hypotension) or side effects such as renal dysfunction
5. Worsening right ventricular function or rising pulmonary artery pressure
6. High or rising natriuretic peptide levels despite optimal therapy
7. Frequent episodes of ventricular arrhythmias despite optimal drug and electrophysiologic therapy
8. Anemia, weight loss, hyponatraemia, or liver dysfunction attributable to heart failure

Indications for urgent inpatient referral

1. Inability to wean intravenous inotropic therapy
2. Need for percutaneous mechanical circulatory support to treat a patient in cardiogenic shock
3. Ventilatory support with use of positive airway pressure for intractable pulmonary edema
4. Refractory ventricular arrhythmias

From Bhagra SK, Pettit S, Parameshwar J. Cardiac transplantation: indications, eligibility and current outcomes. *Heart*. 2019;105:252-260.

TABLE 46-9 CARDIAC TRANSPLANTATION CONTRAINDICATION CRITERIA

1. Active infection (patients with chronic viral infection such as hepatitis B, hepatitis C, and human immunodeficiency virus may be considered if viral titres are undetectable on treatment or following treatment without evidence of other organ damage).
2. Symptomatic cerebral or peripheral vascular disease.
3. Diabetes mellitus with end-organ damage (e.g., nephropathy, neuropathy, proliferative retinopathy). Poorly controlled diabetes with glycosylated hemoglobin persistently >7.5% or 58 mmol/mL is a relative contraindication.
4. Current or recent neoplasm: risk of recurrence should be discussed with the oncologist.
5. Severe lung disease: FEV1 and FVC <50% predicted or evidence of parenchymal lung disease.
6. Irreversible renal dysfunction with estimated glomerular filtration rate <30 mL/min/1.73 m^2.
7. Irreversible liver dysfunction (e.g., cirrhosis).
8. Recent pulmonary thromboembolism (generally in the last 3 months).
9. Pulmonary hypertension with pulmonary artery systolic pressure >60 mm Hg, transpulmonary gradient ≥15 mm Hg and/or pulmonary vascular resistance >5 Wood units. If irreversible with either pharmacologic manipulation or mechanical unloading of the left ventricle, this is an absolute contraindication to isolated heart transplantation.
10. Psychosocial factors including history of non-compliance with medication, inadequate social support, ongoing or recent drug or alcohol use disorder, current smoker.
11. Obesity (body mass index >35 kg/m^2 or weight >140% of ideal body weight).
12. Other multisystem disease with poor long-term survival.

FEV1 = forced expiratory volume in one second; FVC = forced vital capacity.
From Bhagra SK, Pettit S, Parameshwar J. Cardiac transplantation: indication, eligibility and current outcomes. *Heart*. 2019;105:252-260.

a "bridge to candidacy" (i.e., to try to improve a patient's clinical status sufficiently to become eligible for transplantation). A continuous axial-flow device can provide a 65% 2-year survival free of repeat device surgery or disabling stroke. A newer ventricular magnetically levitated centrifugal-flow pump may provide better short-term and 2-year outcomes than the axial-flow pump.[A32]

Because not every hospital could or should be expected to offer all these levels of support for patients with advanced heart failure, there is a general recognition that such services should be concentrated in a limited number of tertiary centers. Centers implanting these devices use criteria such as persistent (>2 months) severe symptoms despite optimal drug and device therapy and other features placing patients at high risk for death (e.g., left ventricular ejection fraction <25%, three or more heart failure hospitalizations in the prior 12 months, peak oxygen consumption <12 mL/kg per minute, dependence on intravenous inotropic therapy, progressive end-organ dysfunction, and deteriorating right ventricular function) to decide who should be considered for mechanical circulatory support.

Organization of Care and Remote Monitoring

Several studies have shown that organized, nurse-led, multidisciplinary care can improve outcomes in patients with heart failure, particularly by reducing recurrent hospital admissions. Thus it is recommended that all patients with heart failure be enrolled in a disease management program. The most successful disease management approach seems to involve education of the patients, their families, and caregivers about heart failure and its treatment (including flexible diuretic dosing and reinforcing the importance of adherence), recognizing (and acting on) early deterioration (dyspnea, sudden weight gain, edema), and optimizing proven pharmacologic treatments. Both home-based and office-based approaches are effective. Even telephone follow-up is of value. New technology enabling noninvasive home telemonitoring of physiologic measures (e.g., heart rate and rhythm, blood pressure, temperature, respiratory rate, weight, and estimated body water content) and implanted devices, which collect similar data and may be interrogated remotely, are also being tested as aids to monitoring and management, but studies to date have not given consistent results. An alert embedded into the electronic health record can provide outpatients with personalized recommendations for increasing the use of guideline-directed medical therapies.[A33] Despite the usefulness of brain-type natriuretic peptide (BNP) in the diagnosis of heart failure and as a prognostic measure, treatment guided by BNP levels has not been shown in randomized trials to be consistently better than standard, evidence-based care.[A34] Conversely, treatment based on hemodynamic data transmitted from an implantable pulmonary artery pressure sensor may reduce heart failure hospitalizations over a 6- to 12-month period.[A35]

Education

Education of the patient, family, and caregivers is valuable (Table 46-10). Self-detection of early signs and symptoms of deterioration provides for earlier intervention. Counseling on the proper use of therapies, with an emphasis on adherence, is critical.

Useful patient-oriented material is available from several reliable sources: the Heart Failure Society of America (https://hfsa.org/patient-hub/heart-failure-facts-information), American Heart Association (http://www.heart.org/HEARTORG/Conditions/HeartFailure/Heart-Failure_UCM_002019_SubHomePage.jsp), National Heart, Lung and Blood Institute (http://www.nhlbi.nih.gov/health/dci/Diseases/Hf/HF_WhatIs.html), the Heart Failure Association of the European Society of Cardiology (https://www.heartfailurematters.org/), and other organizations.

Medication Use Counseling

When appropriate, a patient should be taught how to adjust the dose of diuretic within individualized limits. The dose should be increased (or a supplementary diuretic added) if there is evidence of fluid retention (symptoms of congestion) and decreased if there is evidence of hypovolemia (e.g., increased thirst associated with weight loss or postural dizziness, especially during hot weather or an illness causing decreased fluid intake or sodium and water loss). If hypovolemia is more marked, the doses of other medications also will have to be reduced.

The expected effects, beneficial and adverse, of other drugs should also be explained in detail (e.g., possible association of cough with ACE inhibitor). It is useful to inform patients that improvement with many drugs is gradual and may become fully apparent only after several weeks or even months of treatment. It is also important to explain the need for up-titration of the dose of an ARNI (or ACE inhibitor or ARB), a β-blocker, a mineralocorticoid receptor antagonist, and an SGLT2 inhibitor to the evidence-based target level, a goal that again may require weeks or even months to achieve. Patients should be advised not to use NSAIDs without consultation and to be cautious about using herbal or other nonproprietary preparations (Chapter 30).

Adherence

Education and counseling of the patient, caregiver, and family promote adherence, which is associated with better outcomes. Drug adherence can also be helped by home visits, specialized follow-up programs, and certain pharmacy aids, such as dose allocation (pill-organizing) boxes.

TABLE 46-10 TOPICS THAT SHOULD BE DISCUSSED WITH A PATIENT WITH HEART FAILURE AND WITH HIS OR HER FAMILY AND CAREGIVERS

GENERAL ADVICE
Explain what heart failure is and why symptoms occur
Causes of heart failure
How to recognize symptoms
What to do if symptoms occur
Self-weighing (to identify fluid retention)
RATIONALE FOR TREATMENTS
Importance of adhering to pharmacologic and nonpharmacologic (e.g., dietary) treatments
Smoking advice
Prognosis
DRUG COUNSELING
Rationale (i.e., benefits of individual drugs)
Dose and time of administration
Potential adverse effects (and what, if any, action to take)
What to do in case of missed or skipped doses
Self-management (e.g., flexible diuretic dosing)
REST AND EXERCISE
Rest
Exercise and activities related to work
Daily physical activity
Sexual activity
Rehabilitation
PSYCHOSOCIAL ASPECTS
Depression
Cognitive function
Social support
VACCINATIONS AND IMMUNIZATIONS
Influenza
Pneumococcal
OTHER
Travel
Driving
Dietary and social habits
Control sodium intake when necessary (e.g., some patients with severe heart failure)
Avoid excessive fluids in severe heart failure
Avoid excessive alcohol intake and illicit drugs

Modified from McMurray JJ, Adamopoulos S, Anker SD, et al. ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure 2012: the Task Force for the Diagnosis and Treatment of Acute and Chronic Heart Failure 2012 of the European Society of Cardiology. Developed in collaboration with the Heart Failure Association (HFA) of the ESC. *Eur Heart J*. 2012;33:1787-1847.

Lifestyle Modification

Exercise

Tailored, structured, supervised aerobic exercise is safe and improves functional capacity and quality of life in patients with heart failure.[A36] An appropriate exercise prescription may also reduce hospitalizations and mortality in patients with heart failure. Regular physical activity or exercise training, if available, is recommended for all patients with heart failure who are able to participate.

Diet, Nutrition, and Alcohol

Most guidelines advocate avoidance of foods containing relatively high salt content in the belief that doing so may reduce the need for diuretic therapy, although the benefits of severe sodium restriction to less than 1 gram of sodium per day are unproven.[A37] This recommendation is based on clinical experience, which suggests that excess sodium intake can be a precipitant of clinical decompensation. Some salt substitutes have a high potassium content, which can lead to hyperkalemia.

Restriction of fluid intake is indicated only during episodes of decompensation associated with peripheral edema or hyponatremia. In these situations, daily intake should be restricted to 1.5 to 2.0 L to help facilitate reduction in extracellular fluid volume and to avoid hyponatremia.

Reducing excessive weight will reduce the work of the heart and may lower blood pressure (Chapter 64). Conversely, malnutrition is common in severe heart failure, and the development of cardiac cachexia is an ominous sign. Reduced food intake is sometimes caused by nausea (e.g., related to digoxin use or hepatosplenic congestion) or abdominal bloating (e.g., due to ascites). In these cases, small frequent meals and high-protein and high-calorie liquids may be helpful.

In severe decompensated heart failure, eating and bending may be difficult because of dyspnea—so called "bendopnea."

Moderate alcohol intake is not thought to be harmful in heart failure, although excessive intake can cause cardiomyopathy and atrial arrhythmias in susceptible individuals. In patients with suspected alcoholic cardiomyopathy, abstinence from alcohol may improve cardiac function.

Smoking

Smoking causes peripheral vasoconstriction, which is detrimental in heart failure. Nicotine replacement therapy (Chapter 363) is believed to be safe in heart failure. The safety of bupropion in heart failure is uncertain, especially because it is known to increase blood pressure, and varenicline may increase cardiovascular risk.

Sexual Activity

Sexual activity need not be restricted in patients with compensated heart failure, although dyspnea may be limiting. In men with erectile dysfunction (Chapter 216), treatment with a cyclic guanine monophosphate phosphodiesterase type 5 inhibitor can be useful, but these drugs must not be taken within 24 hours of prior nitrate use, and nitrates must not be restarted for at least 24 hours afterward. Caution should be exercised when sildenafil or another type-5 phosphodiesterase inhibitor is used in addition to sacubitril/valsartan and vericiguat because of the risk of hypotension.

Driving

Patients with heart failure can continue to drive, provided their condition does not induce undue dyspnea, fatigue, or other incapacitating symptoms. Patients with recent syncope, cardiac surgery, percutaneous coronary intervention, or device placement may be restricted from driving, at least temporarily, according to local regulations. Patients holding an occupational or commercial license may also be subject to additional restrictions.

Traveling

Short flights are unlikely to cause problems for a patient with compensated heart failure. For patients with an LVAD, travel should be planned in advance and in conjunction with the heart failure team.[21] Cabin pressure is generally maintained to provide an oxygen level no lower than equivalent to 6000 feet above sea level, which should be well tolerated in patients without severe pulmonary disease or pulmonary hypertension. Longer journeys may cause limb edema and dehydration, owing to insensible fluid loss, aggravated by caffeinated drinks and alcohol, thereby predisposing to venous thrombosis. Avoidance of dehydration is especially important in patients with an LVAD because the function of these devices is sensitive to blood volume. Adjustment of the dose of diuretics and other treatments should be discussed with the patient wishing to travel to a warm climate or a country where the risk for gastroenteritis is high. It is also advisable for heart failure patients to carry a list of medications and contact information for their health care provider and device cards for airport security. In those with an LVAD, contact with a health care provider at the patient's destination may be advisable.

Comorbidity

Comorbid conditions, which are common and important in patients with heart failure, may be due to the underlying cardiovascular disease that caused or contributed to heart failure (e.g., hypertension, coronary artery disease, diabetes mellitus), may arise as a complication of heart failure (e.g., arrhythmias), or can result from an adverse effect of treatment given for heart failure (e.g., gout). The exact causes of other comorbidities in heart failure, such as diabetes (Chapter 210), depression (Chapter 362), sleep apnea (Chapter 374), renal dysfunction (Chapter 116), and anemia (Chapter 144), are complex and uncertain. These and other comorbid conditions, such as chronic obstructive pulmonary disease and asthma, are important because they are a major determinant of prognosis and may limit the use of certain treatments for heart failure (e.g., renal dysfunction limiting use of ACE inhibitors or asthma limiting β-blockers) and because treatment of comorbidities may affect the stability of heart failure (e.g., NSAIDs needed for rheumatic conditions can cause salt and water retention and renal dysfunction). Both prevention (e.g., diabetes mellitus) and treatment (e.g., anemia) of comorbidities are being evaluated as a potential new therapeutic goal in heart failure.

Angina and Ischemia

β-Blockers are of benefit in both angina (Chapter 56) and heart failure. Similarly, ivabradine, which reduces heart rate by inhibiting the I_f current in the sinus node, is also beneficial in both angina and heart failure. Nitrates relieve angina but on their own are not of proven value in chronic heart failure. Calcium-channel blockers should generally be avoided in heart failure because they have a negative inotropic action and cause peripheral edema; only amlodipine has been shown to have no adverse effect on survival, but it may increase the risk for pulmonary edema. Trimetazidine, ranolazine, and nicorandil are antianginal drugs that are available in certain countries; their safety in patients with heart failure is uncertain. Percutaneous and surgical (Chapter 59) revascularization is also of value in relieving angina in selected patients with heart failure (see later). Coronary artery bypass grafting may reduce the risk for death from cardiovascular causes and cardiovascular hospitalization (including heart failure hospitalization) in selected heart failure patients with angina and a reduced ejection fraction.

Atrial Fibrillation

Atrial fibrillation (Chapter 52) may be the cause of or a consequence of heart failure in a patient presenting with atrial fibrillation and a rapid ventricular rate, and the distinction can be difficult, especially because prolonged atrial fibrillation may lead to a rate-related cardiomyopathy. Thyrotoxicosis (Chapter 207) and mitral valve disease (Chapter 60), especially stenosis, must be excluded. Alcohol abuse should also be considered. β-Blockers and digoxin are given to control the ventricular rate. The patient should be supervised closely after the initiation of these treatments because underlying sinus node dysfunction may raise the risk for bradycardia. If the patient presents emergently with severe heart failure, shock, or myocardial ischemia, urgent electrical or pharmacologic cardioversion may be considered (Chapter 54). Catheter ablation (Chapter 52) can reduce hospitalizations and mortality in selected patients with heart failure and atrial fibrillation,[A38] even if the left ventricular ejection fraction is normal,[A39] whereas a strategy of maintaining sinus rhythm with antiarrhythmic drug therapy alone is not superior to controlling the ventricular rate in patients with atrial fibrillation and heart failure. If pharmacologic therapy fails to control the ventricular rate and catheter ablation is contraindicated or unsuccessful, atrioventricular node ablation and pacing may be required (Chapter 54).[22] There is a strong indication for thromboembolism prophylaxis with a direct-acting anticoagulant or warfarin in patients who have heart failure with paroxysmal, persistent, or permanent atrial fibrillation (Chapter 52).

Asthma and Reversible Airway Obstruction

Asthma is a contraindication for use of a β-blocker, but most patients with chronic obstructive pulmonary disease (Chapter 76) can tolerate a β-blocker. Pulmonary congestion can mimic chronic obstructive pulmonary disease. Systemic administration of a corticosteroid to treat reversible airway obstruction may cause sodium and water retention and exacerbate heart failure, whereas inhalation therapy is better tolerated.

Diabetes Mellitus

The prevalence and incidence of diabetes mellitus are high in heart failure. β-Blocker treatment is not contraindicated and is of benefit in patients with diabetes and heart failure. In patients who have heart failure and type 2 diabetes, the SGLT2 inhibitors are the preferred antidiabetic agents.[23] Using sacubitril/valsartan reduces the glycated hemoglobin level and the need to institute insulin treatment compared with using an ACE inhibitor.

Neither insulin nor glucagon-like peptide-1 (GLP-1) receptor agonists (GP-1 Ras) increase the risk of developing heart failure, and both are considered to be safe in patients with heart failure. By comparison, several agents are not recommended in patients with severe heart failure. Thiazolidinediones cause sodium and water retention, metformin may cause lactic acidosis in patients with severe heart failure, and saxagliptin, which increases the risk for developing heart failure, should be avoided. Although there is no evidence of a similar risk with other dipeptidyl peptidase-4 inhibitors, these medications also are not recommended.

Abnormal Thyroid Function

Both thyrotoxicosis and hypothyroidism can cause heart failure (and thyrotoxicosis can cause atrial fibrillation, which may precipitate heart failure). Amiodarone can also induce both hypothyroidism and hyperthyroidism, the latter being particularly difficult to diagnose. The risk for thyroid dysfunction may be less with the related antiarrhythmic agent dronedarone, but dronedarone increases mortality in severe heart failure and should be avoided in patients with stage C or D heart failure or recently decompensated heart failure.

Gout and Hyperuricemia

Hyperuricemia and gout (Chapter 252) are common in heart failure and can be caused or aggravated by diuretic treatment. Sacubitril/valsartan and SGLT2 inhibitors reduce serum uric acid levels. Acute gout attacks are better treated with colchicine, oral steroids, or intra-articular steroids rather than with an NSAID. Allopurinol can prevent gouty attacks more safely than febuxostat.[A40]

Renal Dysfunction

Most patients with heart failure have a reduced glomerular filtration rate. ACE inhibitors, ARBs, sacubitril/valsartan, mineralocorticoid receptor antagonists, and SGLT2 inhibitors often cause an early, but small, further reduction in glomerular filtration rate and rise in serum blood urea nitrogen and creatinine levels, which, if limited, should not lead to discontinuation of treatment. Marked increases in blood urea nitrogen and creatinine, however, should prompt consideration of underlying renal artery stenosis (Chapter 110). Renal dysfunction may also be caused by sodium and water depletion (e.g., due to excessive diuresis, diarrhea, and vomiting) that leads to relative hypovolemia and hypotension. Conversely, renal venous congestion can contribute to renal impairment in patients who are markedly volume-overloaded. Nephrotoxic

agents such as NSAIDs are also a common cause of renal dysfunction in heart failure.

Prostatic Obstruction

For prostatic disease (Chapter 114), a 5α-reductase inhibitor may be preferable to an α-adrenoceptor antagonist, which can cause hypotension and salt and water retention.

Iron Deficiency and Anemia

Iron deficiency is very common in heart failure, for reasons that are uncertain, and may be present without concomitant anemia. Several trials have shown that intravenous ferric carboxymaltose or ferric derisomaltose (Chapter 145) improves symptoms, quality of life, and functional capacity when administered to patients who have a serum ferritin level <100 ng/mL or serum ferritin 100 to 299 ng/mL with a transferrin saturation <20%. In patients with heart failure, this treatment can substantially reduce the risk of hospital readmission for heart failure.[A41,A42]

A normocytic, normochromic anemia (Chapter 144) is also common in heart failure, in part because of the high prevalence of renal dysfunction. Malnutrition, blood loss, and underlying iron deficiency may be contributing factors. SGLT2 inhibitors increase the hematocrit and hemoglobin and often correct anemia, possibly by reducing plasma volume and increasing erythropoiesis. The erythropoiesis-stimulating agent darbepoetin is not of benefit in heart failure patients with anemia.

Depression

Depression (Chapter 362) is common in patients with heart failure, perhaps partly owing to disturbance of the hypothalamic-pituitary axis and other neurochemical pathways but also as a result of social isolation and the adjustment to chronic disease. Depression is associated with worse functional status, reduced adherence to treatment, and poor clinical outcomes. Both psychosocial interventions and pharmacologic treatment are helpful. Selective serotonin reuptake inhibitors are believed to be the best-tolerated pharmacologic agents, whereas tricyclic antidepressants should be avoided because of their anticholinergic actions and potential to cause arrhythmias.

Sleep Apnea

Sleep-disordered breathing, including both obstructive and central sleep apnea (Chapter 374), is common in patients with heart failure. Continuous positive airway pressure can improve the symptoms of obstructive sleep apnea in selected patients (Chapter 374), but adaptive servo-ventilation increases the risk of death in patients with heart failure and central sleep apnea.

Drugs to Use with Caution in Heart Failure

Patients with heart failure, especially if it is severe, often have renal and hepatic dysfunction, so any drug excreted predominantly by the kidneys or metabolized by the liver may accumulate (Chapter 25). Similarly, because of their extensive comorbidity, patients with heart failure are inevitably treated with multiple drugs, thereby increasing the risk for drug interactions.

Drugs that should be avoided, if possible, in heart failure include most antiarrhythmic drugs (including dronedarone, although amiodarone and dofetilide may be used), most calcium-channel blockers (with the possible exception of amlodipine, although this drug may increase the risk for pulmonary edema), corticosteroids, NSAIDs, cyclooxygenase-2 inhibitors, thiazolidinediones, saxagliptin, metformin, many antipsychotics (e.g., clozapine), and antihistamines. The U.S. Food and Drug Administration recently raised the concern that the dopamine agonist pramipexole used to treat Parkinson disease (Chapter 378) also might increase the risk for developing heart failure. Some salt substitutes contain substantial amounts of potassium and must be used cautiously. Other dietary constituents (e.g., grapefruit and cranberry juice) and supplements such as St. John's wort can interact with drugs taken by patients with heart failure, especially warfarin and digoxin. α-Adrenoceptor antagonists, commonly given for prostatic symptoms (Chapter 114), may cause hypotension and fluid retention. A variety of anticancer drugs, including trastuzumab, may aggravate heart failure (see Table 164-2).

Other Subtypes of Heart Failure

Heart Failure with Mildly Reduced Left Ventricular Ejection Fraction

In patients with heart failure and a left ventricular ejection fraction >40%, the SGLT2 inhibitors dapagliflozin and empagliflozin (each 10 mg once daily)[24] reduce the risk of heart failure hospitalization substantially and also improve symptoms and health-related quality of life.[A43,A44] In addition, retrospective analyses of several trials suggest that patients with a left ventricular ejection fraction in the range of 41 to 49% respond favorably to other treatments (e.g., an ARNI [or ACE inhibitor or ARB], a β-blocker, and a mineralocorticoid receptor antagonist) shown to be effective in patients with heart failure and a reduced ejection fraction. These therapies can be used to treat patients with heart failure and mildly reduced ejection fraction, along with diuretics as needed to control fluid retention (Fig. 46-5).

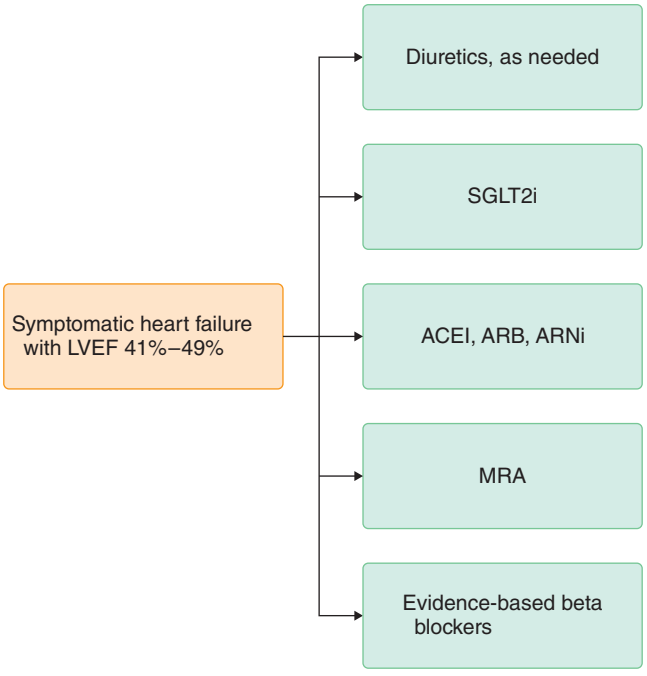


FIGURE 46-5. Treatments for heart failure with mildly reduced left ventricular ejection fraction. ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin-receptor blocker; ARNI = angiotensin receptor-neprilysin inhibitor; LVEF = left ventricular ejection fraction; MRA = mineralocorticoid receptor antagonist; SGLT2i = sodium glucose cotransporter 2 inhibitor. (Reprinted with permission *Circulation*. 2022;145:e895-e1032 ©2022 American Heart Association, Inc.)

Heart Failure with Preserved Left Ventricular Ejection Fraction

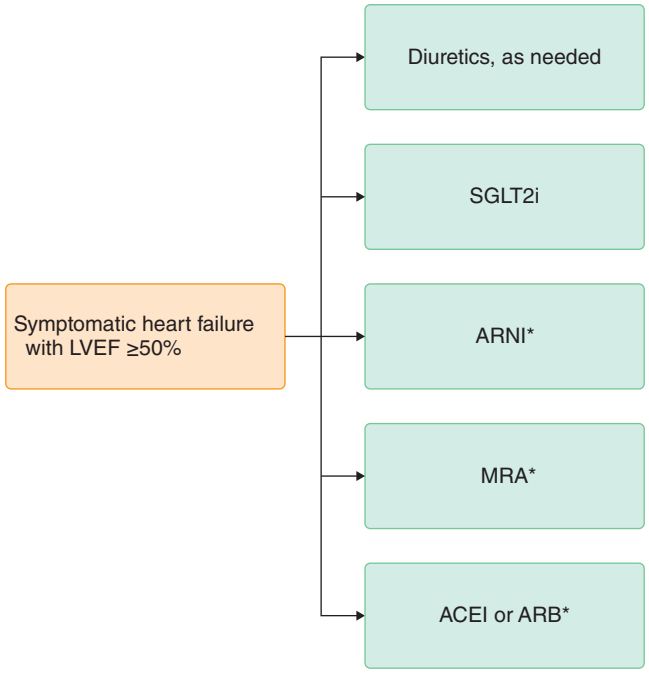
For patients with heart failure and a left ventricular ejection fraction ≥50%, SGLT2 inhibitors (e.g., dapagliflozin 10 mg once daily or empagliflozin 10 mg once daily) reduce the risk of hospitalization for heart failure and improve symptoms and health-related quality of life. Diuretics, as needed to control fluid retention, are also valuable. However, no international consensus exists regarding other pharmacologic therapy (Fig. 46-6). Treatment of the underlying cardiovascular and other disorders that contribute to symptomatic stage C and stage D of heart failure with preserved left ventricular ejection fraction, such as hypertension, myocardial ischemia, and diabetes, is critical and is as for stages A and B (see earlier). In patients with atrial fibrillation, restoration of sinus rhythm or control of the ventricular rate with a β-blocker or a rate-limiting calcium-channel blocker can help control symptoms, although excessive rate control of atrial fibrillation or sinus rhythm may make these patients worse rather than better (Chapter 52). In patients with heart failure and preserved ejection fraction, ivabradine has no benefit on exercise capacity, and isosorbide mononitrate treatment tends to worsen activity levels. Infiltrative cardiomyopathies such as amyloidosis respond to disease-specific therapies (Chapter 47).

Heart Failure Due to Valvular Heart Disease

Heart failure also can arise as a result of regurgitant and stenotic valve disease (Chapter 60). It can sometimes be difficult to determine whether mitral regurgitation is primary or secondary in a patient with heart failure and left ventricular dilation, although a prior history of known valve disease or rheumatic fever may suggest a primary valve problem. The objective of treatment of primary valve disease is the prevention of heart failure by surgical repair or replacement of the diseased valve or valves (Chapter 60). The development of overt heart failure is an ominous sign, sometimes requiring emergent valve replacement (e.g., aortic stenosis) but sometimes indicating that valve replacement may not be possible (e.g., because of severe pulmonary hypertension).

Aortic Stenosis

Evaluation of the aortic valve (Chapter 60) can be difficult in patients with poor left ventricular systolic function. Such patients may have insufficient cardiac output to generate a high gradient across even a severely stenotic valve. Conversely, a calcified and degenerate but nonstenotic aortic valve may appear stenosed simply because it does not open normally in patients with very low cardiac output. A calculated valve area provides a better assessment of the severity of aortic stenosis in these patients. Stress echocardiography (Chapter 43) may help assess the potential for ventricular recovery after relief of aortic stenosis. Transcatheter valve replacement is a valuable technique for patients who have aortic stenosis but are at very high risk for open valve replacement.



*Greater benefit in patients with LVEF closer to 50%.

FIGURE 46-6. Treatments for heart failure with preserved left ventricular ejection fraction. ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin-receptor blocker; ARNI = angiotensin receptor-neprilysin inhibitor; LVEF = left ventricular ejection fraction; MRA = mineralocorticoid receptor antagonist; SGLT2i = sodium glucose cotransporter 2 inhibitor. (Reprinted with permission *Circulation*. 2022;145:e895-e1032 ©2022 American Heart Association, Inc.)

Mitral and Tricuspid Regurgitation

Mitral regurgitation can be a primary cause (organic) or a secondary manifestation (functional) in a patient with heart failure and left ventricular dilation (Chapter 60). In primary mitral regurgitation, surgery sometimes will result in clinical improvement, but some patients with advanced left ventricular dysfunction will not achieve substantial benefit (e.g., mitral valve surgery in a patient with long-standing severe mitral regurgitation). Valve repair is preferable to valve replacement, although neither procedure is proven to improve survival. Generally, medical and device therapy (e.g., CRT) is preferred to isolated valve surgery for secondary regurgitation. The role of transcatheter mitral valve repair is still evolving. Two recent trials have reported conflicting findings, but one suggested that this approach could provide a durable reduction in the risk of death and hospitalization for heart failure in carefully selected patients.[A45] Concomitant tricuspid valve repair may also provide some benefit in patients who have heart failure with both mitral and tricuspid valve regurgitation,[A46] but more data will be required before it can be routinely recommended.

Heart Failure Due to Nonischemic Dilated Cardiomyopathy

Patients with heart failure and normal coronary arteries should be evaluated for possible reversible causes. Untreated hypertension is now an unusual cause of dilated cardiomyopathy in the United States, but hypertension was once a leading cause in the United States and remains a major consideration in many parts of the world. Infiltrative cardiomyopathies (e.g., hemochromatosis, amyloid, sarcoid) and arteritides sometimes have specific recommended therapies (Chapters 47, 83, 174, and 196). Chagas disease (Chapter 318) must be considered in patients from endemic areas. Alcohol and other toxins (e.g., chemotherapeutic agents) are other recognized causes of dilated cardiomyopathy. Dilated cardiomyopathy can also develop in the peripartum period. Most cases of nonischemic dilated cardiomyopathy are usually labeled "idiopathic" (i.e., no specific etiology can be determined), although many may have a genetic origin, especially if there is a positive family history. In many centers routine genetic testing is undertaken in younger patients with unexplained dilated cardiomyopathy, especially in individuals with a family history of heart failure or sudden death and in those with conduction disease (e.g., bundle branch block). First-degree relatives of patients with genetic cardiomyopathies should be counseled and screened. Irrespective of etiology, nonischemic dilated cardiomyopathy should be treated in the same way as dilated ischemic cardiomyopathy.

Heart Failure Due to Hypertrophic Cardiomyopathy

Heart failure can arise in patients with hypertrophic cardiomyopathy because of predominant diastolic dysfunction, associated mitral incompetence, or the development of systolic dysfunction. The management of hypertrophic cardiomyopathy and its complications is often very different from the management of dilated cardiomyopathy (Chapter 47), thereby underscoring the value of echocardiography in the evaluation of the patient with heart failure.

Outpatient Follow-Up

In patients being sent home from the hospital, discharge planning and subsequent management to reduce the risk for readmission are important. Ideally, an effective oral diuretic regimen should have been identified, and fluid-volume and biochemical stability should have been achieved. This optimization of volume status and development of a stable oral regimen before discharge is thought to reduce the risk for early readmission. Treatment with an ARNI (or ACE inhibitor or ARB), a β-blocker, a mineralocorticoid receptor antagonist, and SGLT2 inhibitor should be started in the stabilized patient before discharge. Outpatient follow-up should be arranged to ensure that any of those treatments that have not been started before discharge are initiated after discharge and that the dose of each drug is increased, as tolerated, to the appropriate target.

The key to successful follow-up is the careful tracking of clinical symptoms and the patient's weight, which often involves interviewing not only the patient but also family members, who may be more aware of changes in status than the patient is. Treatment of established heart failure based on natriuretic peptide levels does not appear to improve outcomes compared with best standard care. Continuity of care and seamless transitions from the inpatient to the outpatient setting are crucial aspects of optimal management. Patients with advanced heart failure and patients requiring frequent hospitalization require special attention. Programs that provide telephone-based tracking of daily weights and symptoms can detect deterioration in time to intervene before the need for hospitalization, and an implanted pulmonary artery pressure monitor may be valuable in selected patients. Although these programs may be costly, several evaluations have found them to be cost-effective. Because the care of these patients requires considerable experience and expertise, specialized disease management programs and clinics have been developed and may provide additional benefit compared with traditional care.

PROGNOSIS

The prognosis of patients with heart failure has improved with advances in therapy. Although it is difficult to predict prognosis in individual patients, until recently patients with symptoms at rest (NYHA class IV) have a 30 to 50% annual mortality rate, patients who are symptomatic with mild activity (class III) have mortality rates of 10 to 20% annually, and patients with symptoms only with moderate activity (class II) have a 5 to 10% annual mortality rate. Mortality rates are higher in older patients, men, patients with a reduced left ventricular ejection fraction[25] or underlying coronary heart disease, and patients with higher serum levels of certain biomarkers (e.g., natriuretic peptides and high-sensitivity troponin).[26]

End-of-Life Considerations

Although predicting the trajectory of illness in patients with advanced heart failure is notoriously difficult, it is often apparent when a patient has progressed to end-stage heart failure, commonly associated with concomitant renal failure. In these circumstances, the expertise of the palliative care team may be especially helpful (Chapter 3).[27] Useful websites providing information on palliative care relevant to heart failure are available (https://getpalliativecare.org/whatis/disease-types/congestive-heart-failure-palliative-care/, http://www.goldstandardsframework.org.uk/, and http://www.palliativecarescotland.org.uk/content/links, https://www.hospiceuk.org/what-we-offer/clinical-and-care-support/heart-failure-and-hospice-care). Medications such as parenteral opiates (with an antiemetic) and benzodiazepines may be particularly helpful in relieving dyspnea, anxiety, and pain that arises from ascites, hepatic congestion, lower limb edema, and pressure points. At this stage in the patient's illness, it may be appropriate to discuss withdrawal of conventional treatment, deactivation of an ICD to avoid undesired and unpleasant electrical discharges, and a do-not-resuscitate order if the patient and others involved in the patient's care agree that comfort care is appropriate. Hospice care may be chosen by some at this point.

47 DISEASES OF THE MYOCARDIUM AND ENDOCARDIUM

PERRY M. ELLIOTT AND IACOPO OLIVOTTO

MYOCARDIAL DISEASE

A substantial minority of cases of heart failure result from familial (genetic) or nonfamilial (acquired) disorders, which can be confined to the heart or be multisystem disorders. The term *cardiomyopathy* refers to myocardial disorders in which the heart muscle is structurally and functionally abnormal in the absence of coronary artery disease (Chapter 58), hypertension (Chapter 64), valvular disease (Chapter 60), or congenital heart disease (Chapter 55) sufficient to cause the observed myocardial abnormality. Cardiomyopathies are classified according to ventricular morphology and pathophysiology into four major types: dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, and arrhythmogenic cardiomyopathy (Table 47-1 and Fig. 47-1). Diseases that do not fit into these groups (such as endocardial fibroelastosis and left ventricular noncompaction) are termed unclassified cardiomyopathies. Mixed phenotypes can exist; for example, patients with hypertrophic and dilated cardiomyopathies frequently have a restrictive left ventricular physiology or develop ventricular dilation.

HYPERTROPHIC CARDIOMYOPATHY

DEFINITION AND EPIDEMIOLOGY

Hypertrophic cardiomyopathy is defined as unexplained left ventricular hypertrophy in the absence of abnormal loading conditions (valve disease, hypertension, congenital heart defects) sufficient to explain the degree of hypertrophy. The disease occurs worldwide and in all racial groups, with a prevalence of between 0.2 and 0.5%.

PATHOBIOLOGY

Hypertrophic cardiomyopathy is usually familial with autosomal dominant inheritance. Mutations in sarcomeric contractile protein genes (E-Table 47-1) account for approximately 50 to 60% of cases.[1] More than 1400 different mutations have been identified, with marked variation in disease penetrance and clinical expression. The most common involved genes are *MYH7*, which

47 DISEASES OF THE MYOCARDIUM AND ENDOCARDIUM

PERRY M. ELLIOTT AND IACOPO OLIVOTTO

MYOCARDIAL DISEASE

A substantial minority of cases of heart failure result from familial (genetic) or nonfamilial (acquired) disorders, which can be confined to the heart or be multisystem disorders. The term *cardiomyopathy* refers to myocardial disorders in which the heart muscle is structurally and functionally abnormal in the absence of coronary artery disease (Chapter 58), hypertension (Chapter 64), valvular disease (Chapter 60), or congenital heart disease (Chapter 55) sufficient to cause the observed myocardial abnormality. Cardiomyopathies are classified according to ventricular morphology and pathophysiology into four major types: dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, and arrhythmogenic cardiomyopathy (Table 47-1 and Fig. 47-1). Diseases that do not fit into these groups (such as endocardial fibroelastosis and left ventricular noncompaction) are termed unclassified cardiomyopathies. Mixed phenotypes can exist; for example, patients with hypertrophic and dilated cardiomyopathies frequently have a restrictive left ventricular physiology or develop ventricular dilation.

HYPERTROPHIC CARDIOMYOPATHY

DEFINITION AND EPIDEMIOLOGY

Hypertrophic cardiomyopathy is defined as unexplained left ventricular hypertrophy in the absence of abnormal loading conditions (valve disease, hypertension, congenital heart defects) sufficient to explain the degree of hypertrophy. The disease occurs worldwide and in all racial groups, with a prevalence of between 0.2 and 0.5%.

PATHOBIOLOGY

Hypertrophic cardiomyopathy is usually familial with autosomal dominant inheritance. Mutations in sarcomeric contractile protein genes (E-Table 47-1) account for approximately 50 to 60% of cases.[1] More than 1400 different mutations have been identified, with marked variation in disease penetrance and clinical expression. The most common involved genes are *MYH7*, which

ABSTRACT

Diseases of the myocardium and endocardium commonly present with heart failure and/or arrhythmia. Myocardial diseases are termed cardiomyopathies when they are unexplained by coronary artery, hypertensive, valvular, or congenital heart disease and are classified by their predominant phenotype. Most cardiomyopathies are heritable, with autosomal dominant inheritance, and have a defined genetic cause with pathogenic variants in sarcomere, cytoskeletal, and desmosomal genes that cause hypertrophic, dilated, restrictive, and arrhythmogenic cardiomyopathy. Other uncommon genetic disorders may present with overlapping phenotypes but different inheritance patterns and genetic bases (e.g., hypertrophic cardiomyopathy in Anderson-Fabry disease or Noonan syndrome). Diagnosis of the cardiomyopathies relies on electrocardiography (ECG) and imaging and exclusion of significant abnormalities related to more common cardiac disorders. Management focuses on familial evaluation and counseling regarding genetic and clinical risk, treatments to improve symptoms, assessment of the risk of arrhythmias, and, when necessary, treatments (e.g., implantable defibrillators) to prevent sudden death. Molecular genetic analysis is recommended when there is a diagnostic phenotype and is particularly valuable when cascade screening of family members is feasible. Myocarditis, an inflammatory process of the myocardium, is most often caused by infections (e.g., Chagas disease, virus), toxins (e.g., chemotherapy, recreational drugs), and immunologic disease (e.g., systemic lupus erythematosus). Definitive diagnosis relies on demonstration of inflammation in the myocardium; more often a presumptive diagnosis is made based on clinical and ECG features, because endomyocardial biopsy is usually only performed in the deteriorating patient or to exclude giant cell myocarditis, which is usually fatal if not treated with prolonged immunosuppression. Endocardial disease, characterized as with or without hypereosinophilia, and primary cardiac tumors are rare.

E-TABLE 47-1 SOME GENETIC CAUSES OF CARDIOMYOPATHY

PROTEIN NAME	GENE SYMBOL	INHERITANCE	PHENOTYPE	ESTIMATED FREQUENCY
SARCOMERIC PROTEINS				
Cardiac β-myosin heavy chain	MYH7	AD	HCM; DCM; LVNC; RCM; Laing distal myopathy	HCM 30-40%; DCM 4-6%
Cardiac myosin-binding protein C	MYBPC3	AD	HCM; DCM; LVNC	HCM 30-40%; DCM ~1%
Cardiac troponin T	TNNT2	AD	HCM, DCM, RCM	HCM 10-15%; DCM 3-5%
Cardiac troponin I	TNNI3	HCM: AD; DCM: AD, AR	HCM; RCM; DCM	HCM 2-5%; RCM frequent; DCM < 1%
α-Tropomyosin	TPM1	AD	HCM; DCM	HCM ~1-2%; DCM <1%
Regulatory myosin light chain	MYL2	AD	HCM; DCM	HCM ~1%; DCM rare
Cardiac actin	ACTC1	AD	LVNC; DCM; HCM; CHD	DCM ~1%; HCM ~1%
Essential myosin light chain	MYL3	AD	HCM; DCM	Rare
Cardiac troponin C	TNNC1	AD	HCM; DCM	HCM <1%
Actin, alpha 1, skeletal muscle	ACTA1	AD	HCM, DCM, skeletal/nemaline myopathy	Rare
SARCOMERE AND Z-DISC–RELATED PROTEINS				
Titin	TTN	AD	DCM; LVNC; skeletal myopathy	DCM 15-25%
BCL2-associated athanogene 3	BAG3	AD	DCM; skeletal myopathy	2-4%
FH1/FH2 domain-containing protein 3	FHOD3	AD	HCM	HCM 1-2%
Titin-cap or telethonin	TCAP	AD	HCM; DCM; skeletal myopathy	Rare
Cysteine and glycine-rich protein 3 (cardiac LIM protein)	CSRP3	AD; AR	HCM; DCM	Rare
Four-and-a-half LIM protein 1	FHL1	X linked	HCM, muscular dystrophy	Rare
Myozenin 2	MYOZ2	AD	HCM	Rare
CYTOSKELETAL PROTEINS				
Desmin	DES	AD, AR	DCM; RCM; ACM; skeletal myopathy; CCD	DCM <1%
Filamin C	FLNC	AD	ACM; DCM; RCM; skeletal myopathy	DCM 1%; ACM ~5%
Dystrophin	DMD	XL	DCM; skeletal myopathy	DCM <1%
Caveolin-3	CAV3	AD	HCM; DCM; skeletal myopathy	Rare
α-B crystallin	CRYAB	AD	DCM; skeletal myopathy	Rare
α-, β-, γ-, and δ-sarcoglycans	SGCA, SGCB, SGCG, SGCD	AR; SGCD: AD	DCM; muscular dystrophy	Rare
Striated muscle preferentially expressed protein kinase	SPEG	AR	DCM; skeletal myopathy	Rare
NUCLEAR PROTEINS				
Lamin A/C	LMNA	AD	DCM; skeletal myopathy; CCD; ACM	DCM 4-8%
Emerin	EMD	XL recessive	DCM; skeletal myopathy; CCD	DCM <1%
Dystrobrevin alpha	DTNA	AD	DCM; LVNC	Rare
α-Kinase 3 deficiency	ALPK3	AR/AD	HCM; DCM	HCM 1-2%
PR domain-containing protein 16	PRDM16	AD	LVNC; DCM	Rare
Transmembrane protein 43	TMEM43	AD	ACM; DCM; skeletal myopathy	Rare
ION CHANNEL AND ION CHANNEL RELATED				
Cardiac sodium channel	SCN5A	AD	DCM; CCD; Brugada syndrome, LQTS	DCM <1%
Potassium/sodium hyperpolarization-activated cyclic nucleotide-gated channel 4	HCN4	AD	LVNC; CCD; Brugada syndrome	Rare
Regulatory SUR2A subunit of the cardiac K(ATP) channel	ABCC9	AD	DCM; HCM in Cantú syndrome	Rare
Anoctamin-5	ANO5	AR	DCM; skeletal myopathy	Rare
Voltage-dependent L-type calcium channel subunit alpha-1C	CACNA1C	AD	HCM in Timothy syndrome; LQTS	Rare
DESMOSOMAL PROTEINS				
Plakophilin 2	PKP2	AD, AR	ARVC; DCM	AD 30-40%; AR rare
Desmoglein 2	DSG2	AD	ARVC; ACM; DCM	12-40%
Desmoplakin	DSP	ARVC: AD; Carvajal syndrome: AR	ACM; ARVC; DCM in Carvajal syndrome	ACM/ARVC 6-39%

E-TABLE 47-1 SOME GENETIC CAUSES OF CARDIOMYOPATHY—cont'd

PROTEIN NAME	GENE SYMBOL	INHERITANCE	PHENOTYPE	ESTIMATED FREQUENCY
Desmocollin 2	DSC2	AD	ARVC	Rare
Junction plakoglobin	JUP	ARVC: Naxos disease: AR	ARVC in Naxos disease	Rare
Phospholamban	PLN	AD	ACM; DCM; HCM	DCM founder effect in Holland, otherwise rare
Junctophilin 2	JPH2	AD	HCM	Rare
METABOLIC PROTEINS				
Amylo-1,6-glucosidase	AGL	AR	HCM in Forbes disease	Rare
Acid α-1,4-glucosidase	GAA	AR	HCM, DCM in Pompe disease	Rare
α-Galactosidase A	GLA	XL dominant	HCM in Anderson-Fabry disease	Rare
Lysosomal-associated membrane protein 2	LAMP2	XL dominant	HCM, DCM in Danon disease	Rare
Protein kinase, AMP- activated, γ2 noncatalytic subunit	PRKAG2	AD	HCM; Wolff-Parkinson-White syndrome	Rare
Frataxin	FXN	AR	HCM in Friedreich ataxia	Rare
Hereditary hemochromatosis	HFE	AR	DCM and RCM in hereditary hemochromatosis	Rare
Mitochondrial genes encoding mitochondrial components	MT-TG, MT-TY, MT-ND5, others	Maternal	HCM in MELAS, MERRF syndromes	Rare
Dolichol kinase	DOLK	AR	DCM	Rare
Tafazzin	TAZ	XL recessive	DCM; LVNC in Barth syndrome	Rare
1-Acyl-sn-glycerol-3-phosphate acyltransferase beta	AGPAT2	AR	HCM in Berardinelli-Seip syndrome	Rare
Fumarylacetoacetase	FAH	AR	HCM	Rare
β-Galactosidase	GLB1	AR	HCM in Morquio syndrome A	Rare
β-Glucuronidase	GUSB	AR	HCM in mucopolysaccharidosis VII	Rare
Glycogenin-1	GYG1	AR	HCM; DCM; skeletal myopathy	Rare
Malonyl-CoA decarboxylase, mitochondrial	MLYCD	AR	HCM; LVNC; DCM	Rare
Phosphopantothenate--cysteine ligase	PPCS	AR	DCM	Rare
Solute carrier family 22 member 5	SLC22A5	AR	HCM, DCM long and short QT in primary systemic carnitine deficiency	Rare
Alanine-tRNA ligase, mitochondrial	AARS2	AR	HCM, DCM in combined oxidative phosphorylation deficiency 8	Rare
Acyl-CoA dehydrogenase family member 9, mitochondrial	ACAD9	AR	HCM/DCM in mitochondrial complex I deficiency	Rare
Very long-chain specific acyl-CoA dehydrogenase, mitochondrial	ACADVL	AR	HCM/DCM in very long-chain acyl-CoA dehydrogenase deficiency	Rare
Acylglycerol kinase, mitochondrial	AGK	AR	HCM in Sengers syndrome	Rare
ATP synthase mitochondrial F1 complex assembly factor 2	ATPAF2	AR	Syndromic HCM	Rare
Cytochrome c oxidase assembly factor 5	COA5	AR	Syndromic HCM	Rare
Cytochrome c oxidase assembly factor 6 homolog	COA6	AR	Syndromic HCM	Rare
4-Hydroxybenzoate polyprenyltransferase, mitochondrial	COQ2	AR	Syndromic HCM	Rare
Cytochrome c oxidase assembly protein COX15 homolog	COX15	AR	Syndromic HCM	Rare
Cytochrome c oxidase subunit 6B1	COX6B1	AR	Syndromic HCM	Rare
Dihydrolipoyl dehydrogenase, mitochondrial	DLD	AR	Syndromic HCM	Rare
Mitochondrial import inner membrane translocase subunit TIM14	DNAJC19	AR	Syndromic DCM; LVNC	Rare
Zinc phosphodiesterase ELAC protein 2	ELAC2	AR	Syndromic HCM; DCM	Rare

E-TABLE 47-1 SOME GENETIC CAUSES OF CARDIOMYOPATHY—cont'd

PROTEIN NAME	GENE SYMBOL	INHERITANCE	PHENOTYPE	ESTIMATED FREQUENCY
FAD-dependent oxidoreductase domain-containing protein 1	FOXRED1	AR	Syndromic HCM	Rare
Elongation factor G, mitochondrial	GFM1	AR	Syndromic DCM; HCM; CHD	Rare
Lipoyl synthase, mitochondrial	LIAS	AR	HCM in Leigh syndrome	Rare
39 S ribosomal protein L3, mitochondrial	MRPL3	AR	Syndromic HCM	Rare
39 S ribosomal protein L44, mitochondrial	MRPL44	AR	Syndromic HCM	Rare
28 S ribosomal protein S22, mitochondrial	MRPS22	AR	Syndromic HCM	Rare
Protein MTO1 homolog, mitochondrial	MTO1	AR	Syndromic HCM	Rare
Inorganic pyrophosphatase 2, mitochondrial	PPA2	AR	Syndromic DCM	Rare
Glutamyl-tRNA(Gln) amidotransferase subunit A, mitochondrial	QRSL1	AR	Syndromic HCM	Rare
Protein SCO2 homolog, mitochondrial	SCO2	AR/AD	Syndromic HCM	Rare
Succinate dehydrogenase [ubiquinone] flavoprotein subunit, mitochondrial	SDHA	AR	LVNC; DCM; HCM in Leigh syndrome	Rare
Phosphate carrier protein, mitochondrial	SLC25A3	AR	Syndromic HCM	Rare
Surfeit locus protein 1	SURF1	AR	DCM, HCM in Leigh syndrome	Rare
Transmembrane protein 70, mitochondrial	TMEM70	AR	Syndromic HCM	Rare
ADP/ATP translocase 1	SLC25A4	AR/AD	Syndromic HCM; encephalopathy	Rare
Pyruvate dehydrogenase E1 component subunit alpha, somatic form, mitochondrial	PDHA1	XL dominant	HCM, CCD	Rare
Phosphorylase b kinase regulatory subunit alpha, skeletal muscle isoform	PHKA1	XL	HCM	Rare
Seipin	BSCL2	AR	HCM in Berardinelli-Seip syndrome	Rare
Phosphomannomutase 2	PMM2	AR	Syndromic HCM	Rare
OTHER GENES				
RNA-binding protein 20	RBM20	AD	DCM; LVNC	3-5%
Homeobox protein Nkx-2.5	NKX2-5	AD	LVNC; CHD	<1%
Muscle RING Finger 1 (MuRF1)	TRIM63	AR	HCM; skeletal myopathy	Rare
Transcription factor TBX20	TBX20	AD	DCM; LVNC; CHD	<1%
Hereditary amyloidosis	TTR	AD	HCM and RCM in hereditary amyloidosis	Rare
Alström syndrome protein 1	ALMS1	AR	DCM in Alström syndrome	Rare
Eyes absent 4	EYA4	AD	DCM	Rare
Fukutin-related protein	FKRP	AD, AR	DCM; skeletal myopathy	Rare
Fukutin	FKTN	AD, AR	DCM; skeletal myopathy	Rare
F-box–only protein 32	FBXO32	AR	DCM	Rare
Laminin α2	LAMA2	AR	DCM; skeletal myopathy	Rare
Transcription factor GATA-4	GATA4	AD	DCM; CHD	Rare
Transcription factor GATA-6	GATA6	AD	DCM; CHD	Rare
Kelch-like protein 24	KLHL24	AD/AR	DCM in epidermolysis bullosa	Rare
Cardiotrophin 1	CTF1	AD	DCM	Rare
αT-catenin	CTNNA3	AD	ARVC; ACM	Rare
RAS-MAPK pathway	PTPN11, RAF1, SOS1, KRAS, HRAS, BRAF, NRAS, MEK1-2, RIT1, SHOC2, SOS2, SPRY1, others	AD-de novo	HCM in Noonan, LEOPARD, Costello and CFC syndromes	Rare
Leucine-zipper–like transcriptional regulator 1	LZTR1	AR	HCM in Noonan syndrome	Rare

E-TABLE 47-1 SOME GENETIC CAUSES OF CARDIOMYOPATHY—cont'd

PROTEIN NAME	GENE SYMBOL	INHERITANCE	PHENOTYPE	ESTIMATED FREQUENCY
Dual specificity mitogen-activated protein kinase kinase 1	MAP2K1	AD	HCM in CFC syndrome	Rare
Dual specificity mitogen-activated protein kinase kinase 2	MAP2K2	AD	HCM in CFC syndrome	Rare
E3 ubiquitin-protein ligase CBL	CBL	AD	HCM in Noonan-like syndrome	Rare
Non-POU domain-containing octamer-binding protein	NONO	XL-dominant	LVNC; CHD	Rare
Pleckstrin homology domain	PLEKHM2	AR	DCM; LVNC	Rare

ACM = arrhythmogenic cardiomyopathy; AD = autosomal dominant; AR = autosomal recessive; ARVC = arrhythmogenic right ventricular cardiomyopathy; CCD = cardiac conduction disease; CFC = cardiofaciocutaneous; CHD = congenital heart disease; CPVT = catecholaminergic polymorphic ventricular tachycardia; DCM = dilated cardiomyopathy; HCM = hypertrophic cardiomyopathy; LQTS = long QT syndrome; LVNC = left ventricular noncompaction; MELAS = mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; MERRF = myoclonic epilepsy with ragged red fibers; RCM = restrictive cardiomyopathy; SGCD = sarcoglycan delta; XL = X-linked.

TABLE 47-1 PROFILES OF MYOCARDIAL DISEASE

	HYPERTROPHIC	DILATED	RESTRICTIVE	ARRHYTHMOGENIC
Causes	Genetic (see E-Table 47-1) Infiltrative or storage disease	Myocarditis (see Table 47-3) Metabolic/endocrine Genetic (see E-Table 47-1)	Infiltrative or storage diseases (see Table 47-7) Endomyocardial (e.g., Löffler, carcinoid) Genetic (see E-Table 47-1)	Genetic (see E-Table 47-1)
LV ejection fraction	Increased or normal	Reduced	Normal or reduced	LV and RV normal or mildly reduced until end stage
LV end-diastolic dimension	Usually decreased	Increased	Normal	LV and RV normal or mildly increased until end stage
LV wall thickness	Increased	Normal	Normal or mildly increased	Normal
Atrial size	Increased	Increased	Increased; may be massive	Atria normal until end stage
Valvular disease	Mitral regurgitation (SAM)	Mitral (functional); tricuspid regurgitation in late stages	Mitral and tricuspid regurgitation, rarely severe	
Common symptoms	Dyspnea; chest pain, syncope, palpitation, fatigue Late: orthopnea, PND	Dyspnea, fatigue Late: orthopnea, PND	Dyspnea Late: orthopnea, PND, right-sided heart failure	Palpitations, syncope End stage: right and/or left heart failure
Arrhythmia	Atrial fibrillation, ventricular tachycardia; conduction block in *PRKAG2*, mitochondrial; Fabry disease	Ventricular tachyarrhythmias; heart block in Chagas disease, giant cell myocarditis, laminopathies	Atrial fibrillation; conduction block in sarcoidosis, amyloidosis, desminopathy	Biventricular ectopy and tachycardia

LV = left ventricle; PND = paroxysmal nocturnal dyspnea; PRKAG2 = protein kinase, AMP-activated, gamma 2 noncatalytic subunit mutation; RV = right ventricle; SAM = systolic anterior motion of mitral valve.

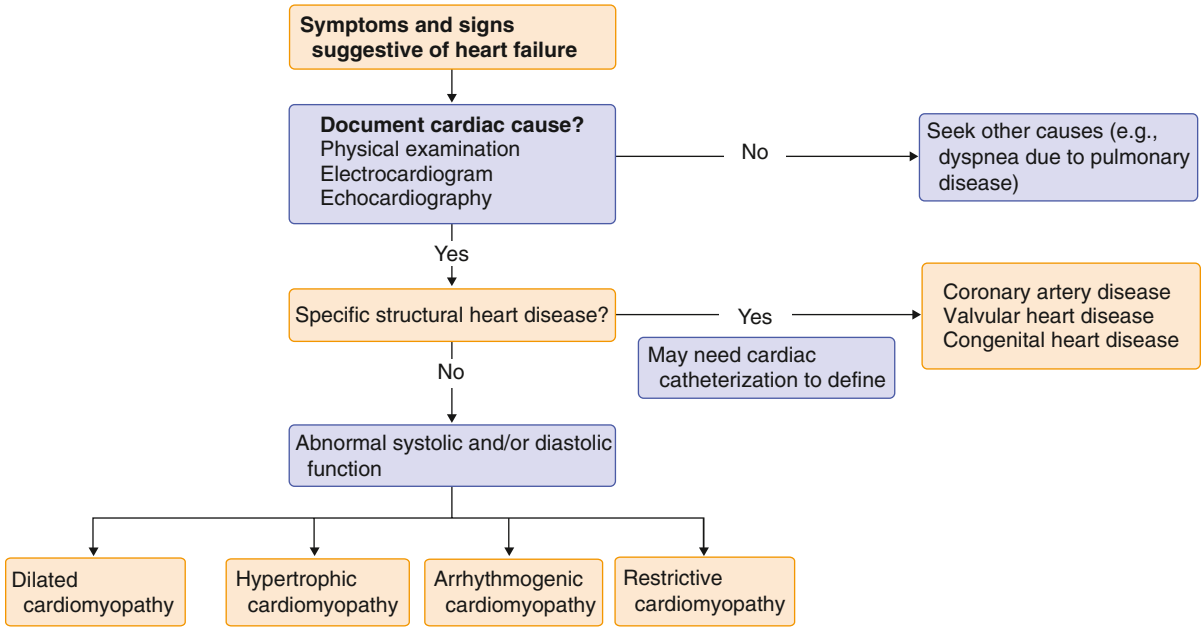

FIGURE 47-1. Initial approach to classification of cardiomyopathy. The evaluation of symptoms or signs consistent with heart failure first includes confirmation that they can be attributed to a cardiac cause. Although this conclusion is often apparent from routine physical examination and electrocardiography, echocardiography serves to confirm cardiac disease and provides clues to the presence of other cardiac diseases, such as valve disease or congenital heart disease. Having excluded these conditions, cardiomyopathy is generally considered to be dilated, restrictive, or hypertrophic, as shown in Table 47-1. Patients with apparently normal cardiac structure and contraction are occasionally found to demonstrate abnormal intracardiac flow patterns consistent with diastolic dysfunction but should also be evaluated carefully for other causes of their symptoms. Most patients with so-called diastolic dysfunction also demonstrate at least borderline criteria for left ventricular hypertrophy, frequently in the setting of chronic hypertension and diabetes. A moderately decreased ejection fraction without marked dilation or a pattern of restrictive cardiomyopathy may represent either a distinct entity or a transition between acute and chronic disease.

codes for the cardiac β-myosin heavy chain, and *MYBPC3*, which codes for myosin binding protein C. A similar clinical phenotype is seen in association with other uncommon genetic disorders, including Noonan syndrome (Chapter 55), Friedreich ataxia (Chapter 389), neurofibromatosis (Chapter 385), hereditary spherocytosis (Chapter 147), respiratory chain disorders, glycogen storage diseases (Chapter 191), and lysosomal storage disorders (Chapter 192), especially Fabry and Danon disease.

Pathology

In its original classical form, hypertrophic cardiomyopathy causes asymmetric myocardial hypertrophy preferentially involving the anteroseptal wall. However, a wide spectrum of patterns is now recognized, including concentric, midventricular, and apical. Older individuals often have hypertrophy that is limited to the basal portion of the sigmoid-shaped septum, frequently in the context of sporadic, genotype-negative disease. The right ventricular free wall and papillary muscles are often involved. The papillary muscles are often hypertrophied, are displaced anteriorly, may be bifid, and occasionally are implanted directly into the mitral leaflet, with poorly developed or absent chordae. The mitral leaflets are consistently elongated, irrespective of the degree of hypertrophy, and are prone to developing systolic anterior motion and dynamic outflow obstruction. Myocardial crypts, apical hypertrabeculation, and apical-septal myocardial bundles constitute ancillary phenotypic traits, which can be found

also in genotype-positive individuals who lack myocardial hypertrophy. Apical aneurysms may develop, particularly in patients with mid-apical hypertrophy and mid-ventricular obstruction.

At the histologic level, hypertrophic cardiomyopathy is characterized by hypertrophy of cardiomyocytes, areas of myocytic disarray, and interstitial fibrosis. Myocyte disarray refers to architectural disorganization of the myocardium, with adjacent myocytes aligned obliquely or perpendicular to each other in association with increased interstitial collagen. The myofibrillar architecture within the myocyte is also disorganized. The coronary microcirculation is affected, with medial and intimal hyperplasia that can obliterate the vessel's lumen and impair vasodilatation.

Pathophysiology

Genetic mutations associated with hypertrophic cardiomyopathy can result in an overall gain of function of the sarcomere, thereby leading to abnormal cellular metabolism and an inefficient utilization of energy. Myocardial hypertrophy, which is a compensatory mechanism to this altered metabolic state, contributes to diastolic dysfunction. Myocardial fibrosis is common and contributes to progressive systolic dysfunction.

About 50% of patients develop left ventricular outflow tract obstruction at rest or with exercise owing to systolic anterior movement of the mitral valve leaflets. Obstruction may also occur at the mid-ventricular level in patients who have distal hypertrophy because of systolic obliteration of the ventricular cavity with the interposition of an abnormally positioned papillary muscle; this type of obstruction is associated with the development of apical aneurysms. The occurrence and severity of obstruction typically vary over time in individual patients and are exacerbated by dehydration, standing, increased adrenergic states, vasodilators, and ingestion of food and alcohol.

CLINICAL MANIFESTATIONS

Most patients are asymptomatic or have only mild or intermittent symptoms, and the diagnosis is often made as a result of family screening or the incidental detection of a heart murmur or an electrocardiographic (ECG) abnormality. However, a lack of symptoms may reflect the patient's long-term adaptation to diminished exercise. Symptoms can develop at any age, even many years after the appearance of ECG or echocardiographic manifestations of left ventricular hypertrophy. On occasion, sudden death or syncope may be the initial presentation.

Symptomatic progression is usually slow and associated with a gradual deterioration in left ventricular function over decades, often associated with the development of atrial fibrillation. Less than 5% of patients have rapid, symptomatic deterioration and often develop refractory heart failure owing to hypokinetic and/or restrictive evolution.

Approximately 20 to 30% of adults develop chest pain (Chapters 39 and 56), which may occur on exertion, at rest, or nocturnally. Postprandial angina associated with mild exertion is typical. Mild to moderate dyspnea on exertion is relatively common. Occasionally, patients may develop paroxysmal nocturnal dyspnea, often due to paroxysmal arrhythmias such as atrial fibrillation. Approximately 20% of patients experience syncope (Chapters 39 and 49),[2] and a similar proportion complain of presyncope. Angina and syncope are most frequent in patients who have dynamic left ventricular outflow obstruction. Palpitations (Chapter 49) are frequent and are usually attributable to supraventricular or ventricular ectopy.

DIAGNOSIS

The initial diagnostic evaluation must include a comprehensive medical history focusing on cardiovascular symptoms, a family history focusing on premature cardiac disease or death, a careful physical examination, a 12-lead ECG, and a two-dimensional echocardiogram.[3] A three- to four-generation family history, which should be obtained in all patients with a new diagnosis of cardiomyopathy, helps determine the probability of familial disease and its mode of inheritance.

Clinical examination of the cardiovascular system is often normal. In the presence of left ventricular outflow tract obstruction, the arterial pulse has a rapid upstroke and downstroke (sometimes with a bisferiens character), the apex beat is sustained or double (reflecting a palpable atrial impulse followed by left ventricular contraction), and auscultation will demonstrate a systolic ejection murmur that is heard loudest at the left sternal edge and that radiates to the right upper sternal edge and apex (Chapter 39). Most patients with left ventricular outflow tract obstruction also have the murmur of functional mitral regurgitation, which results from failure of the mitral valve leaflets to coapt due to the systolic anterior motion of the mitral valve. Physiologic and pharmacologic maneuvers that decrease afterload or venous return (e.g., standing, Valsalva maneuver, inhalation of amyl nitrite) or increase contractility (e.g., a post-extrasystole beat) will increase the intensity of the murmur, whereas interventions that increase afterload and venous return (e.g., squatting or handgrip) will reduce it (see Table 39-8). In contrast, physical signs in most patients who do not have left ventricular outflow tract obstruction are subtle and are limited to features that reflect the hyperdynamic contraction (rapid upstroke pulse) and poorly compliant right (prominent *a* wave in jugular venous pressure) and left (S_4 gallop, double-apex beat) ventricles (Chapter 39).

The general evaluation must always include an overview of potential extracardiac manifestation, which may help distinguish classic disease from rare genotypes that have radically different pathobiology, clinical course, and therapeutic strategies. These diseases include lysosomal storage diseases such Fabry, Danon, and Pompe diseases (Chapter 191); syndromes such as Noonan and LEOPARD; and mitochondrial diseases. Noonan syndrome is characterized by short stature, developmental delay, cutaneous abnormalities, hypertelorism, ptosis, low-set posteriorly rotated ears, and webbed neck. These features are shared with the less common LEOPARD syndrome (Noonan syndrome with multiple lentigines [NSML]). Angiokeratomas, anhidrosis, Raynaud-like symptoms with neuropathy, cornea verticillata, retinal vascular dilation, tinnitus, diarrhea, and proteinuria are typical features of Fabry disease (Chapter 192). Patients with mitochondrial diseases such as mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS) have a matrilinear pattern of inheritance and present with short stature, lactic acidosis, severe exercise intolerance, neurosensory deafness, juvenile-onset diabetes, and strokelike episodes.

Diagnostic Testing

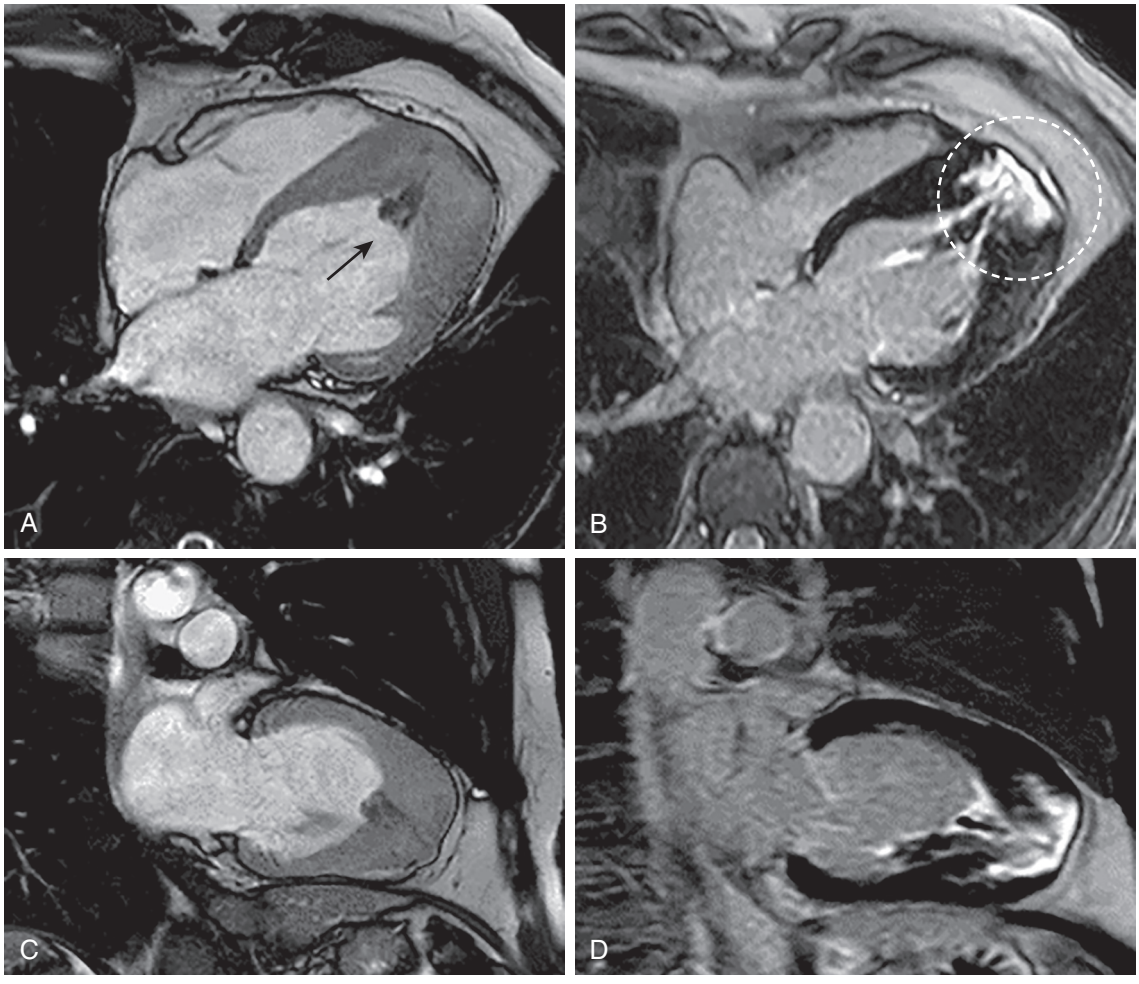
More than 95% of patients have abnormal ECG findings, but no changes are disease specific. The most common abnormalities are increased QRS voltage consistent with left ventricular hypertrophy, left axis deviation (15 to 20%), abnormal Q waves (25 to 30%, most commonly in inferolateral leads), and ST segment or T wave changes (>50%). An isolated increase in the QRS voltage without ST segment changes or T wave inversion is rare in hypertrophic cardiomyopathy. The presence of predominantly distal or apical thickening is associated with giant negative T wave inversion, which is maximal in leads V_3 and V_4.

Two-dimensional echocardiography (Chapter 43), which is the mainstay of diagnostic imaging, may be complemented by magnetic resonance imaging (MRI; Chapter 44) and computed tomography (CT; Chapter 44) for more precise definition of the extent and distribution of the hypertrophy and other relevant phenotypic features. The hypertrophy is often asymmetric and involves the anterior and posterior intraventricular septum (Fig. 47-2). The hypertrophy, however, may be more generalized and involve the free wall of the left ventricle, or it may be localized and confined to areas other than the septum, such as the apex (E-Fig. 47-1), lateral wall, or posterior wall of the left ventricle. Hypertrophy can completely obliterate the left ventricular outflow tract (E-Fig. 47-2). Systolic anterior motion of the mitral valve prevents normal coaptation of the mitral leaflets and results in mitral regurgitation (E-Fig. 47-3).

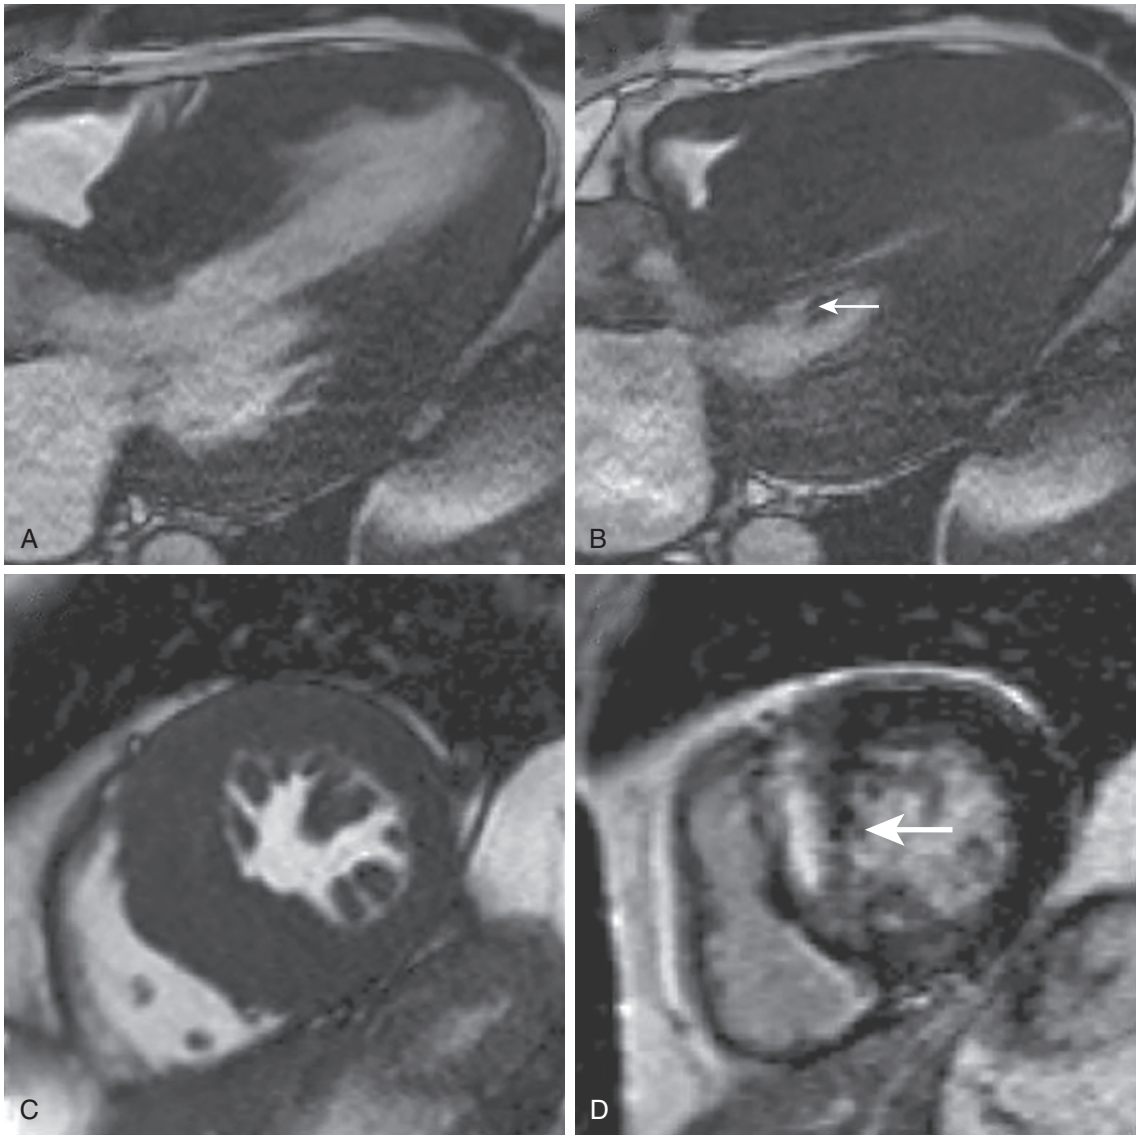
The echocardiogram also can measure left ventricular outflow tract obstruction, both at rest and after provocative maneuvers. Patients with an outflow tract gradient of 30 mm Hg or more are considered to have obstructive disease, with severe obstruction defined as a gradient ≥50 mm Hg. Exercise echocardiography is essential to assess the severity of dynamic obstruction on effort, particularly in physically active individuals, because resting values may be falsely reassuring.

Most patients with hypertrophic cardiomyopathy have left atrial enlargement as well as echocardiographic evidence of diastolic dysfunction. Magnetic resonance imaging provides accurate characterization of tissue and allows the identification of edema and replacement fibrosis (E-Fig. 47-4), while also aiding in the exclusion of rare mimics of hypertrophic cardiomyopathy such as amyloidosis (Chapter 174). Late in the disease, patients often develop left ventricular dilation (E-Fig. 47-5.)

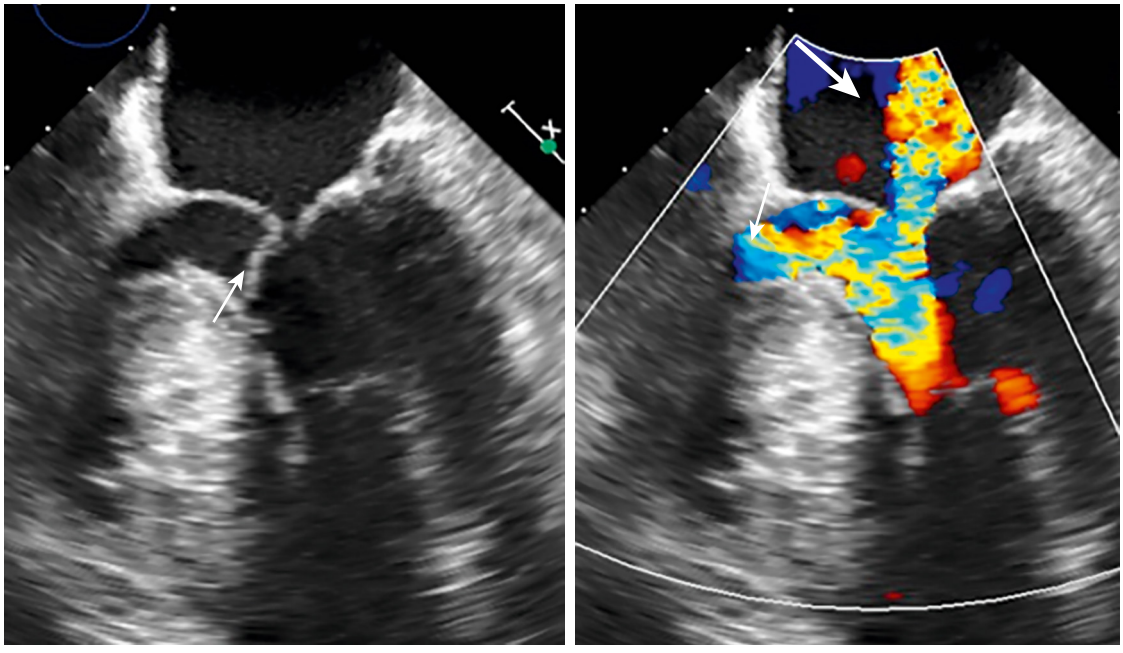
When it is available, cardiopulmonary exercise testing with metabolic gas exchange measurements provides an accurate and reproducible assessment of exercise capacity, which can be followed serially, and it is most useful in patients who have evidence of myocardial fibrosis and progressive heart failure. Cardiac catheterization is rarely required for diagnosis or management, but it may be indicated when measurement of intracardiac pressures is required to guide therapeutic decisions (e.g., in patients with severe mitral regurgitation) and for the exclusion of coexistent coronary artery disease in patients with chest pain.



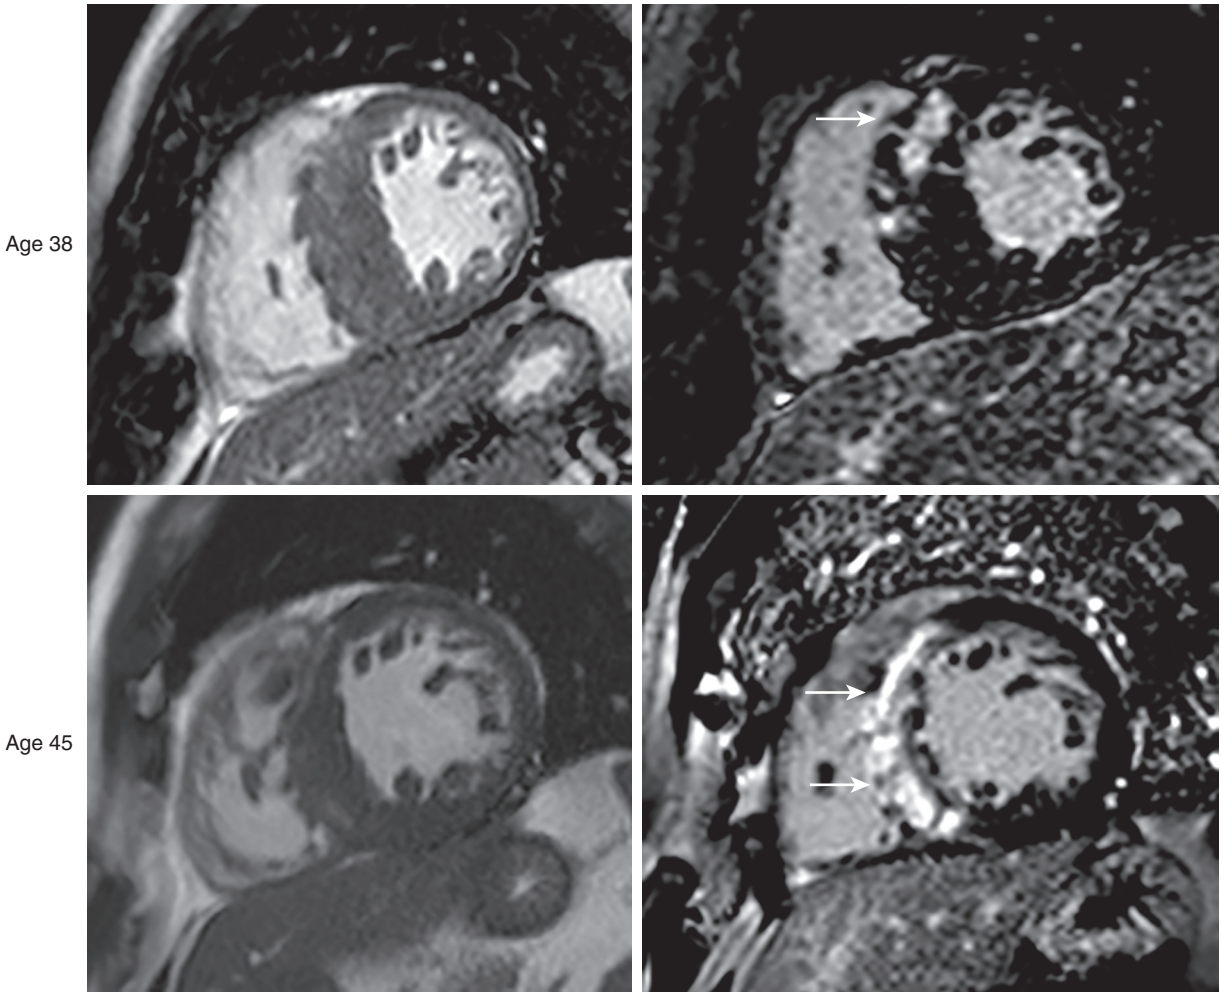
E-FIGURE 47-1. Apical hypertrophic cardiomyopathy. Magnetic resonance imaging shows apical hypertrophy with thrombosis *(small arrow)* and fibrosis *(dotted circle)*.



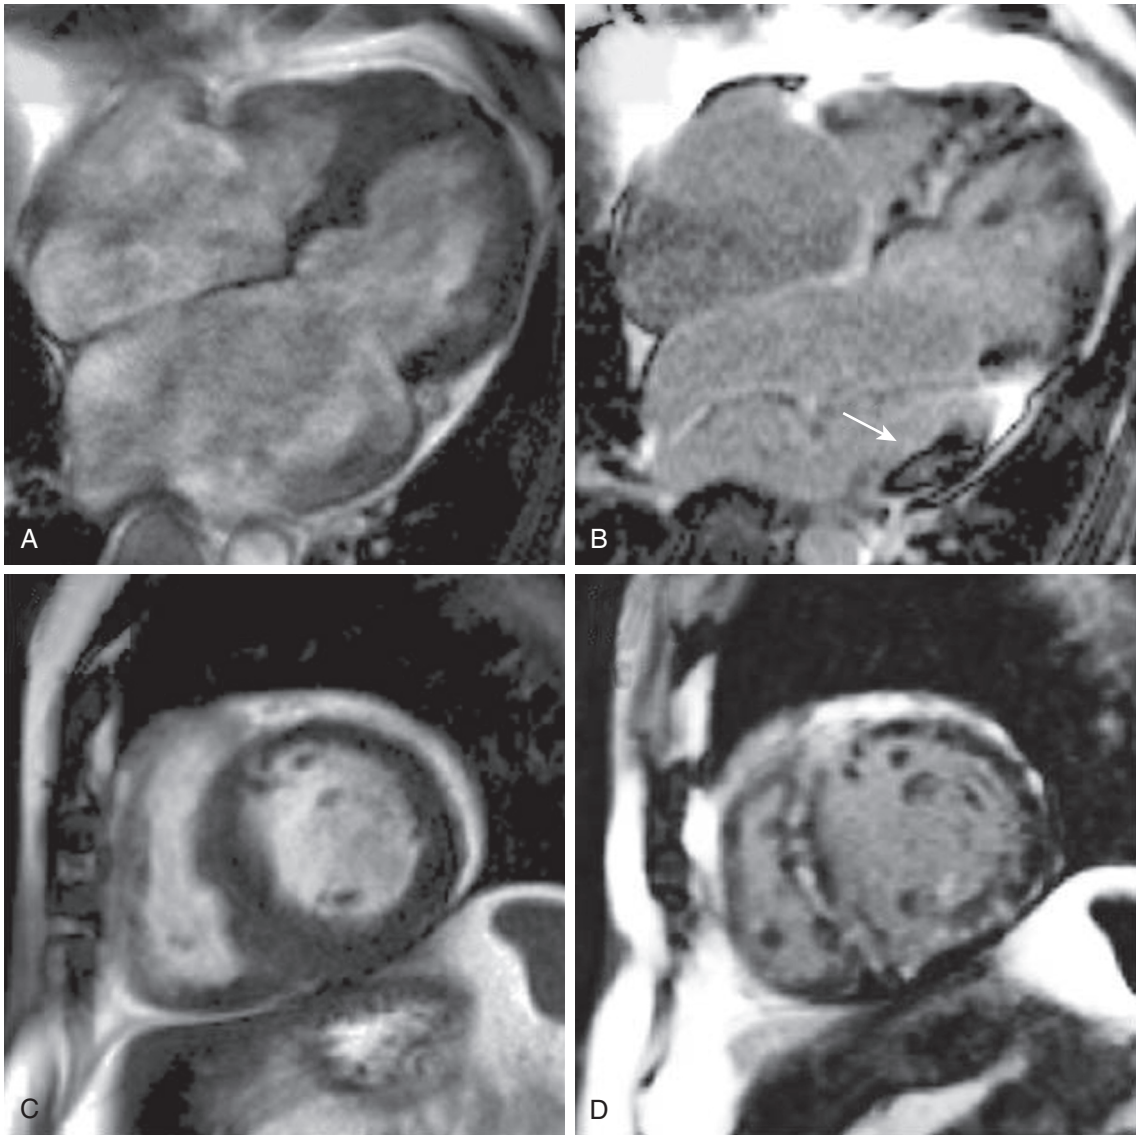
E-FIGURE 47-2. Cardiac magnetic resonance image in a 40-year-old man with hypertrophic cardiomyopathy. Three-chamber cine in diastole (**A**) and systole (**B**). There is mid-cavity obliteration and left ventricular outflow tract obstruction with complete systolic anterior motion of the mitral valve *(small arrow)*. The basal short axis cine (**C**) in diastole measures 30 mm, and there is mid-myocardial scar, visualized as late gadolinium enhancement *(large arrow)* (**D**).



E-FIGURE 47-3. Transesophageal echocardiogram in a patient with hypertrophic cardiomyopathy. Systolic anterior motion of the mitral valve *(small arrow)* prevents normal coaptation and results in functional mitral regurgitation *(large arrow)*.



E-FIGURE 47-4. Progression of myocardial fibrosis from age 38 years to age 45 years. Diffuse septal fibrosis progressed in this patient as shown by late gadolinium enhancement on cardiac magnetic resonance imaging *(arrows)*.



E-FIGURE 47-5. A 50-year-old man with hypertrophic cardiomyopathy in a progressive (dilated) disease phase. The left ventricular ejection fraction is 35%. There is left ventricular dilation, particularly for hypertrophic cardiomyopathy, and severe atrial dilation (**A**, diastolic frame). The maximal wall thickness is known to have reduced during recent follow-up (**C**, was 23 mm, now 18 mm). An extensive, nonischemic myocardial scar comprises an estimated 40% of the myocardium (**B, D**) and left atrial thrombus (*arrow*, **B**).

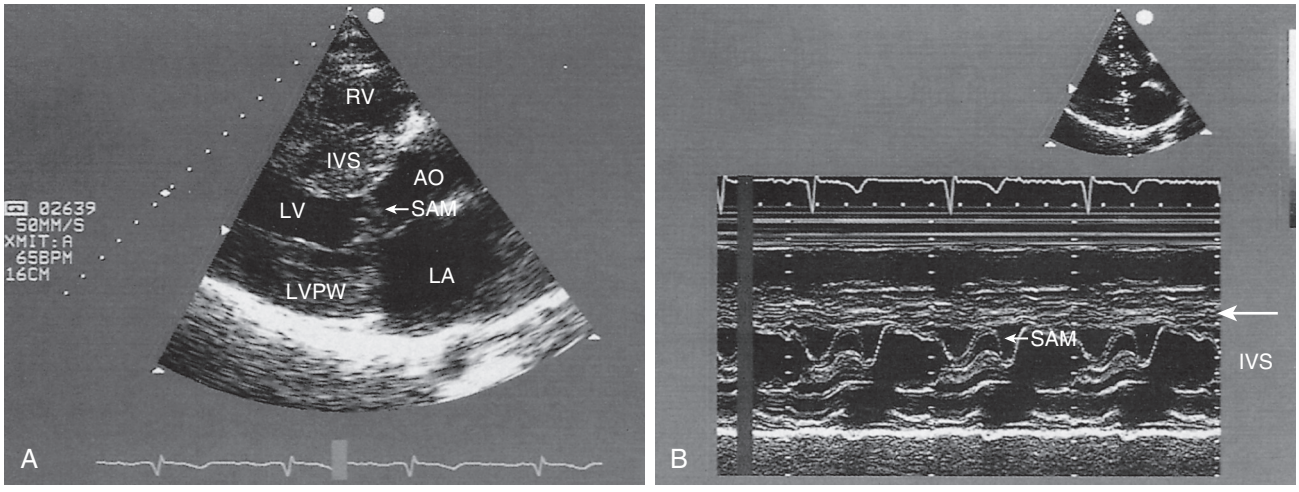


FIGURE 47-2. Hypertrophic obstructive cardiomyopathy. A, The two-dimensional long axis parasternal view shows the chambers of the heart. The left ventricle posterior wall (LVPW) is thickened, and the most striking abnormality is the hypertrophy of the interventricular septum (IVS). In 25% of patients, systolic anterior motion of the mitral valve (SAM) causes dynamic obstruction to left ventricular outflow. **B,** This phenomenon is more clearly shown in the parasternal long axis M-mode echocardiogram. The massive thickening of the septum is also obvious in the M-mode image (IVS). AO = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

Diagnostic Criteria

Hypertrophic cardiomyopathy is defined by a maximal left ventricular wall thickness value of 15 mm or more. A value of 13 mm is considered diagnostic in relatives of probands with an unequivocal diagnosis, particularly if they have a defined genotype. In children, a wall thickness of more than 2 standard deviations above the mean, corrected for age and body size, is generally accepted as diagnostic. In the presence of other causes of left ventricular hypertrophy, such as long-standing systemic hypertension or aortic stenosis, the diagnosis of hypertrophic cardiomyopathy may be problematic. However, secondary hypertrophy rarely exceeds 15 mm, tends to be concentric, and usually lacks the typical valvular and subvalvular mitral abnormalities of hypertrophic cardiomyopathy. Hypertrophy in the highly trained athlete is mild, is rare in women, and typically occurs in association with increased left ventricular dimensions and stroke volume. An ECG tracing showing Q waves or inferolateral repolarization changes in an athlete favors the diagnosis of hypertrophic cardiomyopathy.

TREATMENT

No medical treatments have proven benefit to modify the underlying pathobiology of hypertrophic cardiomyopathy or to slow the long-term progression of the disease. As a result, medical therapy is directed at the control of symptoms, outflow obstruction, and arrhythmias (Fig. 47-3).[4,5] Exceptions include specific therapies for lysosomal storage diseases, such as Pompe disease (Chapter 191) and Fabry disease (E-Fig. 47-6; Chapter 192), and for Friedreich ataxia (Chapter 389). The treatment of the remaining patients with hypertrophic cardiomyopathy focuses on the counseling of family members, the management of symptoms, lifestyle advice related to exercise,[A1] and the prevention of disease-related complications.

Genetic Testing and Familial Screening

Genetic counseling should be offered to all newly diagnosed patients with hypertrophic cardiomyopathy. Genetic testing using next-generation sequencing panels or whole-exome sequencing can exclude rare genotypes and guide cascade screening in families in whom a pathogenic or likely pathogenic variant is identified. However, such variants are found in less than 50% of probands, and a negative test does not exclude the diagnosis of hypertrophic cardiomyopathy. When a pathogenic or likely pathogenic variant is identified, family members may be tested. However, genetic testing remains controversial in minors in the absence of clinical abnormalities, and the pros and cons of early genotyping (versus clinical follow-up) should be carefully considered on an individual basis. Individuals who test positive should be followed at regular intervals, even when the clinical evaluation is negative, because late onset of the disease has been described. Healthy family members in whom the genetic variant is excluded can be reassured and avoid such follow-up evaluations.

Screening with a 12-lead electrocardiogram and echocardiogram takes place at intervals of 12 to 18 months, usually starting at the age of 12 years (unless there is a family history of premature sudden death, the child is symptomatic or a competitive athlete, or there is a clinical suspicion of left ventricular hypertrophy), until full growth and maturation are achieved (usually by the age of 18 to 21 years). Thereafter, if there are no signs of disease expression, screening approximately every few years is advised because the onset of left ventricular hypertrophy may be delayed until well into adulthood in some families. Modified diagnostic criteria (see Table 47-2) consider the high probability that otherwise unexplained ECG and echocardiographic findings in first-degree relatives reflect incomplete disease expression.

Symptomatic Management

Medical Therapy

In patients who have nonobstructive cardiomyopathy, β-blockade may improve chest pain and dyspnea. The dose (starting at a dose equivalent to metoprolol 150 mg/day or propranolol 120 mg/day) should be titrated to achieve a target heart rate of 50 to 70 beats per minute at rest and 130 to 140 beats per minute at peak exercise. Non-dihydropyridine calcium antagonists such as verapamil (starting at a dose of 120 mg/day) and diltiazem (starting at a dose of 180 mg/day) are useful alternatives, particularly in patients with refractory chest pain, but high doses (e.g., verapamil >480 mg/day, diltiazem >360 mg/day) may be required.

In patients with symptoms caused by left ventricular outflow tract obstruction, the main aim of treatment is to reduce intraventricular gradients. Approximately 60 to 70% of patients improve with β-blockers,[A2] although high doses (equivalent to propranolol at 480 mg/day) are frequently required, and side effects are often limiting. When β-blockade alone is ineffective, disopyramide (a negative-inotropic antiarrhythmic agent), titrated to the maximal tolerated dose (usually between 400 and 600 mg/day), may be effective in up to two thirds of patients, but side effects related to the anticholinergic effects (e.g., dry eyes and mouth, urinary retention) limit its use. Disopyramide should be given concomitantly with a β-blocker (e.g., propranolol 120 to 240 mg/day), which will slow the heart rate and also blunt rapid atrioventricular nodal conduction should supraventricular arrhythmias develop. In patients who have left ventricular outflow tract obstruction and are taking a β-blocker and disopyramide, other QT-prolonging drugs (e.g., sotalol or amiodarone) must be avoided because of the potential proarrhythmic effect. In patients with outflow tract gradients, verapamil can be effective, but caution is required in patients with severe obstruction or elevated pulmonary pressures.

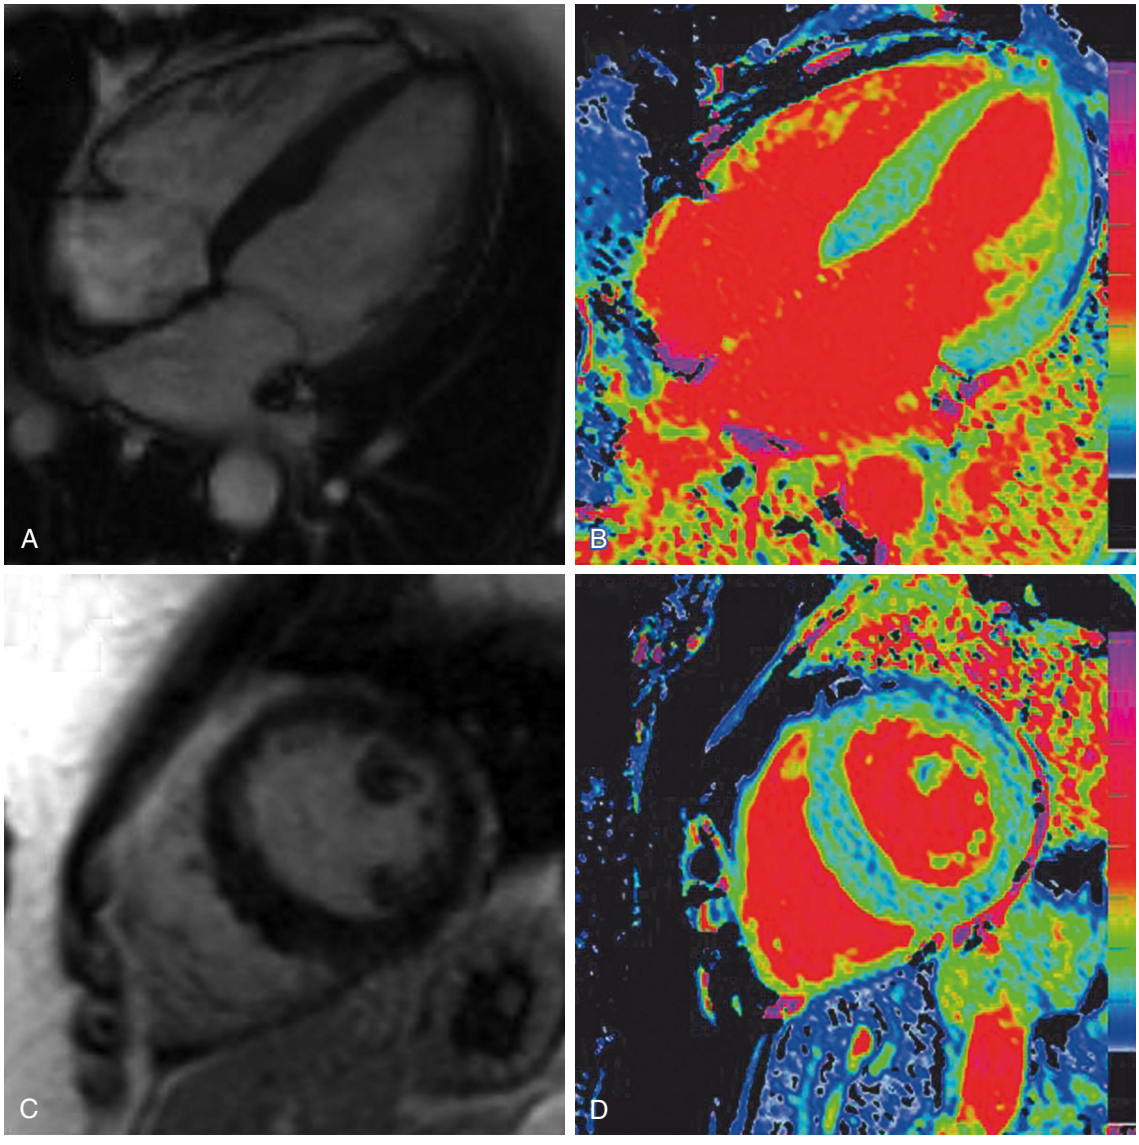
Allosteric inhibitors of cardiac myosin, such as mavacamten (at doses as low as 5 mg orally daily), can reduce obstruction and improve both exercise capacity and quality of life.[A3–A5] Data suggest a benefit in patients with nonobstructive hypertrophic cardiomyopathy as well.[6]

Diuretics (e.g., furosemide, 20 to 40 mg orally, followed by 20 mg/day) are seldom required; if needed in patients who have pulmonary congestion caused by elevated pulmonary pressures due to left ventricular dysfunction, the dose and duration of diuretic therapy should be minimized because injudicious use of these drugs can be dangerous, particularly in patients who have severe diastolic impairment or labile obstruction.

Losartan (100 mg/day) and valsartan (320 mg/day) are safe and may somewhat improve cardiac structure and function, but they have no benefit in terms of slowing the progression of disease.[A6,A7] Similarly, ranolazine (1000 mg twice daily) is safe for reducing ventricular ectopy, but it does not change exercise performance, plasma prohormone brain natriuretic peptide levels, diastolic function, or quality of life.[A8]

Interventional Therapy

Surgical myectomy or percutaneous alcohol septal ablation is indicated in patients who have refractory, symptomatic outflow obstruction (gradient



E-FIGURE 47-6. A 38-year-old man with Fabry disease and cardiac involvement. Cardiac magnetic resonance image shows a mild hypertrophy in the four-chamber (**A**) and short axis end-diastolic (**C**) views. The non–contrast-enhanced T1 map shows blue areas (T1 lowering) present circumferentially at the basal segments (**B, D**). This finding is in keeping with accumulation of glycosphingolipid in myocytes. This case does not have high T1 in the basal inferolateral wall (in many such patients, a red signal indicating fibrosis on this color scale is seen here in an area matched by scarring after contrast enhancement).

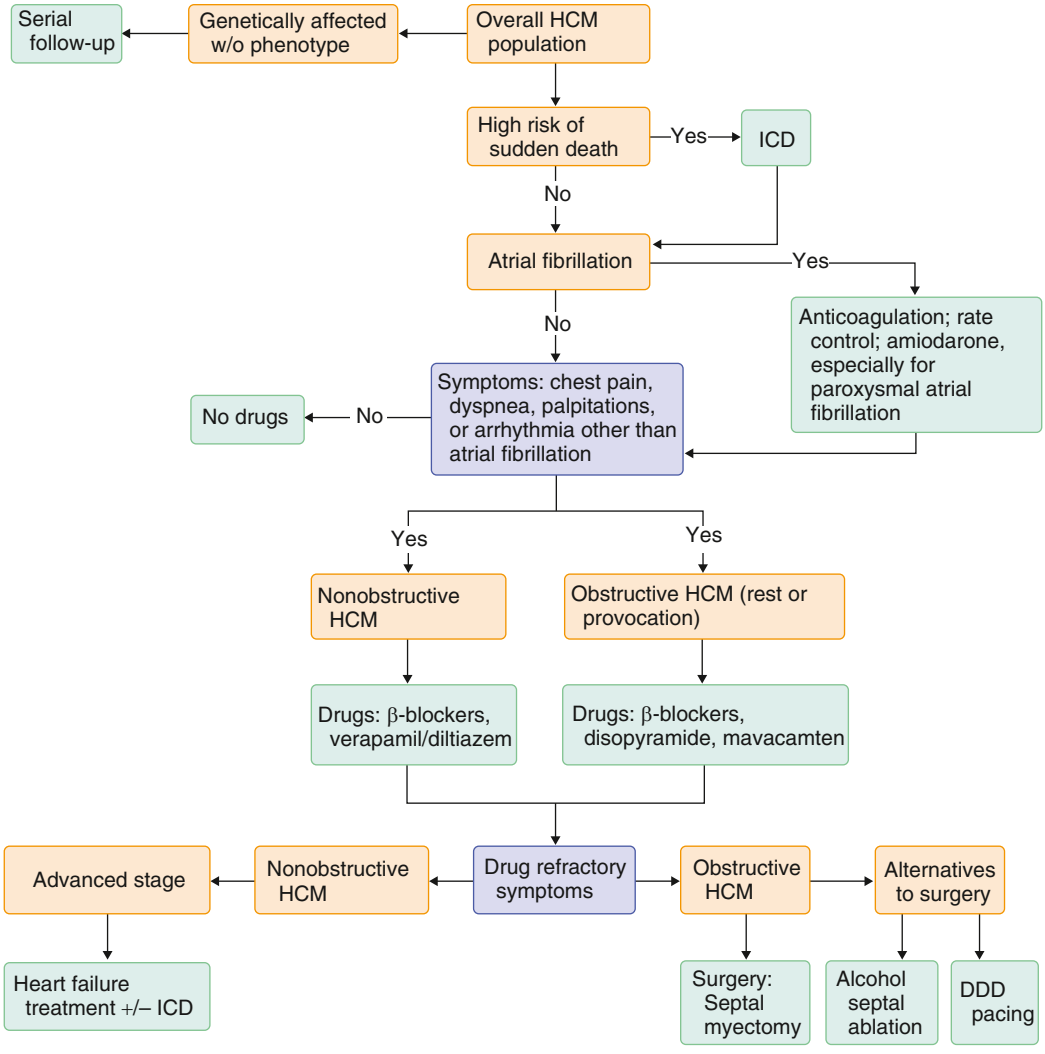


FIGURE 47-3. **Approach to the management of hypertrophic cardiomyopathy (HCM).** DDD = dual chamber; ICD = implantable cardioverter-defibrillator. **(Modified from Maron BJ, McKenna WJ, Danielson GK, et al. American College of Cardiology/European Society of Cardiology clinical expert consensus document on hypertrophic cardiomyopathy. *J Am Coll Cardiol*. 2003;42:1687-1713.)**

>50 mm Hg) despite optimized medical therapy or who are intolerant to it, with data suggesting that alcohol septal ablation may be preferred.[7] Both procedures are safe and effective in expert hands, although surgery is more effective for relieving gradients. Multidisciplinary evaluation by an expert team is advisable to determine the most appropriate therapeutic strategy for an individual patient.

The most commonly performed surgical procedure, which is extended ventricular septal myectomy, either abolishes or substantially reduces the gradient in 95% of cases, reduces mitral regurgitation, and improves exercise capacity and symptoms. Surgery should be performed in an experienced center, where mortality rates should be less than 1% for isolated myectomy. The main complications (atrioventricular block, ventricular septal defects) are uncommon (2 to 5%). When concomitant procedures (e.g., mitral valve repair or replacement, coronary artery bypass grafting) are required or when other significant comorbidities are present, perioperative mortality rates are higher (4 to 5%).

In experienced centers, the selective injection of alcohol into a septal perforator branch of the left anterior descending coronary artery to create a localized septal scar has benefits and risks that are comparable to surgery. The main nonfatal complication is atrioventricular block requiring a pacemaker in 5 to 20% of patients.

In the presence of end-stage disease with extensive myocardial fibrosis and refractory symptoms, heart transplantation is the only therapeutic option. Conversely, a left ventricular assist device is technically challenging to implant and is rarely used because of the small size of the left ventricle.

Atrial Fibrillation

Atrial fibrillation, which is one of the most common complications of hypertrophic cardiomyopathy, occurs in about 25% of patients. In general, the principles of managing atrial fibrillation in patients with hypertrophic cardiomyopathy are similar to those in other conditions (Chapter 52), including the use of anticoagulation because of the significant risk of systemic embolization. Treatment with low-dose amiodarone, 1000 to 1400 mg/week, is effective in maintaining sinus rhythm and in controlling the ventricular response during breakthrough episodes, but it is usually avoided in young patients because of its toxicity. Disopyramide, dofetilide, or sotalol (see Table 52-2) are safe but less effective. In patients who have permanent atrial fibrillation, a ß-blocker, verapamil, or diltiazem are usually required for rate control (see Chapter 52). Transcatheter ablation may be considered in selected patients, but its long-term efficacy is less than 50%, and repeated procedures are often necessary. Marked left atrial dilatation, older age, and worse symptomatic status predict failure to maintain sinus rhythm following ablation.

Prevention of Sudden Death

The overall risk for sudden death in children and adults with hypertrophic cardiomyopathy is approximately 0.5 to 1% per year, but a minority of individuals have a much greater risk for life-threatening ventricular arrhythmia. All patients with hypertrophic cardiomyopathy should be advised to avoid competitive sports and intense physical exertion, which are typical precipitants of sudden death.

The most powerful predictor of sudden cardiac death in hypertrophic cardiomyopathy is a history of previous cardiac arrest. Such patients should receive an implantable cardioverter-defibrillator (ICD; Chapter 54).

In patients without such a history, the identification of high-risk patients can be challenging. The most useful predictors of the risk for sudden death (https://doc2do.com/hcm/webHCM.html) are a family history of premature (<40 years of age) sudden cardiac death, unexplained syncope (unrelated to neurocardiogenic mechanisms), flat or hypotensive blood pressure response to upright exercise, nonsustained ventricular tachycardia on ambulatory ECG monitoring or during exercise, and severe left ventricular hypertrophy on echocardiography (defined as a maximal left ventricular wall thickness of 30 mm or more). Patients without any risk factors do not warrant an ICD. For patients with one risk factor, decisions about an ICD should be individualized on the basis of the patient's age and severity of disease and level of risk that is acceptable to the patient.

TABLE 47-2 DIAGNOSTIC CRITERIA FOR HYPERTROPHIC CARDIOMYOPATHY IN FIRST-DEGREE RELATIVES OF AFFECTED PATIENTS*

MAJOR CRITERIA	MINOR CRITERIA
ECHOCARDIOGRAPHY	
Left ventricular wall thickness ≥13 mm in the anterior septum or posterior wall or ≥15 mm in the posterior septum or free wall	Left ventricular wall thickness of 12 mm in the anterior septum or posterior wall or of 14 mm in the posterior septum or free wall
Severe SAM of the mitral valve (septal-leaflet contact)	Moderate SAM of the mitral valve (no mitral leaflet–septal contact) Redundant mitral valve leaflets
ELECTROCARDIOGRAPHY	
Left ventricular hypertrophy with repolarization changes (Romhilt and Estes)	Complete bundle branch block or (minor) interventricular conduction defects (in left ventricular leads)
T wave inversion in leads I and aVL (≥3 mm with QRS-T wave axis difference ≥30 degrees), V_3-V_6 (≥3 mm), or II and III and aVF (≥5 mm)	Minor repolarization changes in left ventricular leads Deep S wave in lead V_2 (>25 mm)
Abnormal Q waves (>40 msec or >25% R wave) in at least two leads from II, III, aVF (in absence of left anterior hemiblock), and V_1-V_4; or I, aVL, V_5-V_6	Unexplained chest pain, dyspnea, or syncope

*The diagnosis of hypertrophic cardiomyopathy in first-degree relatives of patients with the disease is based on the presence of one major criterion, two minor echocardiographic criteria, or one minor echocardiographic criterion and two minor electrocardiographic criteria.

aVF = augmented voltage unipolar left foot lead; aVL = augmented voltage unipolar left arm lead; SAM = systolic anterior motion.

Modified from McKenna WJ, Spirito P, Desnos M, et al. Experience in clinical genetics in hypertrophic cardiomyopathy. *Heart*. 1997;77:130-132.

PROGNOSIS

Most patients with hypertrophic cardiomyopathy follow a stable and benign course with a low risk for adverse events and a survival similar to that of age- and gender-matched normal populations, but many experience progressive symptoms caused by atrial arrhythmia and gradual deterioration in left ventricular systolic and diastolic function (E-Fig. 47-7). With modern therapy, heart failure–related deaths have become more common than sudden deaths. The mortality rate related specifically to hypertrophic cardiomyopathy is 0.53% per year, with 5- and 10-year cardiomyopathy-related survival rates of 98% and 94%, respectively. The annual incidence of stroke varies from 0.56 to 0.8% per year, rising to 1.9% in patients older than 60 years, and 23% of strokes are fatal. The development of severe systolic heart failure is associated with a poor prognosis, with an overall mortality rate of up to 11% per year. The incidence of infective endocarditis is 1.4 per 1000 person-years overall but 3.8 per 1000 person-years in patients with obstruction.

MYOCARDITIS

DEFINITION AND EPIDEMIOLOGY

Myocarditis, which is an inflammatory process involving the myocardium, can be caused by infections, immune-mediated damage, or toxins (Table 47-3).[8] The incidence and prevalence of myocarditis are difficult to estimate because the clinical presentation varies from asymptomatic ECG abnormalities to hemodynamic collapse and sudden death. Population estimates of the prevalence of myocarditis range from 1 in 100,000 to 1 in 10,000, whereas postmortem studies report myocarditis in up to 12% of young victims of sudden cardiac death. Myocarditis may also be the clinical presentation of the inflammatory phase of an arrhythmogenic cardiomyopathy.

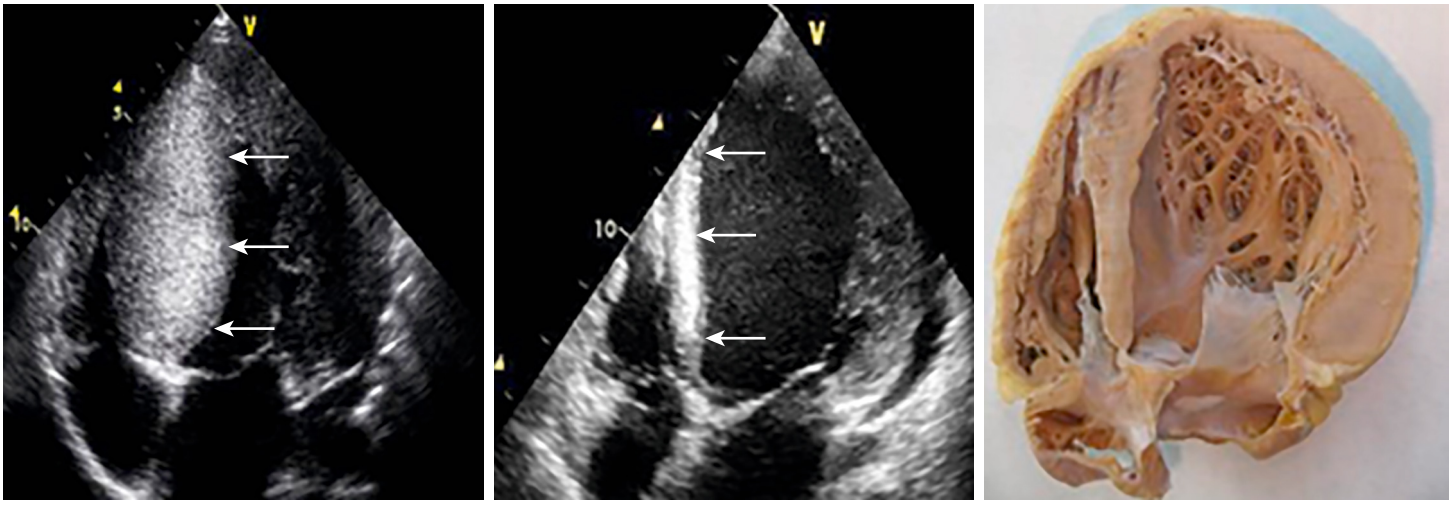
Worldwide, the most common infective myocarditis is Chagas disease, caused by *Trypanosoma cruzi*, a protozoan organism endemic in rural areas of South and Central America (Chapter 318).[9] In the Western world, viral myocarditis is the most common cause of inflammatory heart disease. Human immunodeficiency virus (HIV) infection (Chapter 353) is associated with lymphocytic myocarditis and is a strong predictor of poor prognosis. Smallpox vaccination (Chapter 15) causes myopericarditis with a reported incidence of 7.8 cases per 100,000 vaccine administrations. Other rare myocarditides include giant cell myocarditis, myocarditis complicating autoimmune disorders such as systemic lupus erythematosus (Chapter 245), cocaine abuse (Chapter 365), and as a complication of combination immune checkpoint inhibitor therapy (Chapter 164).

TABLE 47-3 CAUSES OF MYOCARDITIS

INFECTION
Viral
Coxsackievirus, human immunodeficiency virus, echovirus, severe acute respiratory syndrome coronavirus-2, adenovirus, influenza, measles, mumps, parvovirus, poliovirus, rubella, varicella-zoster virus, herpes simplex virus, cytomegalovirus, hepatitis C virus, rabies virus, respiratory syncytial virus, vaccine virus, dengue virus, yellow fever virus
Protozoal
Trypanosoma cruzi, Toxoplasma gondii
Bacterial
Brucella, Corynebacterium diphtheriae, Salmonella, Haemophilus influenzae, Mycoplasma pneumoniae, Neisseria meningitidis (meningococcus), *Streptococcus pneumoniae, Staphylococcus, Mycobacterium, Neisseria gonorrhoeae* (gonococcus), *Vibrio cholerae*
Spirochetal
Treponema pallidum, Borrelia, Leptospira
Fungal
Aspergillus, Candida, Cryptococcus, Actinomyces, Blastomyces, Histoplasma, Coccidioides
Rickettsial
Coxiella burnetii, Rickettsia rickettsii, Rickettsia tsutsugamushi
Parasitic
Trichinella spiralis, Echinococcus granulosus, Taenia solium
IMMUNE-MEDIATED DISORDERS
Alloantigens
Heart transplant rejection
Autoantigens
Eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome), celiac disease, Whipple disease, giant cell myocarditis, Kawasaki disease, systemic lupus erythematosus, systemic sclerosis, sarcoidosis, scleroderma, polymyositis, thrombocytopenic purpura
Allergens (Drugs)
Penicillin, sulfonamides, tetracycline, methyldopa, streptomycin, tricyclic antidepressants, thiazide diuretics, dobutamine, indomethacin
TOXIC CAUSES
Drugs
Anthracyclines, catecholamines, amphetamines, cocaine, cyclophosphamide, 5-fluorouracil, trastuzumab, interferon, interleukin-2, checkpoint inhibitors, clozapine
Physical Agents
Electric shock, radiation, hyperpyrexia
Heavy Metals
Copper, iron, lead
Others
Arsenic, snake bite, scorpion bite, wasp and spider stings, phosphorus, carbon monoxide
GENETIC DISORDERS
Inherited cardiomyopathies with immune-mediated pathogenesis (dilated and right ventricular cardiomyopathy)

PATHOBIOLOGY

Myocarditis is defined histologically by the presence of myocyte injury, with degeneration or necrosis, and an inflammatory infiltrate not due to ischemia. Four patterns are recognized: *active myocarditis*, with myocyte degeneration or necrosis and definite cellular infiltrate with or without fibrosis; *borderline myocarditis*, with a definite cellular infiltrate without evidence of myocardial cellular injury; *persistent myocarditis*, with continued



E-FIGURE 47-7. Progression to end-stage hypertrophic cardiomyopathy. LV = left ventricle; LVEF = left ventricular ejection fraction. (From Pasqualucci D, Fornaro A, Castelli G, et al. Clinical spectrum, therapeutic options, and outcome of advanced heart failure in hypertrophic cardiomyopathy. *Circ Heart Fail*. 2015;8:1014-1021; Olivotto I, Cecchi F, Poggesi C, et al. Patterns of disease progression in hypertrophic cardiomyopathy. *Circ Heart Fail*. 2012;5:535-546; Galati G, Leone O, Pasquale F, et al. Histological and histometric characterization of myocardial fibrosis in end-stage hypertrophic cardiomyopathy: a clinical-pathological study of 30 explanted hearts. *Circ Heart Fail*. 2016;9:e003090.)

active myocarditis on repeated biopsy; and *resolving or resolved myocarditis*, characterized by a diminished or absent infiltrate with evidence of connective tissue healing on repeated biopsy. Despite their widespread use, the so-called Dallas criteria have low specificity and sensitivity, with a diagnostic yield as low as 10 to 20% in some series. Therefore, newer virology techniques used in conjunction with conventional light microscopy include nested polymerase chain reaction or reverse transcription polymerase chain reaction on RNA and DNA extracted from endomyocardial biopsy specimens and immunohistochemical staining for subtypes of infiltrating lymphocytes and abnormal expression of cellular adhesion molecules on interstitial or endothelial cells.

VIRAL MYOCARDITIS

Most data on the pathology of viral myocarditis come from murine models. Initially, there is direct invasion of the myocardium by cardiotropic viruses, which enter the cardiomyocyte through receptor-mediated endocytosis. The viral genome, which is translated intracellularly to produce viral protein or is incorporated into the host cell genome, may contribute to myocyte dysfunction by cleaving dystrophin. In the second phase, activation of the host immune system, including recruitment of natural killer cells and macrophages, increases the expression of proinflammatory cytokines such as interleukin-1 and tumor necrosis factor. Activation of $CD4^+$ T lymphocytes promotes clonal expansion of B lymphocytes, thereby resulting in further myocardial cell damage, inflammation, and the production of circulating antiheart antibodies directed against contractile, structural, and mitochondrial proteins. This autoimmune response may result in long-term ventricular remodeling by direct effects on myocardial structural components or alterations in the extracellular matrix.

CLINICAL MANIFESTATIONS

Some patients report prodromal symptoms of viremia, including fever, myalgia, coryzal symptoms, and gastroenteritis, but many individuals with myocarditis are asymptomatic and manifest only transient ECG abnormalities, such as nonspecific ST segment and T wave abnormalities, pathologic Q waves, and low QRS voltages. Less common presentations include acute myocardial infarction with angiographically normal coronary arteries (Chapter 58), atrioventricular block (Chapter 52), and ventricular arrhythmias (Chapter 53). Patients with impairment of left ventricular function may present with symptoms and signs of fulminant cardiogenic shock (Chapter 93) with acute cardiovascular collapse. In some cases, sudden cardiac death is the first presentation.

DIAGNOSIS

The diagnosis of myocarditis requires a high index of suspicion because it may mimic other common conditions.[10] There are no typical features on echocardiography, but impaired left or right ventricular systolic performance (with or without ventricular dilation), regional wall motion abnormalities, left (or right) ventricular thrombus, diastolic impairment, and pericardial effusions may be present. Cardiac magnetic resonance imaging can detect myocardial inflammation and myocyte injury, with pericellular and cellular edema.

Routine blood tests, such as full blood count and erythrocyte sedimentation rate, are usually unhelpful. Serum markers of myocardial injury, such as troponins T and I, may be elevated, but myocarditis may be proven by biopsy even in the absence of elevated serum troponin levels. Increased levels of autoantibodies against myocardial proteins (such as myosin and the adenine nucleotide translocator protein) are biomarkers of autoimmune myocarditis and correlate with progressive worsening of ventricular function. A microRNA designated as has-miR-Chr8:96 is seen in myocarditis but rarely in myocardial infarction.[11]

Cardiac magnetic resonance imaging with gadolinium enhancement can show evidence of myocarditis (Fig. 47-4), but cardiac catheterization with right ventricular endomyocardial biopsy remains the "gold standard" diagnostic test. In the United States, biopsy has generally been reserved for patients with heart failure refractory to standard management, features suggestive of systemic disease (e.g., connective tissue disease [Chapter 239], amyloidosis [Chapter 174], hemochromatosis [Chapter 196], sarcoidosis [Chapter 83]), or suspicion of giant cell myocarditis because of new-onset heart failure associated with tachyarrhythmias or conduction disease. By comparison, a European consensus statement recommends endomyocardial biopsy to achieve an etiologic diagnosis and to guide potential novel treatment options in patients with "clinically suspected myocarditis."

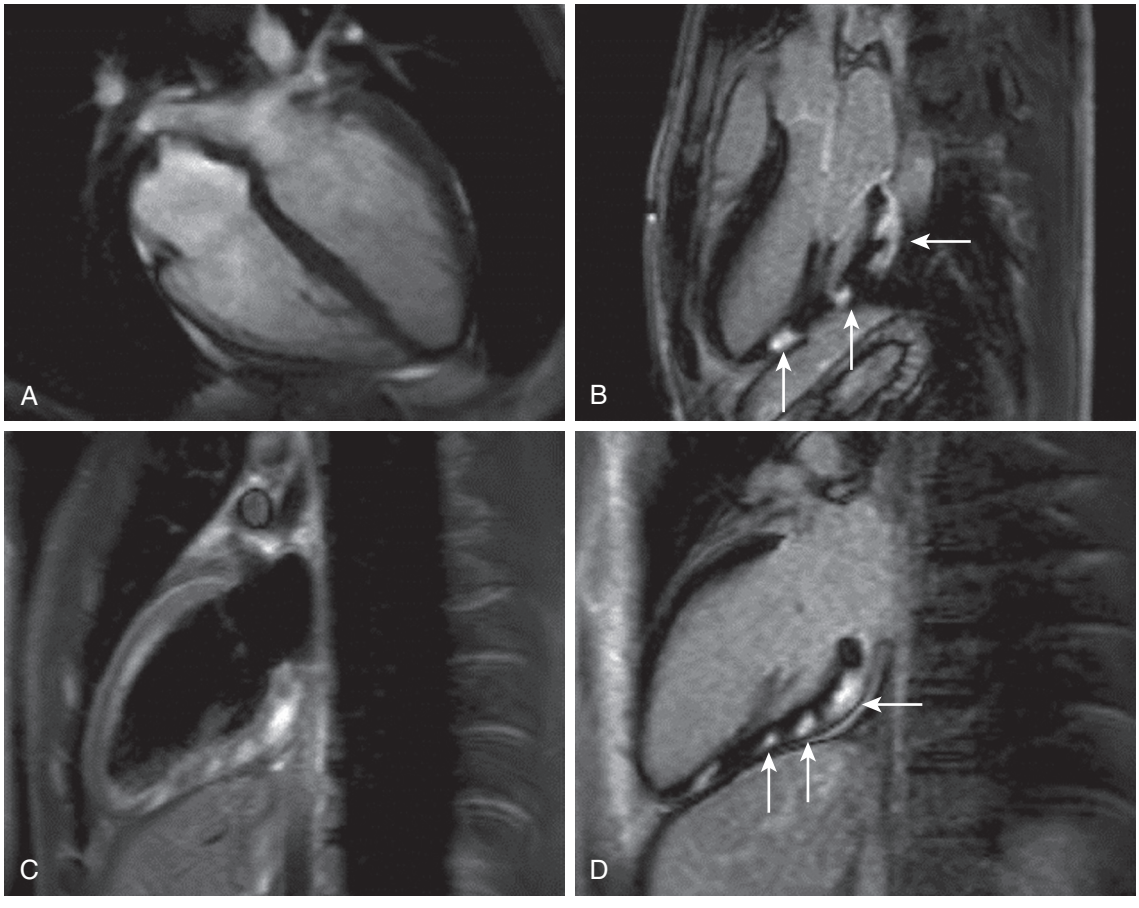


FIGURE 47-4. A 17-year-old man presenting with apparent acute myopericarditis. The four-chamber end-diastolic view (**A**) presents a mildly dilated left ventricle. There is patchy late gadolinium enhancement involving the inferior and lateral walls (**B, D**, *arrows*). Edema is seen on T1 imaging (**C**), and there is extensive late enhancement. The differential diagnosis of this appearance also includes sarcoid and giant cell myocarditis.

Specific Causes

Viral myocarditis may be suspected from the clinical picture of recent febrile illness, often with prominent myalgias, followed by angina-like chest pain, dyspnea, or arrhythmias. Elevated troponin levels support the diagnosis, and increasing viral titers (to coxsackievirus, echovirus, adenovirus, or influenza virus) are consistent with recent infection. The correlation with biopsy-proven myocarditis is strongest with HIV and Lyme disease. Clinical cardiomyopathy occurs in 10 to 40% of patients infected with HIV due to the HIV infection itself or to coinfection with cytomegalovirus.

Giant Cell Myocarditis

Giant cell myocarditis, which accounts for 10 to 20% of biopsy-positive cases of myocarditis, is manifested with the rapid onset of chest pain, fever, and hemodynamic compromise, often with ventricular tachycardia or atrioventricular block. When ventricular tachyarrhythmias or progressive heart failure are major features of clinically suspected myocarditis, particularly in a young person, endomyocardial biopsy is recommended to determine whether giant cell myocarditis is present.

Lyme Disease and Toxoplasmosis

Lyme carditis (Chapter 296)[12] is classically manifested with conduction system abnormalities resulting from infection with *Borrelia burgdorferi*, which is diagnosed serologically. Toxoplasmosis (Chapter 320) myocarditis, due to intermittent rupture of cysts in the myocardium, can cause atypical chest pain, arrhythmias, pericarditis, and symptomatic heart failure. Diagnosis is made from antibody titers.

Severe Acute Respiratory Syndrome Coronavirus-2

Myocarditis is a rare complication of SARS-CoV-2 infection (Chapter 336), with an apparent excess incidence rate of 40 extra events per million persons.[13] The risk of myocarditis also appears to be increased (1 to 10 per million persons) within a week of receiving the first dose of both adenovirus and mRNA vaccines, with a higher increased risk after the second dose of mRNA vaccines (Chapter 337). The risk of vaccine-associated myocarditis after vaccination seems to be higher in people under age 40 years.

Immune-Mediated Myocarditis

Many systemic immune-mediated diseases may present as myocarditis with lymphocytic, eosinophilic, and granulomatous myocardial infiltrates.[14] Specific disorders include sarcoidosis (Chapter 83), systemic lupus erythematosus (Chapter 245), systemic sclerosis (Chapter 246), the antiphospholipid syndrome (Chapter 160), dermato-polymyositis (Chapter 248), eosinophilic granulomatosis with polyangiitis, and other vasculitis syndromes (Chapter 249). Myocarditis can also occur in some organ-specific immune-mediated diseases such as chronic inflammatory bowel diseases (Chapter 127). Hypersensitivity reactions, especially to drugs (Chapter 234), can cause myocarditis that is often associated with peripheral eosinophilia and can be confirmed by endomyocardial biopsy.

TREATMENT

The first-line treatment of myocarditis is supportive with afterload reduction and diuresis (Chapter 46). Patients with fulminant acute myocarditis may require inotropic support, mechanical assist devices, or extracorporeal membrane oxygenation (Chapter 93). After initial stabilization, patients with symptoms and signs of heart failure should receive angiotensin-converting enzyme inhibitors, diuretics, β-blockers, and anticoagulants in accordance with standard guidelines (Chapter 46). Patients with intractable and deteriorating heart failure may require cardiac transplantation (Chapter 46).

The role of immunosuppression is uncertain. In one randomized, placebo-controlled trial of 111 adults with biopsy-proven myocarditis, there was no difference in mortality or improvement in left ventricular function in patients treated with prednisolone plus either cyclosporine or azathioprine. Conversely, in a randomized trial of patients who had major histocompatibility complex expression on endomyocardial biopsy samples and who were randomized to prednisolone (1 mg/kg/day tapering to a maintenance dose of 0.2 mg/kg/day for a total of 90 days) and azathioprine (1 mg/kg/day for a total of 100 days) versus placebo, left ventricular ejection fraction improved in the immunosuppressed group, but no difference was observed in mortality or rates of transplantation or rehospitalization during a 2-year follow-up period. Immunosuppression appears to be beneficial for patients with giant cell myocarditis, and current recommendations extend immunosuppression to other biopsy-proven, infection-negative immune-mediated forms of myocarditis including eosinophilic myocarditis, cardiac sarcoidosis, and lymphocytic myocarditis that is refractory to conventional heart failure therapy.[A9] The optimal regimens remain to be determined, and intravenous immune globulin therapy is not helpful.

PROGNOSIS

Patients with acute myocarditis with mild heart failure or symptoms suggestive of myocardial ischemia or infarction typically improve within weeks without sequelae. An acute presentation of myocarditis with advanced heart failure (ejection fraction <35%) may resolve but can lead to chronic left ventricular dysfunction (dilated cardiomyopathy) or progress to death or cardiac transplantation. Patients who present with acute fulminant myocarditis, however, may have an excellent prognosis, with survival rates of more than 90%. Overall, however, biopsy-proven viral myocarditis is associated with a long-term mortality of almost 20% at 4.7 years, and the presence of biventricular dysfunction at presentation is the best predictor of all-cause mortality. Giant cell myocarditis is usually fatal without heart transplantation, but it can be stabilized by early diagnosis and prompt introduction of immunosuppression.[15]

DILATED CARDIOMYOPATHY

DEFINITION AND EPIDEMIOLOGY

Dilated cardiomyopathy is a heart muscle disorder defined by dilation and impaired systolic function of the left ventricle or both ventricles, in the absence of coronary artery disease, valvular abnormalities, or pericardial disease. In adults, the estimated prevalence is 1 in 250.[16] In children, dilated cardiomyopathy is the most common cardiomyopathy, accounting for up to 58% of cases. Overall, males and females are approximately equally affected, except for dilated cardiomyopathy associated with neuromuscular disorders or inborn errors of metabolism, for which there is male predominance because some of these conditions have an X-linked inheritance.

PATHOBIOLOGY

A number of conditions are associated with dilated cardiomyopathy, including neuromuscular disorders, inborn errors of metabolism, and malformation syndromes. When no identifiable cause is found, the disease is termed idiopathic dilated cardiomyopathy.

Genetic Dilated Cardiomyopathy

Between 20 and 50% of individuals with dilated cardiomyopathy have evidence of familial disease (see E-Table 47-1).[17] Autosomal dominant inheritance, which accounts for the majority of familial cases, has two major forms: isolated dilated cardiomyopathy, which is manifested with a clinical picture of heart failure, and dilated cardiomyopathy, in which an associated arrhythmia (i.e., atrial fibrillation, conduction system disease, ventricular tachycardia, or fibrillation) is usually the initial manifestation. The latter cardiomyopathy may also result in heart failure or be associated with a skeletal myopathy. Genes implicated in nonsyndromic dilated cardiomyopathy include cytoskeletal and sarcomeric protein genes. Truncating mutations in *TTN*, the gene encoding the sarcomere protein titin, occur in approximately 25% of familial cases of dilated cardiomyopathy and in 18% of sporadic cases. Genes implicated in arrhythmogenic forms of dilated cardiomyopathy include desmosomal, intermediate filament, nuclear envelope, and ion channel genes. Mutations in the lamin A/C gene, which encodes a nuclear envelope protein, cause atrial and ventricular arrhythmia and progressive atrioventricular conduction disease, which may precede the development of dilated cardiomyopathy. Truncating in the filamin C gene, which encodes an important intermediate filament protein, causes a mixed arrhythmogenic and dilated cardiomyopathy phenotype, typically with lethal ventricular arrhythmias in adolescents and young adults and with subsequent heart failure in survivors.

X-linked inheritance accounts for between 2 and 5% of familial cases of dilated cardiomyopathy. Neuromuscular disorders account for 26% of cases, 90% of which are Duchenne, Becker, and Emery-Dreifuss muscular dystrophies (Chapter 389). Isolated X-linked dilated cardiomyopathy, also caused by mutations in the dystrophin gene, is characterized by raised serum creatine kinase muscle isoforms but does not result in clinical signs or symptoms of skeletal muscular dystrophy.

Acquired Dilated Cardiomyopathy

Common acquired causes of dilated cardiomyopathy include infectious myocarditis, chemotherapy (Chapter 164), radiation therapy (Chapter 18), alcohol (Chapter 364), cocaine (Chapter 365), nutritional deficiencies (Chapter 197), iron overload (Chapter 196), inflammatory and autoimmune disorders (Chapters 245 and 249), endocrinopathies (Chapter 207), and pregnancy (Chapter 221). Tachycardia-mediated cardiomyopathy (tachycardiomyopathy) is rare and usually reverses once the tachycardia is controlled.

CLINICAL MANIFESTATIONS

The symptoms and signs associated with dilated cardiomyopathy depend on the age of the patient and the degree of left ventricular dysfunction. Although the first presentation may be with sudden death or a thromboembolic event, most patients present with symptoms of high pulmonary venous pressure or low cardiac output (Chapter 45), which can be acute, sometimes precipitated by intercurrent illness or arrhythmia, or chronic. Increasingly, dilated cardiomyopathy is diagnosed incidentally in asymptomatic individuals during family screening.

Adults initially present with reduced exercise tolerance and dyspnea on exertion. With worsening left ventricular function, patients may develop dyspnea at rest, orthopnea, paroxysmal nocturnal dyspnea, peripheral edema, and ascites. Symptoms related to mesenteric ischemia, such as abdominal pain after meals, nausea, vomiting, and anorexia, may dominate, especially in children. Arrhythmia symptoms, such as palpitations, presyncope, and syncope, can occur at any age.

In advanced disease, features of low cardiac output include sinus tachycardia, weak peripheral pulses, and hypotension. The jugular venous pressure may be elevated, and the apical impulse is displaced. Peripheral edema, hepatomegaly, and ascites are common in patients with heart failure. Auscultation of the chest typically reveals basal crackles. Auscultation of the heart may reveal the presence of a third (and sometimes also a fourth) heart sound. In patients with functional mitral regurgitation, a pansystolic murmur may be heard at the apex and radiate to the axilla, but frequently no murmurs are heard, even in the presence of mitral incompetence, especially if cardiac output is very low.

DIAGNOSIS

The electrocardiogram may be normal but more typically shows sinus tachycardia, nonspecific ST segment and T wave changes (most commonly in the inferior and lateral leads), atrial enlargement, and voltage criteria for ventricular hypertrophy. Atrioventricular block raises the possibility of mutations in the lamin A/C or desmin gene. Supraventricular and ventricular arrhythmias are common, particularly in patients who have pathogenic variants in *TTN*, *DSP*, *RBM20*, *LMNA*, and *FLNC*. The chest radiograph is usually abnormal, with an increased cardiothoracic ratio (>0.5) reflecting left ventricular and left atrial dilation. Patients with pulmonary edema have increased pulmonary vascular markings and pleural effusion.

On echocardiography, the presence of ventricular end-diastolic dimensions greater than 2 standard deviations above body surface area–corrected means (or greater than 112% of predicted dimension) and fractional shortening less than 25% are sufficient to make the diagnosis. Other common features include functional mitral and tricuspid regurgitation and abnormalities of diastolic left ventricular function. Cardiac magnetic resonance imaging may show areas of myocardial fibrosis (E-Fig. 47-8).

Other recommended tests (Table 47-4) include a complete blood count and tests of renal, thyroid, and hepatic function. Levels of serum creatine kinase should be measured in all patients with dilated cardiomyopathy because this may provide important clues to the etiology. For example, dystrophin-linked dilated cardiomyopathy has been diagnosed in up to 8% of men with dilated cardiomyopathy and should be considered in men with increased serum creatine kinase levels and an X-linked family history. Other cardiac biomarkers, such as troponin I and troponin T, can be elevated. Plasma B-type natriuretic peptide levels predict survival, hospitalization rates, and listing for cardiac transplantation. Symptom-limited exercise testing, combined with respiratory gas analysis, is a useful technique to assess functional limitation and disease progression in patients with stable dilated cardiomyopathy.

Cardiac catheterization is rarely needed except perhaps to exclude severe coronary artery disease or to provide more precise information about possible valvular heart disease. Endomyocardial biopsy may be diagnostic for myocarditis and for some metabolic or mitochondrial disorders but is rarely advised. Hemodynamic assessment of left ventricular end-diastolic and pulmonary artery pressures may be necessary before transplantation.

TABLE 47-4 LABORATORY EVALUATION OF CARDIOMYOPATHY

CLINICAL EVALUATION
History and physical examination to identify cardiac and noncardiac disorders*
Assessment of ability to perform routine and desired activities*
Assessment of volume status*
LABORATORY EVALUATION
Electrocardiogram*
Chest radiograph*
Ambulatory electrocardiographic monitoring
Two-dimensional and Doppler echocardiogram*
Chemistry
Serum sodium,* potassium,* glucose, creatinine,* blood urea nitrogen,* calcium,* magnesium*
Albumin,* total protein,* liver function tests,* serum iron, ferritin, creatine kinase, thyroid-stimulating hormone,* brain natriuretic peptide, troponin level
Urinalysis
Hematology
Hemoglobin/hematocrit*
White blood cell count with differential,* including eosinophils
Erythrocyte sedimentation rate
INITIAL EVALUATION IN SELECTED PATIENTS ONLY
Titers for suspected infection
Acute viral titers
Human immunodeficiency virus, Epstein-Barr virus
Lyme disease, toxoplasmosis
Chagas disease
Catheterization with coronary angiography in patients with angina who are candidates for intervention*
Serologic studies for active rheumatologic disease

TREATMENT

Supportive therapy includes sodium and fluid restriction, avoidance of alcohol and other toxins, and use of established heart failure medications (Chapter 46). Rest and avoidance of exercise should be recommended only for patients who have myocarditis, peripartum cardiomyopathy, or desmosomal or lamin AC mutations. For other patients, a submaximal exercise regimen is desirable to sustain mobility, to avoid deconditioning, and to maintain physical and psychological health. Patients with atrial fibrillation or with echocardiographic evidence of a left atrial or left ventricular mural thrombosis should be anticoagulated, preferably with a direct-acting anticoagulant (Table 70-6), or with warfarin to an international normalized rate of 2.0 to 3.0 (Table 70-4). An ICD is preferred to medication for primary prevention against sudden cardiac death from ventricular arrhythmia,[A10] and some patients require management for advanced heart failure (Chapter 46) with cardiac resynchronization therapy, inotropic medications, ventricular assist devices, and cardiac transplantation (Chapter 46).

Family Screening

When a pathogenic gene variant has been identified in a proband, cascade genetic testing should be considered in first-degree relatives.[18] The detection of early disease in a family member offers an opportunity to initiate treatment, usually with an angiotensin-converting enzyme inhibitor (e.g., ramipril or perindopril 5 mg daily) or ß-blocker (e.g., bisoprolol 5 mg daily or carvedilol 12.5 or 25 mg twice daily), although the efficacy of such therapy remains to be proven. Precise algorithms to guide the interval of serial evaluation remain to be determined. Even in the absence of a positive genetic test, evaluation of first-degree relatives by history, physical examination, a 12-lead ECG, and a two-dimensional echocardiogram should be considered.

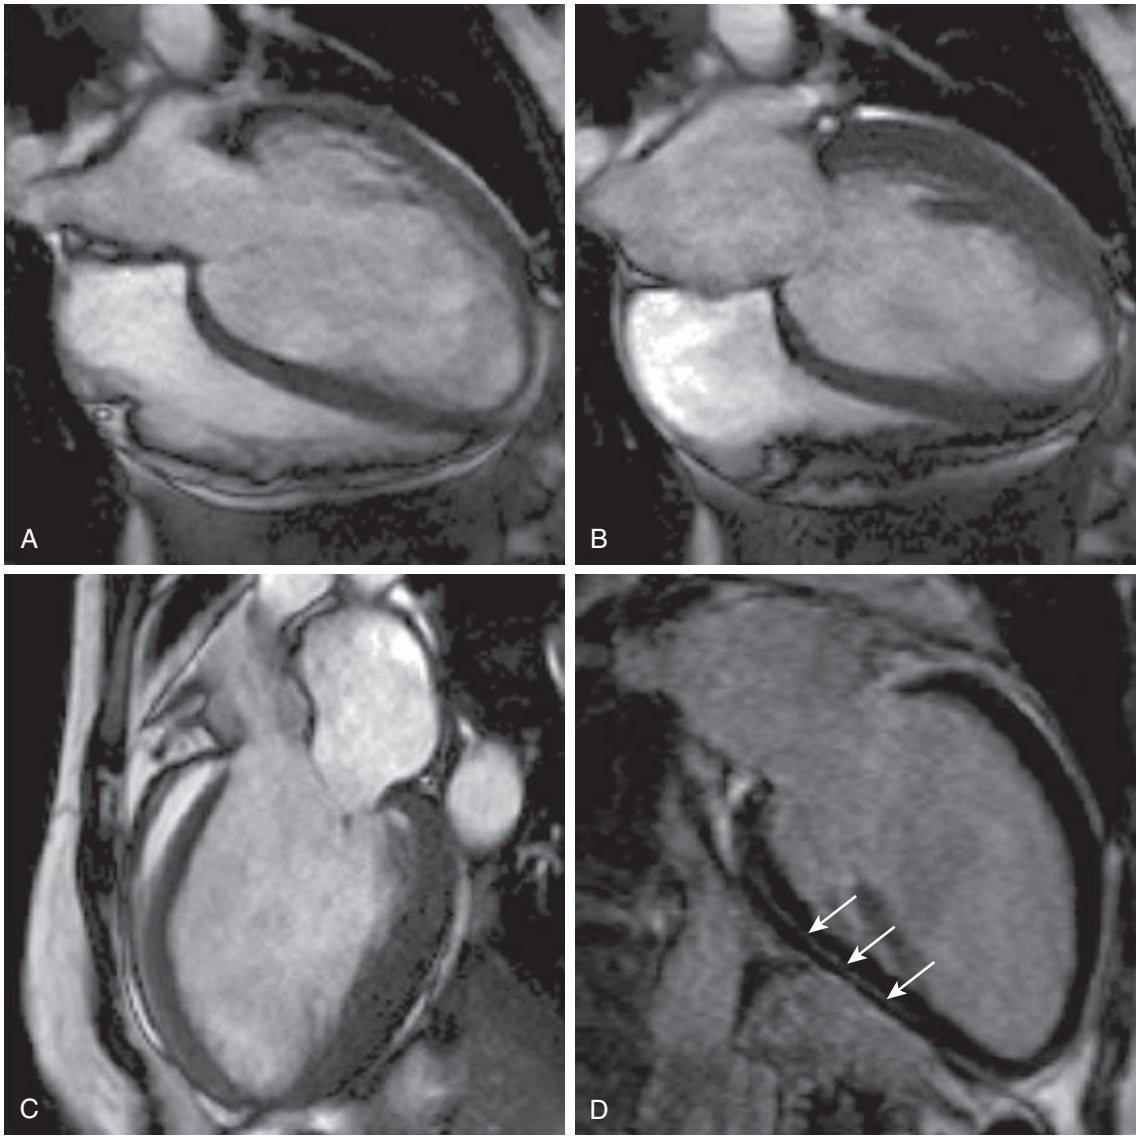
PROGNOSIS

The prognosis of idiopathic and genetically determined dilated cardiomyopathy is related to the etiology, the severity of disease at the time of presentation, and the response to treatment. Most patients improve with treatment, but the 5-year survival is less than 50% in patients who present with severe disease (e.g., ejection fraction <25%, left ventricular end-diastolic dimension >65 mm, peak oxygen consumption <12 mL/kg/minute).

Specific Causes of Dilated Cardiomyopathy

Alcoholic Cardiomyopathy

In the United States, excess alcohol consumption (Chapter 364) contributes to more than 10% of cases of heart failure.[19] Alcohol and its metabolite, acetaldehyde, are cardiotoxins. Myocardial depression is initially reversible but, if alcohol consumption is sustained, can lead to myocyte vacuolization, mitochondrial



E-FIGURE 47-8. A 45-year-old woman with dilated cardiomyopathy, left bundle branch block, and heart failure. The left ventricular ejection fraction is 27%, and the left ventricle is severely dilated (diastolic volume of 288 mL; **A**, diastolic; **B, C**, systolic frames). There is a rim of mid-myocardial late gadolinium enhancement at the inferior wall (*arrows*, **D**).

abnormalities, and myocardial fibrosis. Even in chronic stages, however, the heart failure represents a sum of both reversible and irreversible myocardial dysfunction. The amount of alcohol necessary to produce symptomatic cardiomyopathy in susceptible individuals is not known but has been estimated to be six drinks (~4 oz of pure ethanol) a day for 5 to 10 years. Frequent binging without heavy daily consumption may also be sufficient. Alcoholic cardiomyopathy can develop in patients without social evidence of an alcohol problem. Abstinence leads to improvement in at least 50% of patients with severe symptoms, some of whom normalize their left ventricular ejection fractions. Patients with other causes of heart failure also should limit alcohol consumption.

Chemotherapy

Anthracycline (doxorubicin, daunorubicin, epirubicin) cardiotoxicity (Chapter 164) causes characteristic histologic changes on endomyocardial biopsy with overt heart failure in 5 to 10% of patients who receive doses of 450 mg/m^2 of body surface area or more. Most cardiotoxicity occurs within the first year and is associated with a higher anthracycline dose and a lower left ventricular ejection fraction. Patients who have received anthracyclines in the prepubertal period without apparent cardiotoxicity may develop cardiac failure in young adulthood. The risk is higher in patients who have lower baseline ejection fractions, concomitant radiation therapy, or higher doses of anthracycline. Cyclophosphamide and ifosfamide can cause acute severe heart failure and malignant ventricular arrhythmias. Some tyrosine kinase inhibitors (e.g., sunitinib) cause a reduction in systolic function, especially in the presence of coronary artery disease, but there is good response to withdrawal and conventional medical therapy (Chapter 164). 5-Fluorouracil can cause coronary artery spasm and depressed left ventricular contractility. Up to 11% of patients who receive trastuzumab (Chapter 183), a recombinant monoclonal antibody that binds to human epidermal growth factor type 2, develop dilated cardiomyopathy, which is reversible after withdrawal and conventional drug treatment. The risk for cardiotoxicity increases with previous anthracycline and radiation treatment. Interferon alfa may be associated with hypotension and arrhythmias in up to 10% of patients, and interleukin-2 rarely has been associated with cardiotoxicity. Immune checkpoint inhibitors, which activate antitumor T lymphocytes that then attack cancer cells, can lead to off-target effects, including myocarditis, heart failure, and cardiogenic shock.

The use of ß-blockers (e.g., carvedilol, starting at 6.25 mg twice daily and increasing to 25 mg twice daily in the absence of heart failure, bradycardia, or atrioventricular block)[A11] or renin–angiotensin system blockers (e.g., enalapril, starting at 1.25 mg or 2.5 mg twice daily, increasing to 10 mg twice daily as tolerated with systolic blood pressure >90 mm Hg) with chemotherapy has been associated with better subsequent left ventricular function. However, small sample sizes and potential publication bias limit the clinical interpretability of these findings.

Metabolic and Endocrine Disease

Excess catecholamines, as in pheochromocytoma (Chapter 209), may injure the heart by compromising the coronary microcirculation or by direct toxic effects on myocytes. *Cocaine* (Chapter 365) increases synaptic concentrations of catecholamines by inhibiting reuptake at nerve terminals; the result may be an acute coronary syndrome or chronic cardiomyopathy.

Thiamine deficiency from poor nutrition or alcoholism (Chapter 199) can cause beriberi heart disease, with vasodilation and high cardiac output followed by low output. Calcium deficiency (Chapter 227) resulting from hypoparathyroidism, gastrointestinal abnormalities, or chelation directly compromises myocardial contractility.

Hypophosphatemia (Chapter 105), which may occur in alcoholism, during recovery from malnutrition, and in hyperalimentation, also reduces myocardial contractility. Patients with magnesium depletion (Chapter 105) due to impaired absorption or increased renal excretion (Chapter 105) also may present with left ventricular dysfunction.

Hypothyroidism (Chapter 207) depresses contractility and conduction and may cause pericardial effusions, whereas *hyperthyroidism* increases cardiac output, can worsen underlying heart failure, and may rarely be the sole cause of heart failure. The presenting sign of diabetes (Chapter 210) can be cardiomyopathy, especially with diastolic dysfunction, independent of epicardial coronary atherosclerosis, for which it is a major risk factor. Obesity (Chapter 201) can cause cardiomyopathy with increased ventricular mass and decreased contractility, which improve after weight loss, or it can aggravate underlying heart failure from other causes.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy appears in the last month of pregnancy or in the first 5 months after delivery in the absence of preexisting cardiac disease (Chapter 221).[20] The incidence is between 1 in 3000 and 1 in 15,000 deliveries, with increased risk in older mothers or in the setting of twins, malnutrition, tocolytic therapy, toxemia, or hypertension. Lymphocytic myocarditis, which is found in 30 to 50% of biopsy specimens, suggests an immune component, perhaps cross-reactivity between uterine and cardiac myocyte proteins or an enhanced susceptibility to viral myocarditis. Enhanced oxidative stress triggers activation of cathepsin D, which is a ubiquitous lysosomal enzyme that cleaves serum prolactin in its antiangiogenic and proapoptotic 16-kD form, and that appears to promote endothelial inflammation and impair metabolism and contraction of cardiomyocytes. About 15% of patients have truncating mutations in the same genes that have been implicated in dilated cardiomyopathy, especially the *TTN* gene. Presentation is usually with orthopnea and dyspnea on minimal exertion, most often within the first weeks after delivery when the excess volume of pregnancy would normally be mobilized. Preexisting cardiac disease must be excluded.

TREATMENT

Diuretics facilitate postpartum diuresis, and angiotensin-converting enzyme inhibitors improve symptoms (Chapter 46).[21] Oral bromocriptine (2.5 mg twice daily for 2 weeks, then daily for 6 weeks) can significantly improve the recovery of left ventricular function and may reduce deaths.[A12] The prognosis is improvement to normal or near-normal ejection fraction during the next 6 months in more than 50% of patients. About 4% require heart transplantation, and about 9% die suddenly or from complications of heart transplantation.

Overlap with Restrictive Cardiomyopathy

Diseases causing primarily restrictive cardiomyopathies can occasionally overlap to cause a picture consistent with dilated cardiomyopathy. For example, hemochromatosis (Chapter 196) and sarcoidosis (Chapter 83) should be considered in evaluating any patient with a cardiomyopathy. Amyloidosis (Chapter 174) is less commonly confused with dilated than with hypertrophic cardiomyopathy but should be considered in a patient who has a thick-walled ventricle with depressed contractile function.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

DEFINITION AND EPIDEMIOLOGY

Arrhythmogenic right ventricular cardiomyopathy (ARVC; Chapter 53) is a genetically determined type of cardiomyopathy that is characterized histologically by loss of cardiomyocytes with replacement by fibrous or fibrofatty tissue in the right ventricular myocardium; clinically by ventricular arrhythmias, heart failure, and sudden cardiac death; and histologically by cardiomyocyte loss and replacement. The disease is seen in patients of European, African, and Asian descent, with an estimated prevalence between 1 in 1000 and 1 in 5000 adults.

PATHOBIOLOGY

Arrhythmogenic right ventricular cardiomyopathy is inherited as an autosomal dominant disease with incomplete penetrance, although recessive forms with cutaneous manifestations are recognized (see E-Table 47-1). Most cases are caused by heterozygous mutations in genes encoding components of the desmosomal junction of cardiomyocytes. The most common occur in plakophilin 2, desmocollin 2, desmoplakin, and desmoglein 2. Homozygous mutations in plakoglobin and desmoplakin are responsible for the rare autosomal recessive forms (Naxos disease and Carvajal syndrome, respectively). A highly penetrant and lethal mutation in the transmembrane cytoplasmic protein 43 (TMEM43) has been described in families from Newfoundland. Other genes that rarely cause arrhythmogenic right ventricular cardiomyopathy include desmin (*DES*), phospholamban (*PLN*), and lamin (*LMNA*).

Pathology

The main pathologic feature is progressive loss of right ventricular myocardium, which is replaced by adipose and fibrous tissue. These changes begin in the inflow, outflow, and apical regions of the right ventricle. Aneurysm formation in these areas is typical. Progressive myocardial involvement may lead to global right ventricular dilation. Right ventricular disease is often associated with fibrofatty substitution of the left ventricular myocardium, with the posterolateral wall preferentially affected.

Mutations in desmosomal protein genes may increase the susceptibility of the myocardium to the damaging effects of mechanical stress. The acute phase

of myocardial injury may be accompanied by inflammation. The predilection for the right ventricle has been explained by its thin wall and greater distensibility. As desmosomal proteins interact with many other proteins, including components of the cellular cytoskeleton and intermediate filaments, it is possible that ventricular dysfunction occurs as the result of reduced cytoskeletal integrity and impaired force transduction. Some desmosomal proteins, in particular plakoglobin, are also important signaling molecules that regulate the transcription of many other genes.

Inflammatory infiltrates are present in about 70% of patients in autopsy series. People with arrhythmogenic right ventricular cardiomyopathy also have raised levels of cytokines and anti-DSG2 (desmoglein) antibodies.

CLINICAL MANIFESTATIONS

By convention, the natural history of arrhythmogenic right ventricular cardiomyopathy is divided into phases, but it is not inevitable that patients will progress through all phases. In the early phase, patients are usually asymptomatic, but resuscitated cardiac arrest and sudden death may be the initial manifestations, particularly in adolescents and young adults. The overt arrhythmic phase usually begins in adolescents and young adults, when patients note palpitations or syncope. Symptomatic sustained arrhythmias are usually accompanied by ECG, morphologic, and functional abnormalities of the right ventricle sufficient to fulfill diagnostic criteria for arrhythmogenic right ventricular cardiomyopathy. A small proportion of patients progress to a more advanced phase, which is characterized by diffuse right or left ventricular impairment that requires conventional treatment for heart failure (Chapter 46). Cardiac sarcoidosis (Chapter 83; see later) has many similarities with arrhythmogenic right ventricular cardiomyopathy in terms of presentation and clinical features, and it is sometimes clinically indistinguishable.

DIAGNOSIS

Clinical evaluation includes inquiry for symptoms of arrhythmia (syncope, presyncope, sustained palpitation); a family history of premature cardiac symptoms or sudden death; 12-lead, 24-hour, and maximal exercise ECG testing; and two-dimensional echocardiography with specific right ventricular views. Contrast echocardiography may be required to obtain better endocardial definition of the right ventricular myocardium and apex of the left ventricle. Magnetic resonance imaging (Chapter 44) provides accurate assessment of ventricular volumes as well as noninvasive characterization of the characteristic fibrous tissue and fat that establish the diagnosis and provide prognostic information (Figs. 44-17 and 47-5).[22]

Ventricular arrhythmias with a left bundle branch block morphology, consistent with a right ventricular origin, are characteristic. However, the ECG and arrhythmic manifestations are not specific to arrhythmogenic right ventricular cardiomyopathy and overlap with many other disease states, so standard criteria are recommended for diagnosis (Table 47-5). Because these criteria are highly specific but lack sensitivity for detection of early disease, more sensitive criteria are recommended for first-degree relatives of known cases (Table 47-6). The diagnosis in a proband also raises the possibility of mutation analysis in the family to identify those at risk and in need of serial evaluation as well as those who need no specific follow-up.

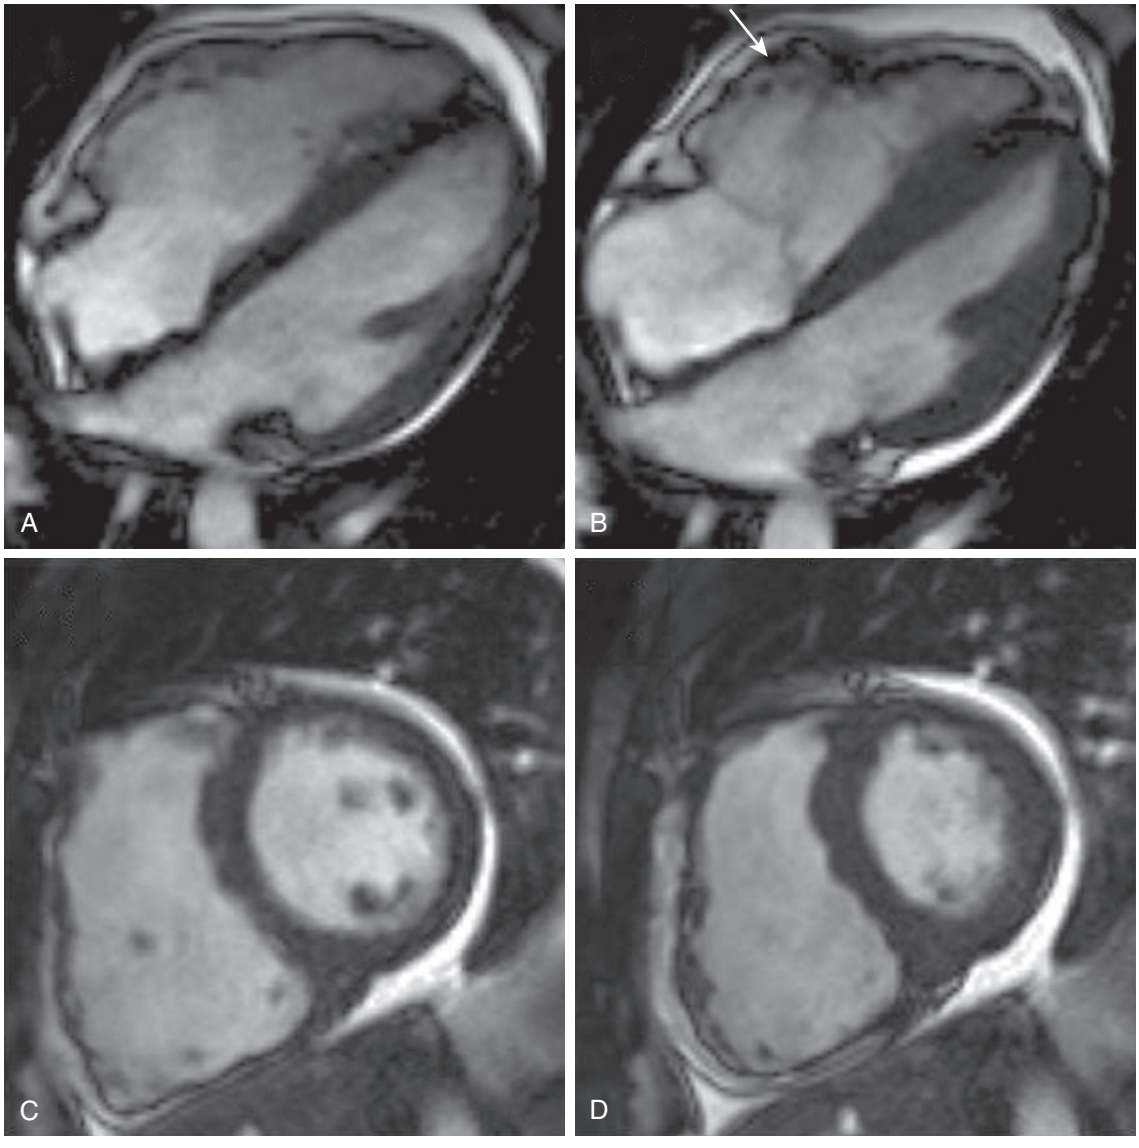


FIGURE 47-5. A 21-year-old man with arrhythmogenic right ventricular cardiomyopathy. End-diastolic (**A**) and end-systolic (**B**) frames from a four-chamber view, with a dilated and impaired right ventricle with a basal wall motion abnormality (*arrow*), confirmed on end-diastolic (**C**) and end-systolic (**D**) short axis views. This individual had no scar in the left ventricle with well-preserved systolic function; scar imaging in the thin right ventricle (with adjacent fat and small effusion) was equivocal.

TABLE 47-5 REVISED TASK FORCE CRITERIA FOR ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY IN PROBANDS*

CRITERIA	
MAJOR	**MINOR**
I. GLOBAL OR REGIONAL DYSFUNCTION AND STRUCTURAL ALTERATIONS*	
By Two-Dimensional Echo • Regional RV akinesia, dyskinesia, or aneurysm • *and* 1 of the following (end diastole): PLAX RVOT ≥32 mm (corrected for body size [PLAX/BSA] ≥19 mm/m^2) PSAX RVOT ≥36 mm (corrected for body size [PLAX/BSA] ≥21 mm/m^2) *or* fractional area change ≤33%	**By Two-Dimensional Echo** • Regional RV akinesia or dyskinesia • *and* 1 of the following (end diastole): PLAX RVOT ≥29 to <32 mm (corrected for body size [PLAX/BSA] ≥16 to <19 mm/m^2) PSAX RVOT ≥32 to <36 mm (corrected for body size [PSAX/BSA] ≥18 to <21 mm/m^2) *or* fractional area change >33% to ≤40%
By MRI • Regional RV akinesia or dyskinesia or dyssynchronous RV contraction • *and* 1 of the following: RV end-diastolic volume indexed to BSA ≥110 mL/m^2 (male) or ≥100 mL/m^2 (female) *or* RV ejection fraction ≤40%	**By MRI** • Regional RV akinesia or dyskinesia or dyssynchronous RV contraction • *and* 1 of the following: RV end-diastolic volume indexed to BSA ≥100 to <110 mL/m^2 (male) or ≥90 to <100 mL/m^2 (female) *or* RV ejection fraction >40% to ≤45%
By RV angiography • Regional RV akinesia, dyskinesia, or aneurysm	
II. TISSUE CHARACTERIZATION OF WALL	
• Residual myocytes <60% by morphometric analysis (or <50% if estimated), with fibrous replacement of the RV free wall myocardium in ≥1 sample, with or without fatty replacement of tissue on endomyocardial biopsy	• Residual myocytes 60% to 75% by morphometric analysis (or 50% to 65% if estimated), with fibrous replacement of the RV free wall myocardium in ≥1 sample, with or without fatty replacement of tissue on endomyocardial biopsy
III. REPOLARIZATION ABNORMALITIES	
• Inverted T waves in right precordial leads (V_1,V_2, and V_3) or beyond in individuals >14 years of age (in the absence of complete right bundle branch block QRS ≥120 msec)	• Inverted T waves in leads V_1 and V_2 in individuals >14 years of age (in the absence of complete right bundle branch block) or in V_4, V_5, or V_6 • Inverted T waves in leads V_1, V_2, V_3, and V_4 in individuals >14 years
IV. DEPOLARIZATION/CONDUCTION ABNORMALITIES	
• Epsilon wave (reproducible low-amplitude signals between end of QRS complex to onset of the T wave) in the right precordial leads (V_1 to V_3)	• Late potentials by SAECG in ≥1 of 3 parameters in the absence of a QRS duration ≥110 msec on the standard ECG • Filtered QRS duration (fQRS) ≥114 msec • Duration of terminal QRS <40 μV (low-amplitude signal duration) ≥38 msec • Root-mean-square voltage of terminal 40 msec ≥20 μV • Terminal activation duration of QRS ≥55 msec measured to the end of the QRS, including R′, in V_1, V_2, or V_3, in the absence of complete right bundle branch block
V. ARRHYTHMIAS	
• Nonsustained or sustained ventricular tachycardia of left bundle branch morphology with superior axis (negative or indeterminate QRS in leads II, III, and aVF and positive in lead aVL)	• Nonsustained or sustained ventricular tachycardia of RV outflow configuration, left bundle branch block morphology with inferior axis (positive QRS in leads II, III, and aVF and negative in lead aVL) or of unknown axis • >500 ventricular extrasystoles per 24 hours (Holter)
VI. FAMILY HISTORY	
• ARVC confirmed in a first-degree relative who meets current Task Force criteria • ARVC confirmed pathologically at autopsy or surgery in a first-degree relative • Identification of a pathogenic mutation† categorized as associated or probably associated with ARVC in the patient under evaluation	• History of ARVC in a first-degree relative in whom it is not possible or practical to determine whether the family member meets current Task Force criteria • Premature sudden death (<35 years of age) due to suspected ARVC in a first-degree relative

*Hypokinesis is not included in this or subsequent definitions of right ventricular (RV) regional wall motion abnormalities for the proposed modified criteria.

†A pathogenic mutation is a DNA alteration associated with ARVC that alters or is expected to alter the encoded protein, is unobserved or rare in a large non-ARVC control population, and either alters or is predicted to alter the structure or function of the protein or has demonstrated linkage to the disease phenotype in a conclusive pedigree.

ARVC = arrhythmogenic right ventricular cardiomyopathy; aVF = augmented voltage unipolar left foot lead; aVL = augmented voltage unipolar left arm lead; BSA = body surface area; ECG = electrocardiogram; MRI = magnetic resonance imaging; PLAX = parasternal long axis view; PSAX = parasternal short axis view; RVOT = right ventricular outflow tract; SAECG = signal-averaged electrocardiogram. Diagnostic terminology for original criteria: this diagnosis is fulfilled by the presence of 2 major, 1 major plus 2 minor, or 4 minor criteria from different groups. Diagnostic terminology for revised criteria: definite diagnosis: 2 major, 1 major and 2 minor, or 4 minor criteria from different categories; borderline: 1 major and 1 minor or 3 minor criteria from different categories; possible: 1 major or 2 minor criteria from different categories.

From Marcus FI, McKenna WJ, Sherrill D, et al. Diagnosis of arrhythmogenic right ventricular cardiomyopathy/dysplasia: proposed modification of the task force criteria. *Circulation*. 2010;121:1533-1541.

Differential Diagnosis

The differential diagnosis includes other inherited cardiomyopathies, the inherited arrhythmia syndromes (long QT syndrome, Brugada syndrome, and catecholaminergic polymorphic ventricular tachycardia; Chapter 53), cardiac sarcoidosis, myocarditis, and causes of right ventricular dilation such as intracardiac or extracardiac shunts (Chapter 55). The differentiation from so-called benign right ventricular outflow tract tachycardia may be problematic, although the 12-lead ECG and right ventricular imaging studies are typically normal, and no familial disease is present. Some patients with desmosomal protein gene mutations demonstrate left ventricular involvement early in the disease (e.g., truncating variants in desmoplakin), whereas survivors may develop a predominant left ventricular dilated cardiomyopathy phenotype with a risk of lethal arrhythmias.

TREATMENT

Pharmacologic treatment is the first-line therapy for patients with well-tolerated, non–life-threatening ventricular arrhythmias, such as frequent ventricular extrasystoles. Treatment of patients with symptomatic ventricular arrhythmias is with an ICD,[23] with supplemental sotalol (160 to 240 mg/day) or even amiodarone (maintenance dose of 200 mg/day). Catheter ablation (Chapter 54) may be required in patients with drug-refractory incessant ventricular arrhythmia

TABLE 47-6 ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY: CRITERIA FOR DIAGNOSIS OF FIRST-DEGREE RELATIVES WHO DO NOT FULFILL CRITERIA AS PROBANDS*

ARVC in a first-degree relative plus one of the following:	
ECG	T wave inversion in right precordial leads (V_2 and V_3)
Signal-averaged ECG	Late potentials seen on signal-averaged ECG
Arrhythmia	Left bundle branch block–type ventricular tachycardia on ECG, on Holter monitoring, or during exercise testing; >200 extrasystoles during a 24-hour period
Structural or functional abnormality of the right ventricle	Mild global right ventricular dilation or reduction in ejection fraction with normal left ventricle; mild segmental dilation of the right ventricle; regional right ventricular hypokinesia

*Any one criterion is adequate for the diagnosis.
ARVC = arrhythmogenic right ventricular cardiomyopathy; ECG = electrocardiogram.
From Hamid MS, Norman M, Quraishi A, et al: Prospective evaluation of relatives for familial arrhythmogenic right ventricular cardiomyopathy reveals a need to broaden diagnostic criteria. *J Am Coll Cardiol*. 2002;40:1445-1450.

or frequent recurrences of ventricular tachycardia after implantation of an ICD, although recurrence is common.

Retrospective analyses of clinical and pathologic series have identified a number of possible predictors of adverse outcome in probands, including an early age at onset of symptoms, competitive sporting activity, severe right ventricular dilation, left ventricular involvement, syncope, episodes of complex ventricular arrhythmias or VT, and increased QRS dispersion on the 12-lead electrocardiogram. ICD implantation is recommended for the prevention of sudden cardiac death in patients with documented sustained ventricular tachycardia or ventricular fibrillation and a reasonable expectation of survival with a good functional status for longer than 1 year. ICD implantation may also be appropriate in patients with extensive disease, including those with left ventricular involvement, or undiagnosed syncope when ventricular tachycardia or ventricular fibrillation has not been excluded as the cause.

Standard heart failure therapy, including diuretics, angiotensin-converting enzyme inhibitors, and β-blockers, is indicated in patients in whom arrhythmogenic right ventricular cardiomyopathy has progressed to severe heart failure or biventricular systolic dysfunction (Chapter 46). Anticoagulation should be considered in the presence of atrial fibrillation (Chapter 52), marked ventricular dilation, or ventricular aneurysms. In patients in whom heart failure is refractory, cardiac transplantation (Chapter 46) should be considered.

PROGNOSIS

Most data on prognosis are derived from small, high-risk populations. By the age of 40 years, event-free survival is 50 to 60% in patients with Naxos disease and some autosomal dominant forms. In patients who have syncope or sustained ventricular arrhythmias and are treated with an ICD, freedom from appropriate shock therapy is about 75% at 48 months after implantation, with 96% of patients alive. Risk factors for sudden cardiac death include genotype,[24] severe right ventricular disease, left ventricular involvement, and a history of unexplained syncope.

RESTRICTIVE CARDIOMYOPATHY

DEFINITION AND EPIDEMIOLOGY

Restrictive cardiomyopathies (Table 47-7) are characterized by stiffness, impaired filling, elevated left ventricular diastolic pressures, and reduced diastolic volume of the left or right ventricle despite normal or near-normal systolic function and wall thickness.[25] Primary (idiopathic) forms are very uncommon, whereas secondary forms, in which the heart is affected as part of a multisystem disorder, usually present at the advanced stage of an infiltrative disease (e.g., amyloidosis or sarcoidosis) or a systemic storage disease (e.g., hemochromatosis). Idiopathic restrictive cardiomyopathy affects both male and female patients and may be manifested in children and young adults.

PATHOBIOLOGY

Approximately 30% of patients with idiopathic restrictive cardiomyopathy have familial disease, and most of these patients will have mutations in the cardiac sarcomere protein genes, particularly *TNNI3* and *MYH7*. These individuals may present with phenotypes that overlap with hypertrophic cardiomyopathy (Fig. 47-6). Mutations in the gene (*DES*) that encodes desmin, which is an intermediate filament, cause restrictive cardiomyopathy associated with skeletal myopathy and cardiac conduction system abnormalities. Wild-type, transthyretin-related cardiac amyloidosis (Chapter 174) is the most prevalent form of restrictive cardiomyopathy, and it increases in frequency in older patients. However, restriction is present only in the late stages of disease, when patients have extensive amyloid infiltration of the myocardial interstitium.

Restrictive cardiomyopathy is seen in hemochromatosis (Chapter 196) and sarcoidosis (Chapter 83), and it also is increasingly seen in cancer survivors as a consequence of diffuse biventricular fibrosis, most often with a nonischemic pattern, caused by chemotherapy (especially high-dose anthracyclines) and chest radiotherapy (Chapter 18).

The macroscopic features of restrictive cardiomyopathy include biatrial dilation and small ventricular cavities. In many hearts, there is thrombus in the atrial appendages and patchy endocardial fibrosis. The histologic features of restrictive cardiomyopathy vary, depending on the cause, but patchy interstitial fibrosis and myocyte disarray can be seen in patients with pure restrictive cardiomyopathy. Amyloidosis, hemochromatosis, and sarcoidosis are among the systemic diseases that cause restrictive cardiomyopathy (see later).

CLINICAL MANIFESTATIONS

Most patients present with symptoms and signs of heart failure and supraventricular arrhythmias, including atrial fibrillation (Chapter 52) and heart block (Chapter 51). Common symptoms include dyspnea on exertion, recurrent respiratory tract infections, general fatigue, and weakness. Symptoms may progress rapidly to dyspnea at rest, orthopnea, paroxysmal nocturnal dyspnea, and abdominal discomfort due to hepatic engorgement. Many patients complain of chest pain and palpitation. Rarely, sudden death is the initial manifestation of the disease.

Physical examination typically reveals an elevated jugular venous pressure, which has a prominent *y* descent and fails to fall (or rises) during inspiration (Kussmaul sign). On cardiac auscultation, the pulmonary component of the second heart sound may be loud if pulmonary vascular resistance is high. A third heart sound and occasionally a fourth heart sound commonly produce a gallop rhythm. Peripheral edema, ascites, and hepatomegaly are common.

DIAGNOSIS

No ECG findings are diagnostic, but the most frequent ECG abnormalities include P mitrale and P pulmonale, nonspecific ST segment and T wave abnormalities, ST segment depression, and T wave inversion, usually in the inferolateral leads. Voltage criteria for left and right ventricular hypertrophy may be present. Some patients with amyloidosis have low-voltage QRS complexes. Conduction abnormalities include intraventricular conduction delay and abnormal Q waves.

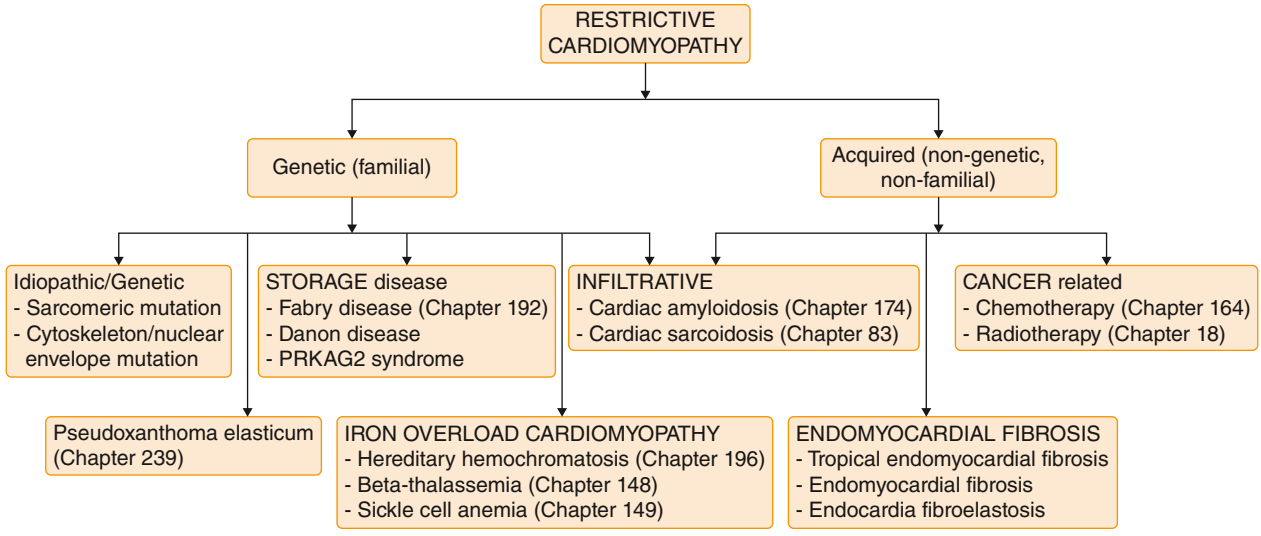

FIGURE 47-6. Classification of restrictive cardiomyopathies. (Adapted from Ditaranto R, Caponetti AG, Ferrara V, et al. Pediatric restrictive cardiomyopathies. *Front Pediatr.* 2022;9:745365.)

On cardiac imaging, both atria are markedly dilated and can dwarf the size of the ventricles in patients with normal global systolic function and a nonhypertrophied, nondilated left ventricle. Pulsed-wave Doppler velocities typically show increased early diastolic filling velocity, decreased atrial filling velocity, increased ratio of early diastolic filling to atrial filling, decreased E wave deceleration time, and decreased isovolumic relaxation time. Pulmonary vein and hepatic vein pulsed-wave Doppler velocities demonstrate higher diastolic than systolic velocities, increased atrial reversal velocities, and atrial reversal duration greater than mitral atrial filling duration. Tissue Doppler imaging usually shows reduced diastolic annular velocities and an increased ratio of early diastolic tissue Doppler annular velocity to mitral early diastolic filling velocity, reflecting elevated left ventricular end-diastolic pressures.

The characteristic hemodynamic feature on cardiac catheterization is a deep and rapid early decline in ventricular pressure at the onset of diastole (Table 62-6 and E-Fig 47-9), with a rapid rise to a plateau in early diastole ("dip-and-plateau" or "square root sign") (Fig. 47-7). Left ventricular end-diastolic, left atrial, and pulmonary capillary wedge pressures are markedly elevated, usually 5 mm Hg or more above right atrial and right ventricular end-diastolic pressures. Volume loading and exercise accentuate the difference between left-sided and right-sided pressures.

The diagnostic evaluation aims to exclude potentially reversible conditions and to distinguish restrictive cardiomyopathy from constrictive pericarditis (Chapter 62). Definitive etiologic diagnosis relies on the demonstration of disease-specific features, such as amyloid protein in amyloidosis (Chapter 174), noncaseating granulomas in sarcoidosis (Chapter 83), abnormal iron studies in hemochromatosis (Chapter 196), or reduced α-galactosidase A levels in Fabry disease (Chapter 192). Endomyocardial biopsy is rarely required to make these diagnoses.

TREATMENT

Diuretics are the main therapy for heart failure symptoms (Chapter 46), but they must be carefully administered so as not to reduce left ventricular filling pressures to the point of hypotension. Angiotensin-converting enzyme inhibitors and β-blockers are commonly recommended despite few data on their benefit. However, all atrioventricular blocking agents, including β-blockers, must be used with caution, because an increase in heart rate is the only mechanism to increase cardiac output in the face of augmented oxygen requirements (e.g., during physical activity). In patients with secondary restrictive cardiomyopathies, specific treatment of the underlying systemic disease is indicated whenever possible (see later). Referral for assessment for possible heart transplantation should be considered early before refractory pulmonary hypertension may develop.

PROGNOSIS

In adults with restrictive cardiomyopathy, the clinical course is usually slow and protracted. Survival from the time of diagnosis is often 10 years or more, except for AL amyloidosis, which progresses much more rapidly. Symptoms of heart failure are generally progressive and respond poorly to treatments for heart failure.

SPECIFIC CLINICAL SYNDROMES

SARCOIDOSIS

The frequency of myocardial involvement in patients with sarcoidosis (Chapter 83) is difficult to determine because it is frequently subclinical and patchy in nature. Postmortem studies suggest that the heart is involved in at least 25% of patients, but clinical cardiac involvement occurs in less than 10% of patients. Clinical manifestations of ventricular dysfunction include heart failure, conduction abnormalities, atrial and ventricular arrhythmias, pericardial effusion, valvular dysfunction, and, rarely, sudden cardiac death. Right-sided heart failure secondary to pulmonary hypertension may occur in patients with extensive fibrotic lung disease. Myocardial infiltration by sarcoid granulomas results in restrictive or dilated cardiomyopathy. The most common site is in the lateral wall of the left ventricle. Papillary muscle involvement is responsible for the most common valvulopathy, mitral regurgitation. Granuloma formation in the basal interventricular septum may cause conduction abnormalities. Ventricular arrhythmias, usually monomorphic ventricular tachycardia, are frequent and may be life-threatening.

DIAGNOSIS

The diagnosis of cardiac sarcoidosis can be challenging given its patchy involvement of the heart.[26] Magnetic resonance imaging identifies areas of edema and fibrosis (the latter evident as patchy areas of late gadolinium enhancement [Fig. 44-16]), whereas ^{18}F-Fluorodeoxyglucose positron emission tomography/computed tomography may demonstrate cardiac inflammation in the active phase of disease (E-Fig. 44-3). In patients with such noninvasive findings, histologic confirmation then may be obtained by a biopsy of other affected organs, such as mediastinal lymph nodes or the liver.

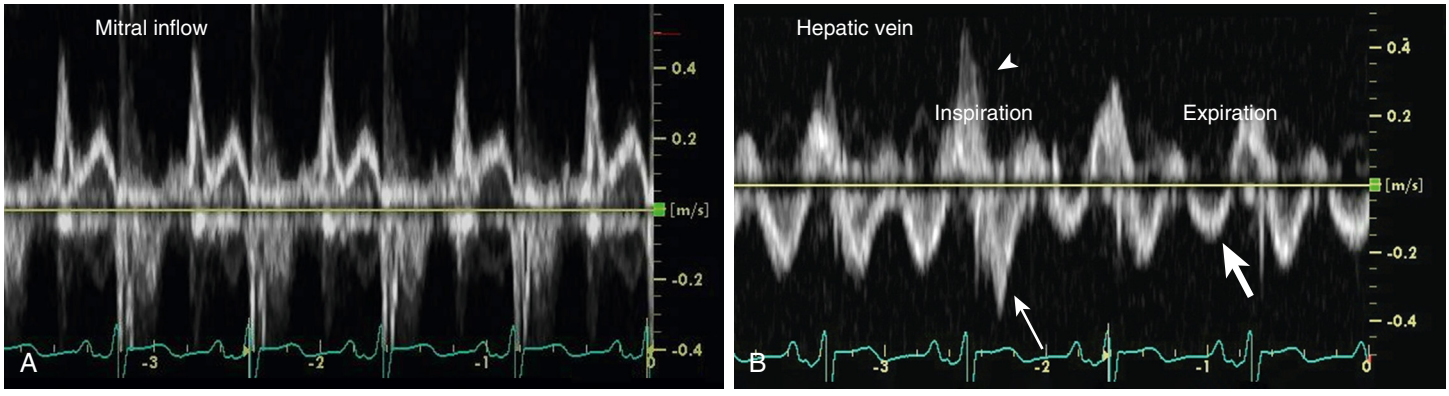
TREATMENT AND PROGNOSIS

Corticosteroid therapy (Chapter 83) may improve arrhythmias. However, heart failure may worsen despite such therapy, so immunosuppressants such as mycophenolate mofetil, methotrexate, or azathioprine may be required. An ICD is generally indicated for ventricular arrhythmias. Estimates for 1-, 5-, and 10-year transplantation-free cardiac survival are 97%, 90%, and 83%, respectively, but heart failure at presentation predicts a poor outcome, with a 10-year transplantation-free cardiac survival of only 53%.

AMYLOIDOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Amyloidosis can result in deposition of amyloid protein in the atria, ventricles, coronary vessels, conduction system, and valves. The degree of cardiac involvement varies among subtypes. Hematologic disorders (Chapter 173) associated with excessive light chain (AL) immunoglobulin production are a common cause of cardiac amyloid. Familial forms caused by the accumulation of mutant proteins (transthyretin or apolipoprotein A) (Chapter 174)



E-FIGURE 47-9. **Differentiation between constrictive pericarditis and restrictive cardiomyopathy. A,** Pulsed-wave Doppler of the mitral inflow shows a restrictive pattern, with early diastolic mitral inflow Doppler velocity greater than late velocity and short deceleration time. **B,** Hepatic vein pulsed-wave Doppler shows increased inspiratory forward velocities *(arrow)*, inspiratory diastolic flow reversals *(arrowhead)*, and minimal expiratory diastolic flow reversals *(thick arrow)*. (From Geske JB, Anavekar NS, Nishimura RA, et al. Differentiation of constriction and restriction: complex cardiovascular hemodynamics. *J Am Coll Cardiol*. 2016;68:2329-2347.)

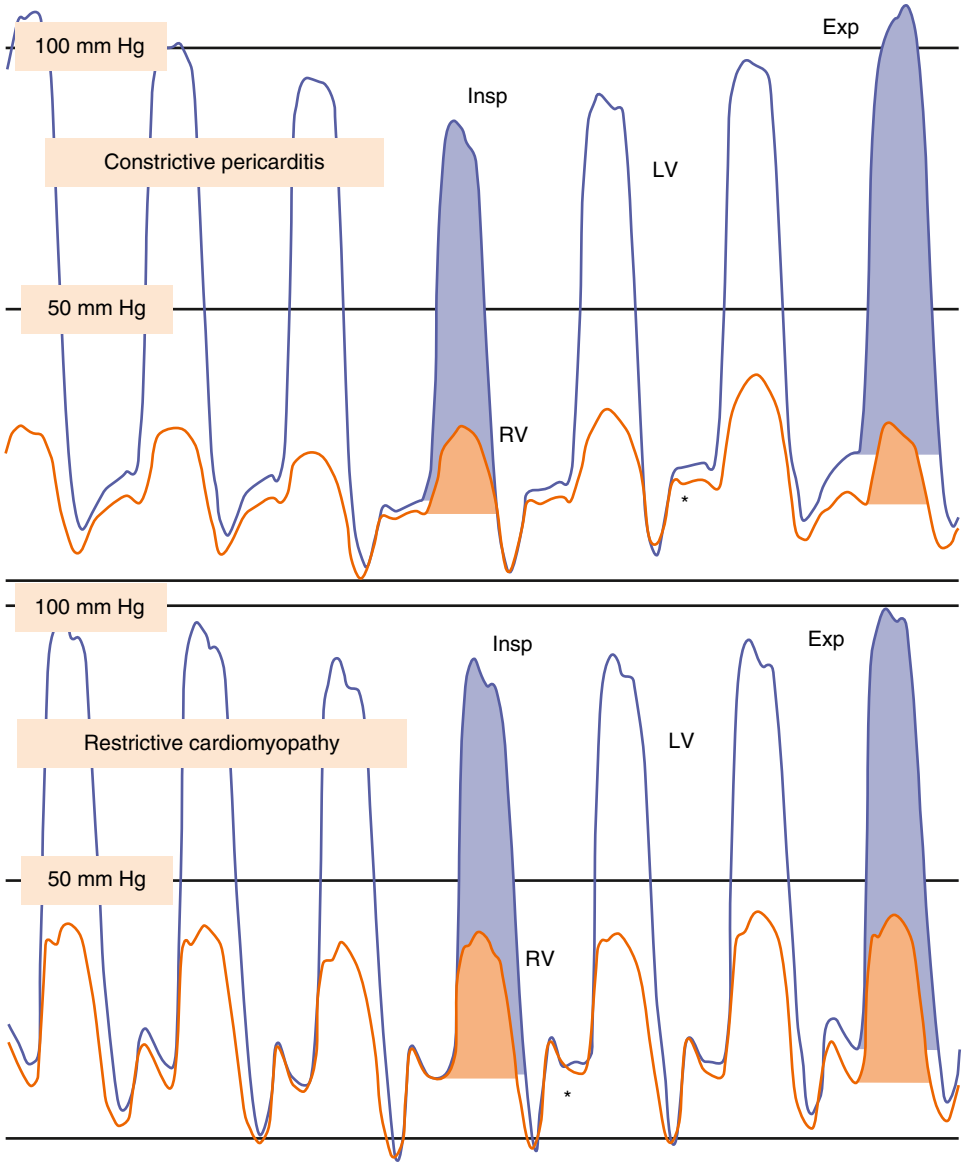


FIGURE 47-7. Simultaneous RV and LV hemodynamic assessment in constrictive pericarditis and restrictive cardiomyopathy. *Top*, Left ventricular (LV) (blue) and right ventricular (RV) (orange) hemodynamic pressure tracings in constrictive pericarditis. End-diastolic filling pressures are elevated and a "square root" sign is present on both pressure tracings (*). Enhanced ventricular interdependence is present, demonstrated by visualization of the systolic area index; RV (gray) and LV (dark gray) areas under the curve are shown for both inspiration (Insp) and expiration (Exp). During inspiration, there is an increase in the area of the RV pressure curve and decrease in the area of the LV pressure curve. *Bottom*, LV and RV pressure tracings in restrictive cardiomyopathy. Although end-diastolic filling pressures are elevated and a square root sign (*) is present, there is no evidence of enhanced ventricular interdependence, with parallel changes in LV and RV pressure curve areas. (Adapted from Geske JB, Anavekar NS, Nishimura RA, et al. Differentiation of constriction and restriction: complex cardiovascular hemodynamics. *J Am Coll Cardiol*. 2016;68:2329-2347.)

have variable cardiac involvement. Secondary amyloidosis, due to deposition of serum amyloid A protein in chronic inflammatory diseases, rarely affects the heart. In late-onset systemic amyloidosis, cardiomyopathy is caused by deposition of normal wild-type transthyretin (TTR); this disease nearly always affects elderly persons (>70 years), with a clinical course that is considerably slower than with other types of amyloid.

DIAGNOSIS

If cardiac amyloidosis is suspected, blood and urine should be analyzed for evidence of a plasma cell dyscrasia (Chapters 173 and 174). The ECG tracing in most forms of cardiac amyloid characteristically shows decreased voltage despite increased wall thickness on echocardiography. Characteristic two-dimensional echocardiographic findings in advanced cardiac amyloidosis are biventricular hypertrophy, thickened valves and interatrial septum, dilated atria, and a small pericardial effusion. The myocardium has a hyperreflective granular texture (Fig. 47-8), best seen on digital image analysis.[27] Echo Doppler in advanced disease demonstrates a restrictive left ventricular filling pattern. Cardiac magnetic resonance imaging may show subendocardial late gadolinium enhancement with abnormal gadolinium kinetics, but it has a 10 to 20% false-negative and false-positive rate.

Transthyretin-related cardiac amyloidosis is particularly avid for 99mTc-phosphate bone tracers (see E-Fig. 44-4). In the setting of a positive 99mTc-phosphate scan without evidence for a plasma clone on blood and urine testing, a diagnosis of transthyretin cardiomyopathy can be made without a biopsy. If both the phosphate scan and blood tests are negative, cardiac amyloidosis is very unlikely. For patients with evidence for a plasma cell dyscrasia, a histologic diagnosis is still required because the presence of uptake on a 99mTc-phosphate scan is not 100% specific for amyloid transthyretin cardiomyopathy.

A definitive diagnosis of amyloidosis requires a tissue biopsy specimen, which can be obtained from other sites. For example, fine-needle aspiration of abdominal fat is positive for amyloid deposits in more than 80% of patients with AL amyloidosis, but is less sensitive for diagnosing other forms of amyloid. If the result is negative, endomyocardial biopsy has a very high sensitivity.

TREATMENT AND PROGNOSIS

Specific therapies to impede precursor protein production and fibril formation should be implemented whenever possible (Chapter 174).[28] Tafamidis (20 to 80 mg daily) can reduce the rate of functional decline and all-cause mortality in transthyretin amyloid cardiomyopathy, but the survival benefit may not be

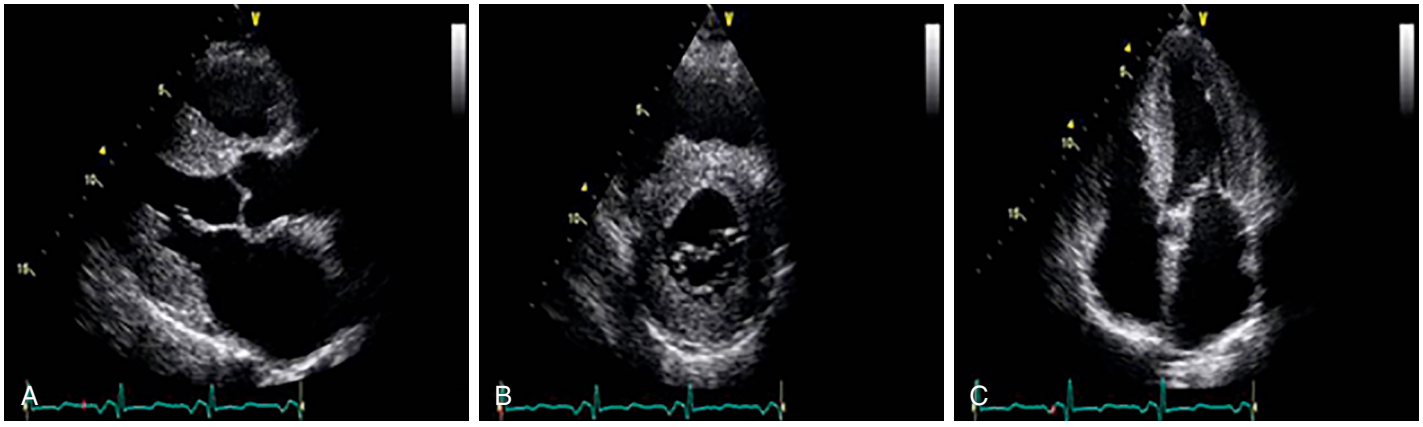

FIGURE 47-8. **Typical echocardiographic features of cardiac amyloidosis. A,** Parasternal long axis showing concentric left ventricular hypertrophy, bright myocardium, and left atrial dilatation. **B,** Parasternal short axis showing concentric left ventricular hypertrophy and bright myocardium. **C,** Apical four-chamber view showing concentric left ventricular hypertrophy and biatrial dilatation. (Images courtesy of Professor Elliott.)

evident until after 2 years of treatment.[A13,A14] Patisiran (0.3 mg/kg intravenously every 3 weeks) may reduce functional decline and adverse cardiac outcomes.[A15] All patients with atrial fibrillation (Chapter 52) should receive anticoagulation (Chapter 70) because of the high intrinsic risk of thromboembolism.

For heart failure (Chapter 46), diuretics, often in high doses (e.g., furosemide, 40 to 80 mg daily), are the mainstay of the palliative heart failure regimen. ß-blockers, angiotensin-converting enzyme inhibitors, and angiotensin II receptor blockers should be used cautiously because they are often poorly tolerated and of unproven efficacy in cardiac amyloidosis. Aldosterone inhibitors might be helpful in advanced cases. Patients may be hypersensitive to digoxin because of enhanced drug binding with amyloid fibrils. Cardiac transplantation remains controversial, but heart transplantation (Chapter 46) with high-dose chemotherapy and with stem cell transplantation (Chapter 163) has been used in patients with AL amyloidosis.

Patients with amyloidosis with heart failure have had a median survival time of less than 1 year and a 5-year survival rate of less than 5%, but new therapies such as tafamidis have reduced mortality by about 30%. Most deaths occur suddenly. Patients with familial amyloidosis have a slower course than do patients with a monoclonal gammopathy.

HEREDITARY HEMOCHROMATOSIS

Hereditary hemochromatosis (Chapter 196) is an autosomal recessive disorder caused by excessive iron deposition in various organs, including the liver, spleen, pancreas, endocrine glands, and heart. In Whites, its prevalence is between 1 in 200 and 1 in 500, with an even higher prevalence in the Irish population. The most common form is caused by mutations in the *HFE* gene, with two missense mutations (*C282Y* and *H63D*) accounting for most cases.

Most patients with classic disease present between the ages of 40 and 60 years with hyperpigmentation, diabetes mellitus, and hepatomegaly. Up to 35% of patients with hemochromatosis experience heart failure, and 36% develop arrhythmias.[29] Restrictive physiologic features dominate early in the disease, followed by ventricular dilation.

DIAGNOSIS

The diagnosis is generally made from the clinical picture, an elevated serum iron level, and a high transferrin saturation. Because paramagnetic ferritin and hemosiderin interact with nearby hydrogen nuclei in tissue water, appropriate MRI sequences evaluating the relaxation time T_2^* is highly sensitive for detecting myocardial iron deposition. Genetic testing is essential, and the diagnosis can be confirmed by endomyocardial biopsy.

TREATMENT

Phlebotomy and iron chelation therapy with deferoxamine (Chapter 196) may improve cardiac function before cell injury becomes irreversible. Standard heart failure treatment (Chapter 46) is generally recommended. Death from hemochromatosis results more often from cirrhosis and liver carcinoma than from cardiac disease.

UNCLASSIFIED CARDIOMYOPATHIES

LEFT VENTRICULAR NONCOMPACTION

Left ventricular noncompaction (LVNC) refers to an abnormal ventricular morphology that is characterized by a thin outer layer of normal or compacted myocardium with an inner noncompacted layer consisting of prominent muscular trabeculae and intra-trabecular recesses that communicate with the ventricular cavity. Current evidence suggests that the compact wall grows by intrinsic proliferation rather than by compaction of the preexisting trabecular layer. For this reason, the term excessive trabeculation is being used to describe the phenomenon.

Left ventricular noncompaction can be caused by genetic variants, most commonly in cardiac sarcomeric proteins *MYH7*, *MYBPC*, and *TTN*,[30] in approximately one-third of patients. However, left ventricular noncompaction has also been reported in athletes, healthy controls, and pregnant women, and it is more frequent in Black individuals.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

When extensive areas are involved, ventricular systolic performance may be impaired and lead to an increased risk of ventricular arrhythmias and systemic emboli. Various diagnostic imaging criteria have been proposed, with MRI (Fig. 47-9) being more sensitive than echocardiography, Excessive trabeculation can be seen in isolation or in association with congenital heart anomalies, cardiomyopathies, and even in physiologic conditions such as pregnancy and highly trained athletes. As a result, extreme caution is needed when diagnosing left ventricular noncompaction, particularly in situations in which physiologic remodeling of the ventricle results in prominent ventricular trabeculae.

TREATMENT AND PROGNOSIS

Treatment, when necessary, is for associated heart failure (Chapter 46), arrhythmias (Chapters 50 and 53), and the risk of emboli (Chapter 70). Natural history and prognosis are not well-established.

TAKOTSUBO SYNDROME

Takotsubo syndrome causes transient left ventricular apical dysfunction that mimics myocardial infarction (Chapter 58).[31] About 90% of affected patients are women, especially postmenopausal women.

Catecholamines play a central role in the pathobiology, with acute episodes often triggered by sudden, unexpected stress or major physical illness or trauma. Many patients have abnormalities in both the structure and activity of brain areas that are related to both emotions and the sympathetic nervous system. Microvascular dysfunction and abnormal vasomotor reactivity are common findings, but it is not clear if these findings are the cause or consequence of an acute episode. Myocardial inflammation, which occurs during the acute phase, may persist in the chronic phase and may contribute to long-term morbidity.

CLINICAL PRESENTATION AND DIAGNOSIS

About 35% of events are triggered by emotional events and about 30% of events are triggered by physical events, with no obvious triggers in the remainder of

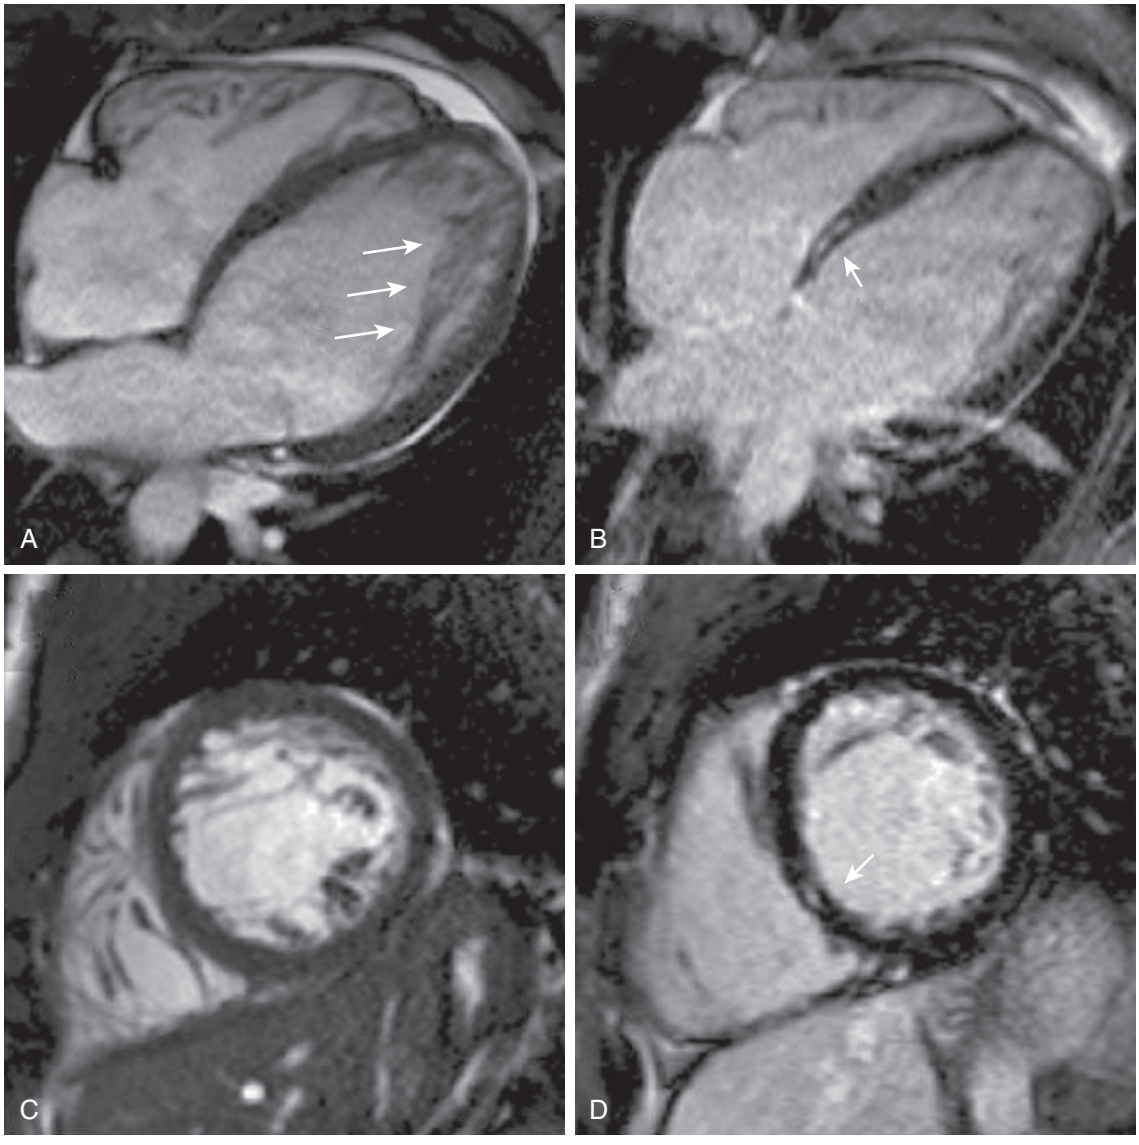

FIGURE 47-9. A 23-year-old White man with left ventricular noncompaction. Four-chamber end-diastolic (**A**) and short axis (**C**) views show left ventricular dilation, prominent trabeculae (*long arrows*), and poorly formed papillary muscles. The ejection fraction was 55%. There is limited mid-myocardial septal late gadolinium enhancement (**B, D**, *short arrows*).

patients. The clinical presentation is usually similar to acute myocardial infarction (Chapter 58), with chest pain, dyspnea, ST-segment elevation or depression, and T-wave inversion on the resting ECG, as well as elevation of serum cardiac troponin levels. Coronary arteriography, which reveals normal epicardial vessels, differentiates Takotsubo syndrome from acute myocardial infarction.

TREATMENT

Conservative treatment with rehydration and removal of the determinants of stress usually results in resolution of the symptoms, ECG changes, and wall motion abnormalities within hours.[32] Patients with left ventricular systolic dysfunction (ejection fraction <40%) should be treated with angiotensin-converting enzyme inhibitors and β-blockers, as in patients who have had an ST elevation myocardial infarction (Chapter 58). Patients may be weaned from both medications once left ventricular function has recovered if patients have no other complications such as tachyarrhythmias or hypertension.

PROGNOSIS

Takotsubo syndrome has a 4 to 5% in-hospital mortality related to cardiogenic shock and cardiac arrest. Survivors may experience long-term cardiac and noncardiac health problems, with an increased long-term mortality.

DISEASES OF THE ENDOCARDIUM

Endocardial fibrosis, fibroelastosis, and thrombosis are subclassified into endomyocardial diseases with hypereosinophilia (hypereosinophilic syndromes) and endomyocardial disease without hypereosinophilia (e.g., endomyocardial fibrosis) (see Table 47-7).

HYPEREOSINOPHILIC SYNDROME

Hypereosinophilic syndromes are a rare and heterogeneous group of disorders defined as persistent blood eosinophilia ($>1.5 \times 10^9$/L) for more than 6 consecutive months, associated with evidence of eosinophil-induced organ damage in the absence of causes of hypereosinophilia, such as allergic drug reactions, parasitic, and malignant disorders (Chapter 156). Pathogenic mechanisms include stem cell mutations that lead to expression of PDGFRA-containing fusion genes, mainly the *FIP1L1-PDGFRA* fusion gene, with constitutive tyrosine kinase activity and sustained overproduction of interleukin-5 by activated T-cell subsets. Clinically, hypereosinophilic syndrome can be classified into chronic eosinophilic leukemia, lymphocytic hypereosinophilic syndrome, myeloproliferative hypereosinophilic syndrome, and idiopathic hypereosinophilic syndrome. The term organ-restricted eosinophilic disease, such as eosinophilic gastroenteritis, dermatitis, or pneumonia, is used when a specific organ or tissue is the exclusive target of eosinophilic infiltration and damage. The term Löffler fibroplastic endocarditis with eosinophilia has been used to describe cardiac damage caused by direct toxicity of circulating eosinophils in patients with persistent hypereosinophilia, but its use is now discouraged.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hypereosinophilic syndrome is a rare disorder that tends to occur in patients 20 to 50 years of age, but all age groups are affected. Cardiac involvement generally evolves in three phases: an early necrotic stage that involves the

endomyocardium, which is usually asymptomatic but can be manifested as acute heart failure; a thrombotic stage, in which thrombi develop on the ventricular endocardium, sometimes causing peripheral emboli; and the final fibrotic stage, endomyocardial fibrosis, which causes restrictive cardiomyopathy and damage to atrioventricular valves.[33] Chest pain, cough, dyspnea or orthopnea, and edema of the lower extremities are typical symptoms. Some patients may develop arrhythmias.

The characteristic two-dimensional echocardiographic findings include endocardial thickening, apical obliteration of one or both ventricles by an echogenic material, hyperdynamic contraction of the spared ventricular walls with bilateral atrial enlargement, and a restrictive pattern on echo Doppler. Endomyocardial biopsy, which should be considered when myocardial involvement is suspected and which remains the gold standard for diagnosis, shows eosinophils and/or their granular products in cardiac tissue.

TREATMENT

Patients should be treated as for the hypereosinophilic syndrome (Chapter 156). Heart failure (Chapter 46) and cardiac arrhythmias (Chapter 52 and 53) should be managed in accordance with consensus guidelines. Chronic oral anticoagulation (Chapter 70) is indicated in patients who have an intracavitary thrombus and/or recurrent thromboembolic events.

TROPICAL ENDOMYOCARDIAL FIBROSIS

Tropical endomyocardial fibrosis is probably the most common type of restrictive cardiomyopathy worldwide.[34] The disease occurs predominantly within the tropics and affects mostly children and adolescents, usually from low socioeconomic backgrounds. Its cause is unknown, but potential contributors include infection, autoimmunity, genetic predisposition, ethnicity, diet, climate, and poverty.

Severe hypereosinophilia is found in some patients early in the initial stage of the illness; it is characterized by febrile illness, pancarditis, facial and periorbital swelling, pruritus, urticaria, and neurologic symptoms. This phase is followed by ventricular thrombosis that affects the apices and the subvalvular apparatus and then evolves to endocardial fibrosis. The final stage is characterized by restrictive physiology, atrioventricular valve regurgitation, and marked atrial dilation. Death results from complications of chronic heart failure but can occur suddenly from thromboembolism or arrhythmia.

Atrial fibrillation is common at presentation. In advanced disease, the electrocardiogram shows low-voltage QRS complexes, nonspecific ST-T wave changes, and conduction abnormalities. Echocardiography demonstrates apical obliteration, reduction of ventricular cavity size, and tethering or retraction of mitral or tricuspid leaflets or both. There is no specific laboratory test, and hypereosinophilia is present only early in the disease.

There is no specific treatment for endomyocardial fibrosis. Medical treatment is used to control the heart failure (Chapter 46) and arrhythmias (Chapters 52 and 53). Surgical endocardial resection, combined with valve repair or replacement, has an early postoperative mortality between 15 and 30%. The overall prognosis is poor, with about a 45% mortality rate at 1 year, increasing to nearly 90% at 3 years.

CARCINOID SYNDROME

EPIDEMIOLOGY AND PATHOBIOLOGY

Carcinoid tumors are rare (1 in 100,000) neuroendocrine malignant neoplasms originating mostly from enterochromaffin cells in the gastrointestinal tract (Chapter 213). Carcinoid syndrome, with flushing, diarrhea, and bronchospasm, occurs after tumor cells metastasize to the liver and the vasoactive substances produced by the tumors enter the systemic circulation through the hepatic vein. Carcinoid heart disease occurs in up to 70% of cases of carcinoid syndrome.

The typical cardiac lesion is the carcinoid plaque, which is composed of smooth muscle cells, myofibroblasts, and elastic tissue that forms a fibrous layer on the endocardial surface of the right ventricle and atrium, the valve leaflets, and the subvalvular apparatus, including the chordae and papillary muscles. The tricuspid valve plaques tend to develop on the ventricular side of the leaflets, where they adhere to the mural endocardium and cause valvular regurgitation. On the pulmonary valve, the predominant lesion is stenosis. In patients with a patent foramen ovale, left-sided valvular involvement can occur. Occasional patients may have concomitant myocardial metastases and pericardial effusions from direct tumor invasion.

The most common presentation is dyspnea with signs and symptoms of right-sided heart failure. The electrocardiogram and radiograph are nonspecific. Echocardiography shows thickening of the tricuspid valve, the subvalvular apparatus, and the pulmonary valve. In severe disease, the tricuspid leaflets are retracted and fixed, with loss of normal coaptation. Similar findings can be seen on cardiac magnetic resonance imaging.

TREATMENT AND PROGNOSIS

Treatment of the underlying carcinoid with a somatostatin analogue can improve systemic symptoms (Chapter 213).[35] Valve replacement now has an operative mortality of less than 10% (Chapter 213). Without treatment, patients with carcinoid heart disease have a mean life expectancy of 1.6 years, but cardiac surgery for valve disease is associated with a better outcome.[36]

NONBACTERIAL THROMBOTIC (MARANTIC) ENDOCARDITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Platelet-fiber masses that are adherent to the mitral or aortic valves are seen in about 20% of patients with malignant tumors, especially mucin-producing adenocarcinomas, melanomas, leukemias, and lymphomas. The lesions are sterile, commonly verruciform, and without accompanying inflammation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Nonbacterial thrombotic endocarditis is virtually always asymptomatic but occasionally is a source of systemic emboli. Because of the small size of many of the emboli, the first presentation is often with cerebral symptoms. Larger lesions are detectable by echocardiography, but even transesophageal echocardiography is not sufficiently sensitive to identify lesions that may be found at autopsy and that may have been the source of systemic emboli.

TREATMENT

No treatment has been proved efficacious. However, systemic anticoagulation similar to that used in patients with tumor-associated deep venous thrombosis is often tried (Chapters 68 and 157).

CARDIAC TUMORS

Cardiac tumors can involve any part of the heart (Fig. 47-10).

MYOCARDIAL TUMORS

Most primary cardiac tumors (Table 47-8) are benign. However, all tumors that extend from other tissues into the heart are malignant, as are metastatic lesions.[37]

EPIDEMIOLOGY AND PATHOBIOLOGY

Primary tumors of the heart are unusual, with a prevalence of 1 in 2000 to 1 in 4000 in autopsy series. Nearly all these primary tumors are benign myxomas, although fibromas, lipomas, and fibroelastomas also occur. Rhabdomyomas are seen in children, especially with tuberous sclerosis (Chapter 385). The rare primary malignant tumors include sarcomas, especially angiosarcomas (see Table 47-8). Rarely, a primary mesothelioma or lymphoma may originate in the heart.

Up to 20% of advanced cancers may involve the pericardium, epicardium, or cardiac chambers either by direct extension of the primary tumor or by metastatic disease. Direct extension occurs principally from cancers of the lung, breast, esophagus, and mediastinum. Extension through the inferior vena cava to the right atrium and even to the right ventricle occurs with cancers of the kidney, adrenal gland, and liver. Metastatic spread is most common with melanomas or lymphomas.

PERICARDIAL TUMORS

CLINICAL MANIFESTATIONS

Pericardial tumors almost always result from direct extension of tumors, principally lung and breast, which produce a pericardial effusion that can progress to cardiac tamponade (Chapter 62). Patients typically are asymptomatic or minimally symptomatic in terms of the cardiac involvement until the effusion is large, although they often may be very ill because of progressive tumor elsewhere.

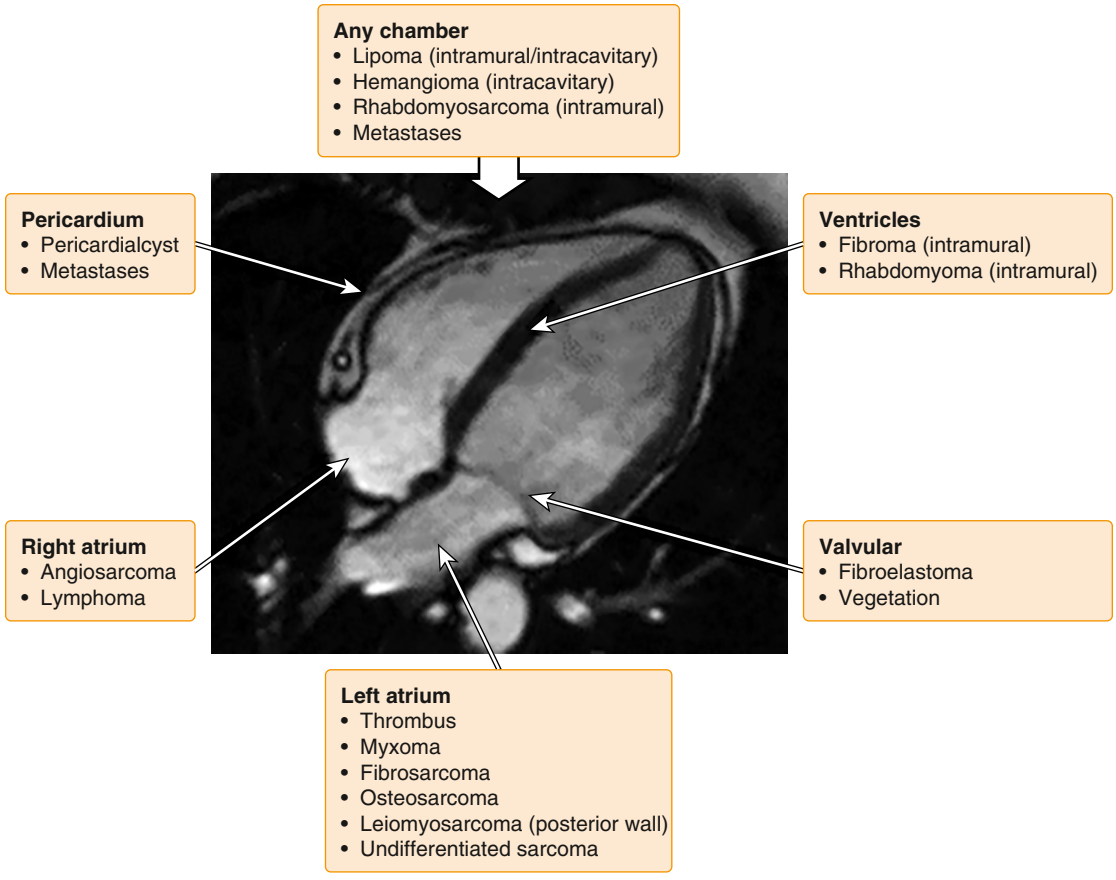

FIGURE 47-10. The typical locations of the most common cardiac tumors. Note, however, that the location of the various conditions can vary, and many cardiac tumors can occur in any chamber. (From Motwani M, Kidambi A, Herzog BA, et al. MR imaging of cardiac tumors and masses: a review of methods and clinical applications. *Radiology*. 2013;268:26-43.)

TABLE 47-8 CARDIAC TUMORS

PRIMARY
Benign

Rhabdomyoma
Fibroelastoma
Malignant
Sarcoma
Mesothelioma
Lymphoma
SECONDARY
Direct Extension
Lung cancer
Breast cancer
Mediastinal tumors
Metastatic Tumors
Malignant melanoma
Leukemia
Lymphoma
Venous Extension
Renal cell cancer
Adrenal cancer
Liver cancer

DIAGNOSIS

The diagnosis is often suspected in a patient with advanced malignant disease on the basis of evidence of heart failure, hypertension, or arrhythmia and is confirmed by echocardiography. The differentiation between pericardial involvement by tumor and postradiation pericarditis depends on pericardiocentesis, often guided by echocardiography, and cytologic examination.

TREATMENT

Cardiac tamponade must be treated with urgent pericardiocentesis, preferably under echocardiographic or radiologic guidance (Chapter 62). Although such a procedure can be life-saving and provide short-term to intermediate-term palliation, control of the effusion often requires prolonged drainage, administration of intrapericardial chemotherapeutic agents, or limited or full pericardiectomy (Chapter 62). Some patients with pericardial tumors may respond to aggressive systemic chemotherapy, but recurrent accumulation of fluid is sufficiently likely that creation of a pericardial window should be considered before hospital discharge.

PROGNOSIS

In many cases, a tumor that is causing pericarditis has extended or will eventually extend through the pericardial space and into the myocardium, so no therapy is likely to be successful. The prognosis is very poor, except in unusual cases in which the tumor responds dramatically to systemic therapy.

INTRACAVITARY TUMORS

MYXOMA

DEFINITION AND EPIDEMIOLOGY

A myxoma is a benign polypoid neoplasm that originates from endocardial cells and is attached to the interatrial septum, usually protruding into the left atrium but occasionally into the right atrium and rarely into the ventricles. Myxomas are more common in women, especially between the ages of 30 and 60 years, than in men. These tumors can be familial and are rarely associated with other systemic abnormalities.

CLINICAL MANIFESTATIONS

Myxomas are slow growing and usually do not produce symptoms or signs until they enlarge. The typical presentation is with a tumor embolus, whereby usually small portions of the myxoma break loose and cause a single embolism or a shower of emboli. However, a large embolism from a

myxoma can be of sufficient size to obstruct a medium-sized artery. Some patients have systemic symptoms, including fever, malaise, and arthralgias, as part of a clinical syndrome that may be confused with bacterial endocarditis (Chapter 61) or a collagen vascular disease. Large myxomas can prolapse into the mitral valve orifice during diastole, or they may obstruct blood flow from the left atrium to the left ventricle and mimic rheumatic mitral stenosis.

DIAGNOSIS

A myxoma large enough to obstruct the mitral orifice can produce an audible "tumor plop" when the myxoma prolapses and obstructs blood flow during diastole, at the same time that the opening snap of mitral stenosis would typically be heard. If obstruction is incomplete, the tumor plop may be followed by a diastolic rumble. As obstruction becomes more severe, cardiac output may fall precipitously. Echocardiography (Chapter 43) is usually definitive; transesophageal echocardiography provides a higher sensitivity than does transthoracic echocardiography, and magnetic resonance imaging can be helpful.

TREATMENT

Surgical removal is generally curative, although myxomas can be multiple or recur in about 5% of cases. Follow-up postoperative echocardiography is generally recommended. However, the optimal frequency and duration for follow-up screening are uncertain.

OTHER PRIMARY INTRACAVITARY TUMORS

Papillary fibroelastomas are rare, typically frondlike tumors that may arise from a cardiac valve, often the mitral valve, and are generally detected incidentally by echocardiography. However, like myxomas, they can be manifested with systemic or even coronary emboli. Surgical excision is usually successful.

Angiosarcomas, which are more frequent in men than in women, typically involve the pericardium and right atrium. They cause obstruction with clinical signs and symptoms of right-sided heart failure. These sarcomas are generally not amenable to therapy.

EXTENSION OF TUMOR INTO THE CARDIAC CAVITIES

Direct extension of tumor up the inferior vena cava into the right atrium can be seen with renal cell carcinomas and less commonly with liver and adrenal cancers. In some cases, tumor extension is accompanied by adherent clot, and either the tumor or the clot may cause obstruction or pulmonary emboli (Chapter 68). No treatments are generally successful, and the prognosis is grim.

INTRAMYOCARDIAL TUMORS

Primary malignant intracardiac tumors are rare, with an incidence rate of about 35 per 100 million. The most common tumors are sarcomas (Chapter 187), lymphomas (Chapters 171 and 172), and mesotheliomas (Chapters 86 and 177). Current overall survival rates for these tumors at 5 years are about 10%, 35%, and 25%, respectively.

Benign tumors in the myocardium include lipomas, fibromas, and rhabdomyomas. Primary malignant tumors include sarcomas, lymphomas, and mesotheliomas. Metastatic tumors include melanomas, lymphomas, and leukemias. The tumors may be clinically silent, or they may produce arrhythmias or even impinge on coronary arteries, thereby causing ischemic syndromes. Large tumors may protrude into the cardiac chamber and cause obstruction. Therapies are not successful, except for occasional patients whose metastatic tumors may respond to systemic chemotherapy or whose primary tumors have been cured by heart transplantation.

48 PRINCIPLES OF ELECTROPHYSIOLOGY

GLENN I. FISHMAN

The rhythmic beating of the heart reflects the tightly regulated and exquisitely integrated activity of numerous protein complexes that control the flow of ions across cell membranes, including channels, transporters, exchangers, and gap junction channels.[1] The human heart beats almost 3 billion times during a normal lifespan, and even brief periods of dysfunction may lead to life-threatening consequences. Thus, the failure rate of cardiac rhythmicity is exceptionally low. Nonetheless, inherited syndromes, as well as acquired heart disease, may affect cardiac rhythmicity, and these disorders lead to substantial morbidity and mortality, including sudden cardiac death (Chapter 50). This chapter reviews the molecular, cellular, and organ-level determinants of cardiac rhythmicity and relates these principles to fundamental mechanisms responsible for clinically important arrhythmias.

BASIC CONCEPTS

The function of the heart as a highly dynamic pump is intricately entwined with the tightly regulated electrical activation of its constituent cardiomyocytes. During each cardiac cycle, an electrical impulse known as an *action potential* is spontaneously generated by a relatively small number of pacemaker cells in the sinoatrial node, which is located at the junction of the right atrium and the superior vena cava. The impulse then propagates through the right and left atrium, which is represented by the P wave on the electrocardiogram (ECG; Chapter 42). After depolarizing the atria, the impulse enters the atrioventricular (AV) node, which is located in the inferior septal region of the right atrium, where a delay occurs. This delay allows time for the atria to contract and fill the ventricles. The delay in the AV node represents most of the isoelectric portion of the PR interval on the ECG (Fig. 42-2). The usual duration of atrial activation, including delay in the AV node, is up to 140 msec and can be measured directly as the atrial-His interval. The impulse then travels into the specialized infranodal conducting system, which is composed of the His bundle, right and left bundle branches, and Purkinje network. The Purkinje network, which extends throughout the ventricular endocardium, rapidly conducts impulses, thereby allowing nearly simultaneous activation of the ventricles. Once out of the Purkinje network, the impulse proceeds relatively slowly from the endocardial to epicardial surface of the ventricles.

myxoma can be of sufficient size to obstruct a medium-sized artery. Some patients have systemic symptoms, including fever, malaise, and arthralgias, as part of a clinical syndrome that may be confused with bacterial endocarditis (Chapter 61) or a collagen vascular disease. Large myxomas can prolapse into the mitral valve orifice during diastole, or they may obstruct blood flow from the left atrium to the left ventricle and mimic rheumatic mitral stenosis.

DIAGNOSIS

A myxoma large enough to obstruct the mitral orifice can produce an audible "tumor plop" when the myxoma prolapses and obstructs blood flow during diastole, at the same time that the opening snap of mitral stenosis would typically be heard. If obstruction is incomplete, the tumor plop may be followed by a diastolic rumble. As obstruction becomes more severe, cardiac output may fall precipitously. Echocardiography (Chapter 43) is usually definitive; transesophageal echocardiography provides a higher sensitivity than does transthoracic echocardiography, and magnetic resonance imaging can be helpful.

TREATMENT

Surgical removal is generally curative, although myxomas can be multiple or recur in about 5% of cases. Follow-up postoperative echocardiography is generally recommended. However, the optimal frequency and duration for follow-up screening are uncertain.

OTHER PRIMARY INTRACAVITARY TUMORS

Papillary fibroelastomas are rare, typically frondlike tumors that may arise from a cardiac valve, often the mitral valve, and are generally detected incidentally by echocardiography. However, like myxomas, they can be manifested with systemic or even coronary emboli. Surgical excision is usually successful.

Angiosarcomas, which are more frequent in men than in women, typically involve the pericardium and right atrium. They cause obstruction with clinical signs and symptoms of right-sided heart failure. These sarcomas are generally not amenable to therapy.

EXTENSION OF TUMOR INTO THE CARDIAC CAVITIES

Direct extension of tumor up the inferior vena cava into the right atrium can be seen with renal cell carcinomas and less commonly with liver and adrenal cancers. In some cases, tumor extension is accompanied by adherent clot, and either the tumor or the clot may cause obstruction or pulmonary emboli (Chapter 68). No treatments are generally successful, and the prognosis is grim.

INTRAMYOCARDIAL TUMORS

Primary malignant intracardiac tumors are rare, with an incidence rate of about 35 per 100 million. The most common tumors are sarcomas (Chapter 187), lymphomas (Chapters 171 and 172), and mesotheliomas (Chapters 86 and 177). Current overall survival rates for these tumors at 5 years are about 10%, 35%, and 25%, respectively.

Benign tumors in the myocardium include lipomas, fibromas, and rhabdomyomas. Primary malignant tumors include sarcomas, lymphomas, and mesotheliomas. Metastatic tumors include melanomas, lymphomas, and leukemias. The tumors may be clinically silent, or they may produce arrhythmias or even impinge on coronary arteries, thereby causing ischemic syndromes. Large tumors may protrude into the cardiac chamber and cause obstruction. Therapies are not successful, except for occasional patients whose metastatic tumors may respond to systemic chemotherapy or whose primary tumors have been cured by heart transplantation.

48 PRINCIPLES OF ELECTROPHYSIOLOGY

GLENN I. FISHMAN

The rhythmic beating of the heart reflects the tightly regulated and exquisitely integrated activity of numerous protein complexes that control the flow of ions across cell membranes, including channels, transporters, exchangers, and gap junction channels.[1] The human heart beats almost 3 billion times during a normal lifespan, and even brief periods of dysfunction may lead to life-threatening consequences. Thus, the failure rate of cardiac rhythmicity is exceptionally low. Nonetheless, inherited syndromes, as well as acquired heart disease, may affect cardiac rhythmicity, and these disorders lead to substantial morbidity and mortality, including sudden cardiac death (Chapter 50). This chapter reviews the molecular, cellular, and organ-level determinants of cardiac rhythmicity and relates these principles to fundamental mechanisms responsible for clinically important arrhythmias.

BASIC CONCEPTS

The function of the heart as a highly dynamic pump is intricately entwined with the tightly regulated electrical activation of its constituent cardiomyocytes. During each cardiac cycle, an electrical impulse known as an *action potential* is spontaneously generated by a relatively small number of pacemaker cells in the sinoatrial node, which is located at the junction of the right atrium and the superior vena cava. The impulse then propagates through the right and left atrium, which is represented by the P wave on the electrocardiogram (ECG; Chapter 42). After depolarizing the atria, the impulse enters the atrioventricular (AV) node, which is located in the inferior septal region of the right atrium, where a delay occurs. This delay allows time for the atria to contract and fill the ventricles. The delay in the AV node represents most of the isoelectric portion of the PR interval on the ECG (Fig. 42-2). The usual duration of atrial activation, including delay in the AV node, is up to 140 msec and can be measured directly as the atrial-His interval. The impulse then travels into the specialized infranodal conducting system, which is composed of the His bundle, right and left bundle branches, and Purkinje network. The Purkinje network, which extends throughout the ventricular endocardium, rapidly conducts impulses, thereby allowing nearly simultaneous activation of the ventricles. Once out of the Purkinje network, the impulse proceeds relatively slowly from the endocardial to epicardial surface of the ventricles.

ABSTRACT

The rhythmic beating of the heart reflects the tightly regulated and exquisitely integrated activity of numerous protein complexes that control the flow of ions across cell membranes, including channels, transporters, exchangers, and gap junction channels. The human heart beats almost 3 billion times during a normal lifespan, and even brief periods of dysfunction may lead to life-threatening consequences. Thus, the failure rate of cardiac rhythmicity is exceptionally low. Nonetheless, inherited syndromes, as well as acquired heart disease, may affect cardiac rhythmicity, and these disorders lead to substantial morbidity and mortality, including sudden cardiac death (Chapter 50). This chapter reviews the molecular, cellular, and organ-level determinants of cardiac rhythmicity and relates these principles to fundamental mechanisms responsible for clinically important arrhythmias.

The QRS complex on ECG represents depolarization of the bundle branches and ventricular myocardium.

Subpopulations of myocytes within the heart have unique electrical properties that reflect regional specialization. Myocytes within the sinoatrial and AV nodes produce spontaneous action potentials that reflect their pacemaking function. Cells within the His-Purkinje network are optimized to rapidly deliver excitatory current to the large mass of ventricular myocardium, whereas ventricular myocytes display action potentials optimized to facilitate excitation-contraction coupling, that is, to trigger the release of calcium ions from the sarcoplasmic reticulum and to promote the actomyosin cross-bridge formation that underlies cardiac contraction (Chapter 41). Abnormalities in cardiac electrophysiology, whether the result of mendelian disorders, oligogenic syndromes, or environmental stressors that evoke acquired heart disease, can lead to disturbances in the initiation, propagation, or conduction of electrical impulses and, as a result, to a wide variety of arrhythmic syndromes.

IONIC BASIS OF CARDIAC ELECTROPHYSIOLOGY

THE CARDIAC ACTION POTENTIAL

The cardiac action potential (Fig. 48-1) is a recording of a cell's membrane potential, V_m, versus time. During each cardiac cycle, ions move back and forth across the cardiomyocyte cell membrane, thereby changing V_m. The cardiac action potential, which reflects the integrated behavior of numerous individual ionic currents, is largely dominated by the movement of Na^+, Ca^{2+}, and K^+ ions. These ions traverse the cell membrane through ion-selective pores formed by assemblies of integral membrane-spanning proteins and accessory proteins. The behavior of these ionic pathways is highly regulated, and permeation of specific ions is influenced by multiple factors, the most prominent of which are changes in membrane potential (i.e., voltage gating), ligand binding, second messengers such as cyclic adenosine monophosphate, and post-translational modification. Channel function and, by extension, action potential behavior are dynamically tuned in response to normal physiologic factors, especially heart rate. However, a number of pathologic stressors influence channel activity, including acquired syndromes that are associated with cardiac hypertrophy and failure, as well as an ever-growing number of congenital diseases. Regardless of the underlying pathology, the effects on action potential behavior may trigger arrhythmic activity.

The cardiac action potential is divided into phases, each reflecting the major ionic movements that take place. In working cardiomyocytes, such as ventricular or atrial myocytes, the *resting membrane potential* during diastole, or phase 4 of the cardiac action potential, is determined by the baseline ionic and charge gradients that exist across the sarcolemmal membrane. These gradients are generated by pumps and transporters, the most important of which is the Na^+, K^+-ATPase. This energy-requiring electrogenic pump, which is the major target of ouabain-like compounds such as digoxin, extrudes three Na^+ ions from the intracellular compartment in exchange for two K^+ ions, thereby resulting in directionally opposite gradients of Na^+ ions (outside > inside) and K^+ ions (inside > outside). Under resting conditions, a subset of membrane channels highly permeable to K^+ is open, but those that allow for the passage of other ions such as Na^+ or Ca^{2+} are only minimally permeable. As a consequence, the concentration gradient promotes the movement of potassium ions from inside to outside of the cell, until the resulting excess of negative charge within the cell balances the diffusional forces and an electrochemical equilibrium is established. The equilibrium potential for a given ion is calculated by the *Nernst equation*, where E_{eq} is the equilibrium potential, R is the universal gas constant, T is the absolute temperature, z is the valence of the ionic species, and F is Faraday constant:

$$E_{eq} = \frac{RT}{zF} ln\left(\frac{[X]_{out}}{[X]_{in}}\right)$$

If the cell membrane were *only* permeable to K^+ ions, at the measured concentrations of intracellular and extracellular K^+, the resting membrane potential would be approximately −100 mV. However, because of the slight but measurable permeability to other ionic species, which have Nernst potentials that are less negative than that for K^+, the actual resting membrane potential in a typical ventricular cardiac myocyte is closer to −85 mV.

When the cardiac cell is depolarized to its excitatory threshold, an action potential is triggered through a series of highly regulated time-dependent changes in ionic conductances (see Fig. 48-1B). The fast sodium current is activated and very rapidly depolarizes the membrane during phase 0 of the

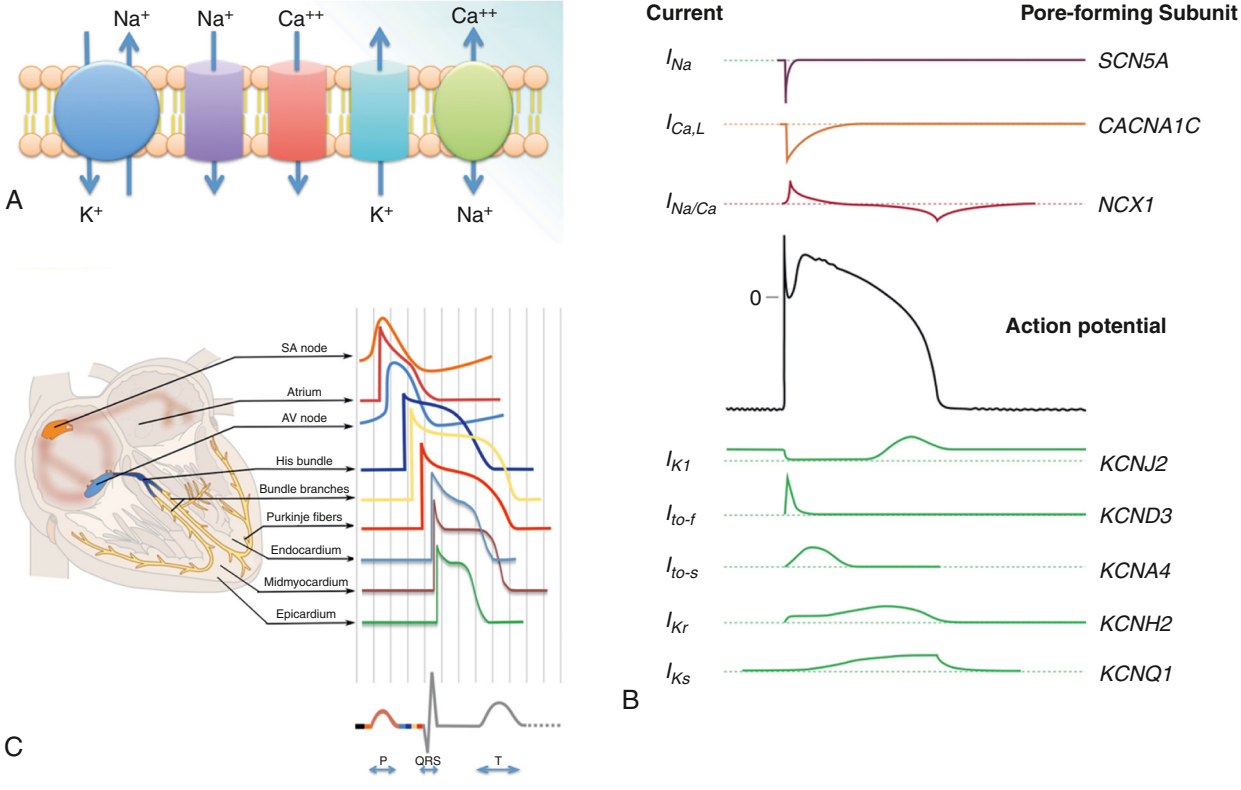

FIGURE 48-1. Ion channels and the cardiac action potential. A, Key channels involved in cardiac excitability and generation of the cardiac action potential. Inward currents are carried by Na^+ channels *(purple)* and Ca^{2+} channels *(red)*. Repolarizing currents are primarily carried by K^+ channels *(blue)*. The Na^+/K^+ ATPase is an energy-requiring exchanger that pumps Na^+ out of the cell in exchange for K^+ and is essential for establishing resting ionic gradients and the resting membrane potential. **B,** Time course and relative magnitude of ionic currents active during the cardiac action potential. Inward currents are represented by downward deflections and outward currents by upward deflections. **C,** Action potentials from different regions of the heart and their relationship to the surface electrocardiogram are indicated. (Adapted from Marbán E. Cardiac channelopathies. *Nature*. 2002;415:213-218.)

action potential. The sodium current is inactivated at the peak of depolarization, which is approximately +40 mV. The increase in V_m during phase 0 activates several additional voltage-gated currents. A transient outward potassium current, or I_{to}, partially *re*polarizes the cell, thereby producing a small notch in the action potential, denoted as phase 1. The increase in V_m during phase 0 also activates, albeit more slowly, the inward L-type calcium current, $I_{Ca\text{-}L}$. It is this trigger for Ca^{2+} that is responsible for Ca^{2+}-induced release from the sarcoplasmic reticulum and is integral to the process of excitation-contraction coupling (Chapter 41). The inward Ca^{2+} current is balanced by several outward repolarizing currents, including the rapid component of the delayed rectifier potassium current I_{Kr}, the slow component of the delayed rectifier potassium current I_{Ks}, and the electrogenic Na^+-Ca^{2+} exchanger, thereby resulting in a plateau in the action potential known as phase 2. When the outward potassium currents increase and the calcium current decreases at the end of phase 2, the action potential progresses to phase 3, which is the phase of rapid repolarization. The inward rectifier potassium current I_{K1} contributes significantly to this final phase of repolarization and brings the action potential back to its resting membrane potential, or phase 4, at which point the cell is primed for another action potential.

Action potential recordings from atrial cardiomyocytes and from cells of the His-Purkinje system are qualitatively similar to those described previously, but with some notable differences that primarily reflect the differential expression of repolarizing potassium currents that tend to abbreviate (in the case of atrial cells) or lengthen (for Purkinje cells) the action potential duration (see Fig. 48-1C).

The relatively small populations of cells in the sinoatrial node (SAN) and atrioventricular node (AVN) express unique complements of ionic currents that are responsible for spontaneous depolarization during phase 4 and the triggering of action potentials. Pacemaker cells express substantially less I_{K1} compared with ventricular myocytes, and as a consequence, their minimum V_m is −65 mV, and they do not repolarize to the same extent as working ventricular cardiomyocytes. In addition, pacemaker cells display what is known as the funny current, I_f, which is activated by *hyper*polarization and carried by sodium. Activation of I_f during phase 4 slowly depolarizes the cell membrane. In addition, a subsarcolemmal calcium clock contributes to diastolic depolarization through the spontaneous, rhythmic release of Ca^{2+} from the sarcoplasmic reticulum, a process that is linked to the voltage clock through the activity of the sodium-calcium exchange current, I_{NCX}. Inasmuch as there is minimal fast inward I_{Na} expressed in nodal cells, the action potential triggered by this spontaneous phase 4 depolarization is due to activation of calcium currents carried by $I_{Ca,L}$ and $I_{Ca,T}$. The magnitude of I_f and I_{Ca}, and hence the slope of phase 4 depolarization as well as the upstroke velocity of the action potential in pacemaker cells, is augmented by adrenergic stimulation, which produces a chronotropic response.

Owing to considerable regional heterogeneity in the density of individual ionic currents, even within distinct compartments of the heart such as the ventricular myocardium, not all ventricular action potentials are identical (see Fig. 48-1C). Much of this heterogeneity is due to differences in the magnitude of various repolarizing K^+ currents. For example, although electrotonic coupling through gap junction channels mitigates this intrinsic heterogeneity, action potentials recorded from epicardial, mid-myocardial, and endocardial cells show substantial differences in morphology, both at rest and especially in response to provocative stimuli such as changes in rate or pharmacologic agents. Moreover, action potential morphology is not static; it varies in response to changes in physiologic state. *Action potential duration adaptation*, which reflects the normal shortening of the action potential observed during increased heart rate, provides a mechanism to preserve adequate time for ventricular filling during diastole. Action potential duration shortening in this setting is due to a net increase in repolarizing currents, primarily from increased I_{Ks} and reverse-mode I_{NaCa}. This adaptation is regulated, at least in part, by the kinetics of activation and inactivation of the channels that are responsible for these currents, as well as their modulation by various signaling cascades, such as those regulated by the autonomic nervous system. However, maladaptive regulation of ionic currents is a frequent manifestation of acquired forms of heart disease, and this pathologic electrical remodeling may amplify intrinsic heterogeneities in cardiac electrophysiology and form a substrate that promotes arrhythmic behavior.

IMPULSE PROPAGATION

In the intact heart, action potentials not only must be generated but also must propagate from cell to cell as a wave of excitation throughout the atrial and ventricular myocardium. For successful propagation, the upstream excited cell must provide sufficient charge to bring the membrane potential, V_m, of downstream cells up to their excitation threshold potential. Gap junctions, which comprise arrays of intercellular channels, provide the structural basis for this electrotonic flow of current from cell to cell. For propagation to be successful, the ratio of the charge generated to charge consumed during the excitation cycle, known as the safety factor, must be greater than 1.

Unlike nerves, the action potential duration of human cardiomyocytes is quite long, on the order of 200 msec. This longer action potential duration is required so that each myocyte has sufficient time for contraction and relaxation before the next heartbeat. Impulses that arrive too early in the cardiac cycle will not produce normal action potentials. If the impulse occurs during the upstroke or plateau phase (phases 0 to 2), the sodium channels will not have had sufficient time to recover from fast inactivation, and the cell displays *absolute refractoriness*. If the impulse occurs somewhat later, during phase 3 of the action potential, a supranormal stimulus is required to overcome the potassium currents that remain active during the terminal portion of the action potential, a phenomenon known as *relative refractoriness*. Moreover, because not all of the sodium channels will have recovered from inactivation, the rate of rise of voltage during phase 0 of the premature beat may be diminished.

MOLECULAR BASIS OF CARDIAC ELECTROPHYSIOLOGY

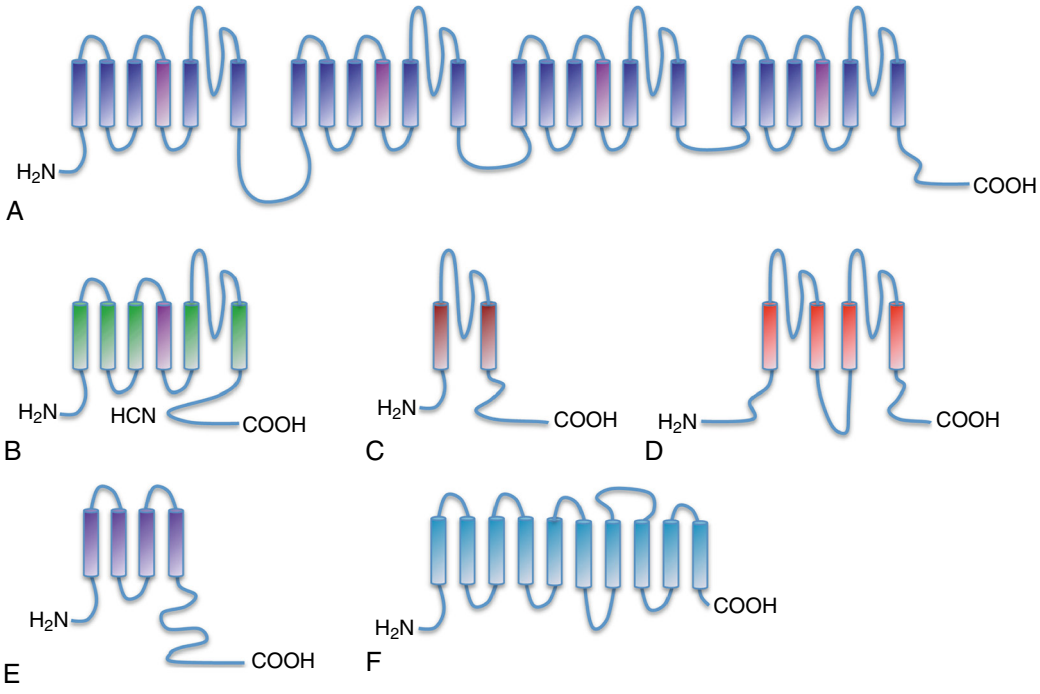
The individual currents that are responsible for cardiac excitability reflect the integrated behavior of various protein complexes that are assembled into ion-specific channels, transporters, and exchangers.[2,3] At the molecular level, ion channels comprise multi-subunit glycoproteins, including a pore-forming major, or α-subunit, and one or several accessory proteins (E-Fig. 48-1). The latter influence a range of channel properties, including trafficking of the major subunit to the sarcolemmal membrane, as well as regulation of channel biophysical properties, that is, the opening and closing of the channel in response to various factors such as membrane voltage, ligands, mechanical stimuli, second messengers, or post-translational modification.

SODIUM CHANNELS

Voltage-gated sodium channels are responsible for the activation and propagation of the cardiac action potential. Not surprisingly, acquired and inherited syndromes that affect the function of voltage-gated sodium channels in the heart are responsible for a broad range of arrhythmic phenotypes. Cardiac sodium channels activate extremely rapidly, within 1 msec, and begin to inactivate almost completely within several milliseconds. The very small proportion of channels that remain active for several hundred milliseconds results in the persistent or late Na^+ current, I_{NaL}.

The most abundant cardiac sodium channel comprises a pore-forming α-subunit known as $Na_v1.5$ and several smaller accessory subunits, or β-subunits, designated $Na_v\beta1$ to 4. The α-subunit is an approximately 260-kD protein that consists of four homologous domains, each comprising six transmembrane segments.[4] Substantial experimental work has identified the key regions of the protein that regulate channel properties, including voltage dependence, activation, and inactivation, as well as the binding sites for pharmacologic agents such as local anesthetics, antiarrhythmic drugs, and neurotoxins. The β-subunits are single-membrane-spanning proteins that associate with $Na_v1.5$ through their extracellular immunoglobulin-fold domains. They serve to increase the delivery of the α-subunit to the sarcolemmal membrane and to influence channel function. The β-subunits also enhance the subcellular localization of the channel and its interactions with various adaptors, signaling molecules, and cytoskeletal proteins. In addition to $Na_v1.5$, several "neuronal" α-subunits are expressed at low levels in the heart and likely contribute to regional heterogeneity in sodium channel function. Mutations in $Na_v1.5$, in specific β-subunits, and in several interacting regulatory and scaffolding proteins all may influence the behavior of the sodium current in the heart and thereby produce a range of arrhythmic syndromes, including long QT syndrome type 3 (LQT3) and Brugada syndrome (Chapter 53).[5]

The I_f current contributes to phase 4 depolarization in pacemaker cells and is a reflection of the activity of hyperpolarization-activated cyclic nucleotide gated, or *HCN* channels. The full channels are composed of dimers of *HCN* proteins, each of which has six transmembrane domains. *HCN4* and *HCN1* are the predominant isoforms found in the nodes, whereas *HCN2* is found throughout the conduction system. Binding of cyclic adenosine monophosphate, a key second messenger in the adrenergic signaling cascade, to the carboxy terminus of the channel shifts activation positively, thereby



E-FIGURE 48-1. Structure of the pore-forming subunits of ion channels expressed in the heart. Individual barrels represent transmembrane domains. increasing the slope of phase 4 depolarization and linking autonomic tone to heart rate.

CALCIUM CHANNELS

Voltage-gated calcium channels are important for generating the action potential in the sinoatrial and atrioventricular nodes and for excitation-contraction coupling in virtually all contractile cardiomyocytes.[6] The dominant forms expressed in the heart are the L-type (large and long-lasting) and the T-type (tiny and transient) calcium channels, both of which include pore-forming α-subunits, similar in overall structure to that of voltage-gated sodium channels.

L-type Ca^{2+} channels comprise an α_1 subunit, a noncovalently bound β accessory subunit ($Ca_v\beta 1$-4), and an alternatively spliced α_2-δ-subunit that is post-translationally processed through cleavage and disulfide bond formation. The dominant α_1-subunit in the heart is $Ca_v1.2$, whereas $Ca_v1.3$ is restricted primarily to nodal and atrial cells. Both α_1-subunits are alternatively spliced to produce variants that are uniquely regulated.

The related T-type calcium channels are also found in the heart but display distinct biophysical properties compared with L-type Ca^{2+} channels; they activate at more negative voltages (−70 mV) and inactivate more rapidly. The major isoform expressed in the heart is $Ca_v3.1$ and, to a lesser extent, $Ca_v3.2$. These channels are normally restricted to the nodes, Purkinje cells, and atrial myocytes. In pacemaking cells, the T-type currents contribute to phase 4 depolarization. Mutations in Ca^{2+} channel subunits are also responsible for a number of arrhythmic syndromes, including Timothy syndrome (LQT8) and a subset of individuals with Brugada syndrome.

POTASSIUM CHANNELS

Numerous classes of potassium channels are expressed in the heart, where they contribute to repolarization and maintenance of the resting membrane potential.[7] The heterogeneous expression of potassium channels in different regions and cell types is largely responsible for the variable action potential morphologies that are observed. As with sodium and calcium channels, potassium channels are formed from the assembly of pore-forming subunits along with various accessory β-subunits. However, α-subunits of potassium channels include between two and six transmembrane domains, and the full channel is formed as a dimer or tetramer, depending on the specific subfamily. Dysregulation of expression and function of potassium channels is quite common in many acquired forms of heart disease. The resulting loss of repolarizing currents leads to action potential duration prolongation and acquired long QT syndrome. In addition, heritable mutations that diminish potassium currents are responsible for several forms of inherited long QT syndrome, whereas gain of function mutations may produce the short QT syndrome.

Voltage-gated potassium channels, or *Kv* channels, are activated by membrane depolarization. Numerous classes of *Kv* channels have been identified in the heart. The α-subunits are six transmembrane domain proteins. Unlike sodium and calcium channels, functional potassium channels are formed by the assembly of four such subunits and various β-subunits. The transient outward current is composed of two components, $I_{to,fast}$ and $I_{to,slow}$; both are rapidly activated and contribute to phase 1 of the cardiac action potential, but their recovery kinetics differ. $I_{to,fast}$ is particularly prominent in the epicardial layer of the ventricles, especially in the right ventricle. This differential expression is thought to contribute to the pathology of J wave syndromes, including Brugada syndrome.

The other major class of voltage-gated potassium channels in the heart is responsible for the delayed rectifier currents, broadly classified as I_K currents.[8] These channels include the ultra-rapidly activating I_{Kur}, which is restricted to atrial myocytes, and the delayed rectifier currents, I_{Kr} and I_{Ks}, both of which contribute to phase 3 repolarization of the cardiac action potential. I_{Kr} activates and inactivates rapidly and shows strong inward rectification; that is, current moves more easily (but not exclusively) in the inward direction than in the outward direction, although it is the outward current that is physiologically relevant. I_{Ks} activates slowly and does not display inward rectification. Both currents also show marked regional heterogeneity. Numerous cardiac and noncardiac medications, as well as heritable syndromes that reduce the magnitude of these currents (particularly I_{Kr}), result in action potential duration prolongation and acquired or heritable long QT syndrome.

The second major class of potassium currents in the heart are the *Kir* currents carried by inwardly rectifying potassium channels. I_{K1} is observed in both atrial and ventricular cardiomyocytes. Conductance through these channels is high at negative membrane potentials, so this current is critical for terminal repolarization (phase 3) and for setting the resting membrane potential (phase 4). Another inwardly rectifying potassium current is carried by I_{KATP} channels. The full channels include not only the pore-forming subunit but also auxiliary *SUR* subunits, which are targets for channel inhibition by the sulfonylurea class of drugs. Because I_{KATP} currents are inhibited by intracellular adenosine triphosphate, they are activated in the setting of ischemia. The augmented outward current shortens action potential duration and abbreviates systole, thereby diminishing energetic requirements. Thus I_{KATP} channels provide a link between metabolic state and membrane excitability. Importantly, the resulting action potential duration shortening diminishes refractoriness, which may enhance the risk for re-entrant arrhythmias. The last major class of inward rectifiers includes the acetylcholine- and adenosine-activated potassium channels, which are encoded by $K_{ir}3.1$ and $K_{ir}3.4$. These channels, which are enriched in nodal and atrial cardiac myocytes, are activated when ligands bind to muscarinic or purinergic G protein–coupled receptors, which facilitate the uncoupling of $G_{\beta\gamma}$ from G_α and the activation of the K_{ir} channels by the released $G_{\beta\gamma}$.

GAP JUNCTION CHANNELS

Gap junction channels, which are responsible for the electrotonic coupling of cardiac myocytes, are essential for normal impulse propagation throughout the myocardium. The channels are formed by the hexameric assembly of connexin monomers, each of which is a tetramembrane spanning protein. Connexin 43[9] is the dominant isoform expressed in ventricular and atrial myocardium, whereas connexin 40 is also abundantly expressed in the atrium. The nodes express variable amounts of connexin 45 and connexin 30.2, and the bundle branches and Purkinje fibers express significant levels of connexin 40. Gap junctions in the node integrate the intrinsic beating rate of each nodal cell into a single functional unit. Abnormalities in connexin expression and function, a process known as pathologic gap junction remodeling, are observed in atrial and ventricular myocardium in many acquired forms of heart disease. The remodeling contributes to aberrant impulse propagation and predisposes to arrhythmic behavior. In addition, germline or somatic mutations in cardiac connexin genes are associated with arrhythmic syndromes, especially atrial fibrillation.

MECHANISMS OF ARRHYTHMOGENESIS

Cardiac arrhythmias, which are disturbances in the rate or rhythm of the heartbeat, are a reflection of abnormal impulse formation or conduction. Inasmuch as cardiac myocytes reside within a complex multicellular environment and are electrotonically coupled by gap junction channels, arrhythmic syndromes almost always reflect a complex interplay of individual, or *cell autonomous*, properties within a multicellular network. Most clinically important arrhythmias arise in the setting of acquired heart disease, in which pathologic *electrical remodeling*, resulting from dysregulation of ion channel expression or function, accompanies *structural remodeling*. However, many arrhythmic syndromes, including those that are drug-induced, result from, or are exacerbated by, genetic variations, including disease-causing alterations in coding regions that directly affect the function of proteins, which regulate cardiac electrophysiology, as well as sequence variants in regulatory or other noncoding genome regions, which appear to regulate transcriptional and post-transcriptional behavior.

DISORDERS OF IMPULSE FORMATION

In the healthy heart, the sinus node, which is located at the junction of the right atrium and the superior vena cava, is the predominant pacemaker. Secondary pacemakers with intrinsically slower pacing rates are found further downstream in the specialized conduction system within the atrioventricular node and the His-Purkinje system. The firing rate of pacemaker cells is regulated primarily by autonomic tone: sympathetic stimulation increases the slope of phase 4 depolarization, whereas parasympathetic stimulation decreases the slope by augmenting repolarizing currents. Nodal suppression may result from pharmacologic agents, such as β-adrenergic blockers, calcium channel blockers, or digitalis, as well as from fibrotic diseases. Moreover, mutations in several genes that affect the voltage clock (*SCN5A* and *HCN4*), the calcium clock (*RYR2* and *CASQ2*), or both (*ANKB*) may cause familial sinus node dysfunction.

Conversely, under pathologic conditions, myocardial cells outside the specialized conduction system may exhibit spontaneous activity, a phenomenon termed *abnormal automaticity*. Abnormal automaticity is

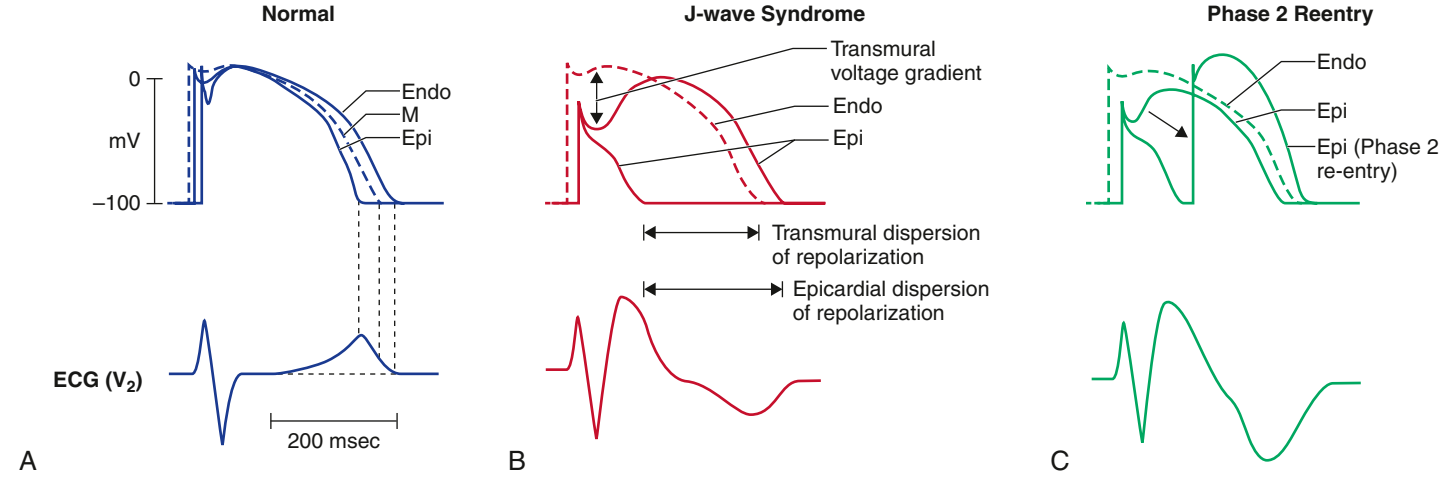

FIGURE 48-2. Cellular basis for J-wave syndromes and phase 2 re-entry. Under normal conditions, the ST segment is isoelectric because of the absence of transmural voltage gradients at the level of the action potential plateau. Accentuation of the phase I notch under pathophysiologic conditions, such as loss-of-function of I_{Na} or gain-of-function of I_{to} leads to loss of the action potential dome at some epicardial sites but not others, producing ST and T wave changes typically observed in Brugada syndrome. Loss of the action potential dome in epicardium but not endocardium results in the development of a marked transmural dispersion of repolarization and conduction of the action potential dome, from sites at which it is maintained to sites at which it is lost, thereby causing local reexcitation via a phase 2 re-entry mechanism. (Modified from Antzelevitch C, Brugada P, Brugada J, et al. Brugada syndrome: from cell to bedside. *Curr Probl Cardiol*. 2005;30:9-54.)

most often seen with ischemia or reperfusion, in which maximum diastolic potentials are reduced to approximately −60 mV to −50 mV, a level at which Na^+ or Ca^{2+} channels may reach their activation threshold and trigger action potentials.

AFTERDEPOLARIZATIONS AND TRIGGERED ACTIVITY

During cardiac repolarization, a number of inward and outward currents are active, and small changes in conductance of individual channels can markedly affect the trajectory of repolarization. *Afterdepolarizations*, which are abnormal oscillations in membrane potential, occur either during (early afterdepolarizations) or after (delayed afterdepolarizations) an action potential.[10] Afterdepolarizations of sufficient magnitude to evoke an action potential produce triggered activity. Early afterdepolarizations are almost always observed in the setting of abnormal action potential duration prolongation, which provides sufficient time for *re*-activation of L-type Ca^{2+} channels during the plateau phase of the action potential. Thus, congenital syndromes, as well as bradycardia, hypokalemia, hypomagnesemia, antiarrhythmic medications, and many noncardiac drugs, are associated with QT prolongation and promote early afterdepolarizations. Conversely, rapid pacing and drugs that shorten the action potential duration tend to suppress early afterdepolarizations. Early afterdepolarizations in the setting of action potential duration prolongation often trigger *torsades de pointes* (Chapter 53), a polymorphic ventricular tachycardia, especially when there is increased dispersion of repolarization. Delayed afterdepolarizations, in contrast, are usually the result of intracellular Ca^{2+} overload and are typically seen in the setting of catecholamine excess, ischemia, toxic concentrations of digitalis-like agents, and some congenital syndromes, including catecholaminergic polymorphic ventricular tachycardia. The excessive Ca^{2+} load activates the electrogenic Na^+-Ca^{2+} exchanger, producing a depolarizing transient inward current, I_{TI}.

DISORDERS OF IMPULSE CONDUCTION

During each cardiac cycle, impulses must be generated in pacemaker cells within the sinus node, and a wave of excitation must propagate throughout the atria, travel down the specialized conduction system (including the atrioventricular node and His-Purkinje network), and then activate the ventricular myocardium. Processes that diminish intercellular coupling, such as fibrosis or calcification of the specialized conduction system, can diminish the safety factor for conduction and produce varying degrees of heart block. Inherited defects in conduction have been observed with mutations in sodium channel subunits *SCN5A* and *SCN1B*, which affect phase 0 of the cardiac action potential; in *KCNJ2*, which affects terminal repolarization and the resting membrane potential; and in a number of developmental disorders that affect the cardiac conduction system, such as Holt-Oram syndrome, Emery-Dreifuss muscular dystrophy, and myotonic dystrophy type 1. Conduction block may also be seen with the secondary electrical remodeling that is associated with structural heart disease and with many cardioactive drugs.

RE-ENTRY

Re-entry is considered the most common mechanism responsible for clinically significant cardiac arrhythmias, including both supraventricular and ventricular disorders. Fundamentally, re-entry involves self-perpetuating waves of excitation that circulate around an inexcitable obstacle. Depending on the number of re-entrant waves within a tissue (one or multiple), their size, and their spatial stability, the surface ECG may reveal a relatively organized rhythm, such as atrial flutter or monomorphic ventricular tachycardia, or a seemingly disorganized rhythm, such as atrial fibrillation or polymorphic ventricular tachycardia. Re-entry normally requires the presence of unidirectional block within a "fast" conducting pathway around an obstacle, combined with recirculation of the impulse from a second "slow" pathway in the retrograde direction, as might be the case at a bifurcating Purkinje-ventricular junction or around scar tissue of a healed myocardial infarction (E-Fig. 48-2). However, the "obstacle" may also be viable myocardium that is inexcitable owing to its intrinsic electrophysiologic properties, such as cellular uncoupling or refractoriness, a phenomenon referred to as *functional block*. Because refractoriness is critically dependent on the action potential duration, areas of myocardium with prolongation of the action potential duration may form a suitable substrate for functional re-entry.

Heterogeneity in action potential duration and the concomitant *dispersion of refractoriness* also play critical roles in the maintenance of arrhythmic behavior, especially through a phenomenon known as *phase 2 re-entry*. This term refers to the flow of current during phase 2 of the cardiac action potential from a depolarized cell to neighboring cells that are more fully repolarized and not refractory to reexcitation. This principle is best characterized in the J wave syndromes,[11] especially Brugada syndrome, in which loss of function of inward currents (I_{Na} or I_{Ca}) or gain of function of outward currents (I_{to}, $I_{K\text{-}ATP}$) causes loss of the action potential dome during phase 2 and an abbreviated action potential duration in a subset of cardiac myocytes. Current can then flow into these cells from neighboring cells in which the action potential dome is maintained, thereby causing local reexcitation, a closely coupled extrasystole, and the initiation of re-entry. In Brugada syndrome, this process is thought to arise in the right ventricular outflow tract, where the transient outward current density is significantly greater in the epicardium compared with the endocardium (Fig. 48-2).

49 APPROACH TO THE PATIENT WITH SUSPECTED ARRHYTHMIA

JEFFREY E. OLGIN

CLINICAL MANIFESTATIONS

Patients with suspected arrhythmias can present in a variety of ways. Typical symptoms include palpitations, syncope, and presyncope (dizziness). On occasion, arrhythmias can manifest more subtly as exercise intolerance, lethargy, and vague complaints of malaise or without any symptoms at all. Conversely, arrhythmias occasionally manifest as aborted sudden cardiac death (cardiac arrest; Chapter 50). The specific differential diagnosis, prognosis, and treatment of these symptoms are determined by the severity of the symptom (i.e., whether it results in syncope) and whether the patient has underlying structural heart disease. In general, the likelihood of a life-threatening arrhythmia, such as ventricular tachycardia or ventricular fibrillation, in a patient with symptoms of palpitations or syncope is significantly greater in a patient who has structural heart disease. Therefore, the determination of whether structural heart disease is present is a key step in the diagnosis and prognosis of patients with suspected arrhythmias. The exception to this general rule is in patients with a significant family history suggestive of an inherited arrhythmia syndrome (e.g., long QT syndrome, Brugada syndrome), for whom a family history of syncope and/or sudden death should prompt referral to a cardiac electrophysiologist.

Palpitations

Palpitations, defined as an awareness of an irregular or rapid heartbeat, are most commonly due to ectopic beats—namely, premature atrial contractions (PACs; Chapter 52) and premature ventricular contractions (PVCs; Chapter 53)—or to tachyarrhythmias. A careful history can often distinguish benign palpitations from those that need further evaluation. It can be useful to have the patient tap out with a finger what the palpitations feel like. An irregularly irregular pattern suggests atrial fibrillation, whereas a more regular, rapid pattern suggests a sustained tachycardia. A reliable symptom suggesting that palpitations are caused by a tachyarrhythmia, particularly a supraventricular tachycardia, is the sensation of a regular, rapid-pounding sensation in the neck. Conversely, most patients who complain of symptoms from PACs or PVCs are often more aware of the post-extrasystolic pause or the accentuated output of the post-extrasystolic beat than of the actual premature beat itself. Most patients who have symptoms suggestive of premature beats but not of sustained tachycardia do not require further evaluation if they have no other symptoms and no evidence of structural heart disease—that is, an otherwise normal cardiac history, physical examination, and electrocardiogram (ECG; see Table 39-4). If, however, the symptoms are not due to a single occasional extrasystole or are accompanied by presyncope or syncope, further evaluation is required (Fig. 49-1). Antiarrhythmic therapy is usually not necessary to treat PACs or PVCs unless the symptoms are frequent or severe. β-Blockers (e.g., metoprolol 25 mg/day or atenolol 25 mg/day) are first-line therapy in highly symptomatic patients with documented PACs or PVCs. Recent data suggest that patients in whom PVCs exceed 24% of beats during 24-hour monitoring may have a higher risk of developing PVC-induced cardiomyopathy.[1]

Palpitations are the most common presentation of tachyarrhythmias, whereas bradyarrhythmias rarely manifest as palpitations. Most tachyarrhythmias in patients without structural heart disease are due to supraventricular tachycardias (Chapter 52) that resolve spontaneously within several seconds. When the tachyarrhythmia is more prolonged, it often resolves with simple interventions that increase vagal (parasympathetic nervous system) influence on the heart (generally the atrioventricular [AV] node). Patients themselves can cough several times, perform the Valsalva maneuver, exhale forcefully against a closed glottis for several seconds, immerse their face in ice water, or even rub gently on their eyeballs. A physician can use carotid sinus massage (Chapter 52), performed by pressing and rubbing the carotid pulse just below the angle of the mandible for 5 to 15 seconds. This maneuver should be avoided in elderly patients and in patients with a history of cerebrovascular accident, known carotid artery stenosis, or carotid bruit on auscultation. In patients with structural heart disease, palpitations may signify ventricular tachycardia (Chapter 53), particularly if they occur with syncope or presyncope. An occasional patient without structural heart disease may have idiopathic ventricular

ABSTRACT

Patients with suspected arrhythmias can present in a variety of ways. Typical symptoms include palpitations, presyncope (dizziness), and syncope. On occasion, arrhythmias can manifest more subtly as exercise intolerance, lethargy, and vague complaints of malaise or without any symptoms at all. Conversely, arrhythmias occasionally manifest as aborted sudden cardiac death (cardiac arrest). This chapter discusses the causes, diagnosis, and treatment of these conditions.

KEYWORDS

syncope
palpitations
arrhythmia
neurocardiogenic
bradycardia
tachycardia

TABLE 49-1 CAUSES OF SYNCOPE AND THEIR PREVALENCE

NEUROCARDIOGENIC CAUSES
Vasovagal (8-41% of patients)
Situational (1-8% of patients)
Micturition
Defecation
Swallow
Cough
Carotid sinus syncope (0.4% of patients)
Neuralgias
Psychiatric disorders
Medications, exercise
ORTHOSTATIC HYPOTENSION (4-10% OF PATIENTS)
DECREASED CARDIAC OUTPUT
Obstruction to flow (1-8% of patients)
Obstruction to left ventricular outflow or inflow: aortic stenosis, hypertrophic obstructive cardiomyopathy, mitral stenosis, myxoma
Obstruction to right ventricular outflow or inflow: pulmonic stenosis, pulmonary embolism, pulmonary hypertension, myxoma
Other heart disease
Pump failure, myocardial infarction, coronary artery disease, coronary spasm, tamponade, aortic dissection
ARRHYTHMIAS (4-38% OF PATIENTS)
Bradyarrhythmias: sinus node disease, second- and third-degree atrioventricular block, pacemaker malfunction, drug-induced bradyarrhythmias
Tachyarrhythmias: ventricular tachycardia, torsades de pointes (e.g., associated with congenital long QT syndrome or acquired QT prolongation), supraventricular tachycardia
NEUROLOGIC AND PSYCHIATRIC DISEASES (3-32% OF PATIENTS)
Migraine
Transient ischemic attacks
UNKNOWN (13-41% OF PATIENTS)

Adapted from Kapoor W. Approach to the patient with syncope. In: Braunwald E, Goldman L, eds. *Primary Cardiology*, 2nd ed. Philadelphia: Saunders; 2003.

TABLE 49-2 CLINICAL FEATURES SUGGESTING SPECIFIC CAUSES

DIAGNOSTIC CONSIDERATION
Neurocardiogenic
Symptoms after prolonged motionless standing; sudden unexpected pain; fear; or unpleasant sight, sound, or smell
Syncope in a well-trained athlete after abrupt cessation of exertion (without heart disease)
Situational syncope during or immediately after micturition, cough, swallowing, or defecation
Syncope with throat or facial pain (glossopharyngeal or trigeminal neuralgia)
Organic Heart Disease (e.g., coronary artery disease, aortic stenosis, primary arrhythmia, obstructive hypertrophic cardiomyopathy, pulmonary hypertension)
Brief loss of consciousness, no prodrome, history of heart disease
Syncope during exertion
Family history of sudden death
Neurologic
Seizures: confusion for >5 min after regaining consciousness
Transient ischemic attack, subclavian steal, basilar migraine: syncope associated with vertigo, dysarthria, diplopia, arm exercise
Migraine: syncope associated with antecedent headaches
Other Vascular
Carotid sinus: syncope with head rotation or pressure on the carotid sinus (as in tumors, shaving, tight collars)
Orthostatic hypotension: syncope immediately on standing
Subclavian steal or aortic dissection: differences in blood pressure or pulse between the two arms
Drug-Induced
Patient is taking a medication that may lead to long QT syndrome, orthostasis, or bradycardia
Psychiatric Illness
Frequent syncope, somatic complaints, no heart disease, inconstant circumstances of events

Adapted from Kapoor WN. Syncope. *N Engl J Med*. 2000;343:1856-1862.

tachycardia (typically arising from the ventricular outflow tracts; Chapter 53), but such patients generally have a more benign course than patients with structural heart disease and are readily curable with ablation (Chapter 54).

Presyncope and Syncope

Syncope, defined as a sudden loss of consciousness, and presyncope, or lightheadedness, are caused by global impairment of blood flow to the brain (Table 49-1). Syncope can be a manifestation of tachyarrhythmias, bradyarrhythmias, or neurocardiogenic syncope, or it can be unrelated to any arrhythmia. A careful history and physical examination are necessary to exclude other cardiac causes (e.g., acute ischemia, aortic stenosis) or neurologic causes. Important historical features that suggest an arrhythmic cause are an association with palpitations and the lack of any neurologic deficits preceding or following the event. Left ventricular outflow obstruction, due either to aortic stenosis (Chapter 60) or hypertrophic obstructive cardiomyopathy (Chapter 47), can present as syncope, often during or just after exertion.

Important differential diagnoses include conditions other than lightheadedness that may be termed dizziness by the patient. Vertigo (Chapter 396), a sense of imbalance or of the "room spinning," and ataxia (Chapter 379) can usually be distinguished by the history and physical examination. The possibility of seizures (Chapter 372) must also be evaluated; syncope from an arrhythmia or neurocardiogenic syncope occasionally results in seizure-like activity, and seizures can sometimes be confused with syncope. The most important distinguishing feature is that postictal symptoms, a key feature of seizure disorders, are absent when syncope is the result of an arrhythmia or a neurocardiogenic event. Patients with syncope from an arrhythmia usually awaken without any neurologic residual, unless the patient experienced a cardiac arrest with prolonged hypoxia and required resuscitation. Among patients who are hospitalized with a first episode of syncope and in whom pulmonary embolism cannot be excluded based on a low Wells score (see Table 68-3) and a negative D-dimer assay, pulmonary embolism may be found in 25% of patients who do not have another obvious cause of their syncope and in about 13% of patients who do have an alternative explanation for their syncope. By comparison, among all patients who present to an emergency department with syncope, only about 1.5% of patients appear to have pulmonary emboli.[2]

Because most spells of episodic loss of consciousness occur outside medical observation, the history is the most critical part of the evaluation (Table 49-2).[3] Each syncopal episode should be reviewed in detail, with special attention to symptoms preceding the episode, events during unconsciousness, and the symptoms and time course of regaining orientation after consciousness is restored. Information from a witness can be essential to the evaluation. About 20% of syncopal events are associated with an injury, but recurrent neurocardiogenic events are less likely to result in injury.[4]

The patient's presymptomatic activity and positioning, as well as symptoms when the syncopal episode began, are important clues to diagnosis. Seizures or cardiac arrhythmias can occur in any body position, but recumbent patients rarely develop neurocardiogenic (vasovagal) syncope and never have orthostatic hypotension. Prodromal lightheadedness, dizziness (but uncommonly vertigo), bilateral tinnitus, nausea, diffuse weakness, and dimming of vision are symptoms of cerebral hypoperfusion and support the diagnosis of syncope, which may be from a cardiac, orthostatic, or neurocardiogenic cause. Loss of consciousness so rapid that a prodrome is absent may occur with seizures and with some cardiac arrhythmias such as asystole, which typically causes loss of consciousness within 4 to 8 seconds in the upright position but usually requires 12 to 15 seconds in the recumbent position. Palpitations during the prodrome suggest a tachyarrhythmia. The activity of the patient immediately before the onset of symptoms may also provide clues. Syncope associated with the cessation of exertion or with anxiety or pain suggests neurocardiogenic syncope, whereas symptoms during exertion suggest an arrhythmia or left ventricular outflow obstruction due to aortic stenosis (Chapter 60) or hypertrophic obstructive cardiomyopathy (Chapter 47). Syncope associated with a change in posture suggests orthostatic causes, whereas syncope while straining at urination suggests situational neurocardiogenic syncope.

A witness's description of the events during the episode of unconsciousness is very helpful. Although body stiffening and limb jerking occur with generalized seizures, similar movements can result from cerebral hypoperfusion, especially if perfusion is not restored rapidly. Such muscle jerking is often multifocal and can be synchronous or asynchronous. In contrast to epileptic seizures,

which generally produce tonic-clonic activity for at least 1 to 2 minutes, muscle jerking in syncope rarely persists for longer than 30 seconds. If an arrhythmia continues or the patient is physically maintained upright, tonic stiffening of the body followed by jerking movements of the limbs can occur. Occasionally, motor movements identical to a tonic-clonic seizure occur, and a mistaken diagnosis of epilepsy can be made. Urinary incontinence during the spell is frequently used to support or refute a diagnosis of epilepsy; however, fainting with a full bladder can result in incontinence, whereas seizures with an empty bladder will not. Tongue biting favors seizures.

The time frame over which consciousness and orientation are regained is perhaps the most important clue in differentiating seizures from syncope. Recovery of orientation after neurocardiogenic syncope occurs within seconds of regaining consciousness. Recovery of orientation after self-reversible arrhythmia-associated syncope is usually proportional to the duration of the unconsciousness and is usually rapid (0 to 10 seconds). Life-threatening arrhythmias (e.g., prolonged asystole or ventricular fibrillation) usually do not resolve without resuscitation, and the confusion after regaining consciousness may be permanent owing to ischemic brain injury (Chapter 50). By comparison, the period of confusion after seizures, often accompanied by agitation, continues for 2 to 20 minutes after recovery of consciousness.

DIAGNOSIS

The likelihood of an arrhythmic cause of syncope is higher in patients with underlying heart disease, a systolic blood pressure below 90 or above 180 mm Hg, a QRS duration >130 msec, or a QTc interval >480 msec. Arrhythmias are generally categorized as bradyarrhythmias (slow heart rates; see Chapter 51), tachyarrhythmias (fast heart rates; see Chapters 52 and 53), or premature beats (single extrasystoles from the atrium or the ventricle—PACs [see Fig. 52-1 or PVCs [see Fig. 53-1], respectively) (see Table 49-1). Although not a primary arrhythmia, neurocardiogenic syncope is a related diagnostic and management issue because its symptoms are frequently similar to those of arrhythmias and because neurocardiogenic syncope secondarily results in bradycardia (see later). A systematic approach can optimize the likelihood of identifying the cause of transient loss of consciousness (Table 49-3).[5]

Bradyarrhythmias

Bradyarrhythmias (Chapter 51) can be due to dysfunction in the sinoatrial node, AV node, or His-Purkinje system (below the AV node). Sinus bradycardia manifests as a slow atrial (sinus) rate and can occur at rest or as an inappropriately slow rate during exercise (chronotropic incompetence). Sinus arrest can be intermittent, when transient loss of sinus activity (loss of the P wave on the ECG) causes brief sinus pauses, or persistent, with prolonged loss of atrial activation. The sinus rate and even the presence of sinus pauses are influenced by autonomic tone. Therefore, healthy individuals—particularly younger patients and well-trained athletes (with high vagal tone)—have occasional sinus slowing, often during sleep. A sinus pause of more than 3 seconds is considered pathologic if it is associated with symptoms while a patient is awake. Sinus bradycardia and sinus arrest can also be the result of medications, typically β-blockers and calcium-channel blockers. When not "physiologic" or due to medications, sinus bradycardia and sinus arrest are the result of intrinsic conduction system disease. Sinus bradycardia, especially if it is intermittent, can also signify disease of the right coronary artery.

Bradyarrhythmias from AV nodal disease result from the failure of impulse conduction from the atrium to the ventricle. Like the sinus node, the AV node is dramatically affected by autonomic tone. Mobitz type I second-degree AV block (Wenckebach block; see Fig. 51-6) can be seen during periods of high vagal tone (such as while sleeping) and is not necessarily pathologic; for example, it does not progress to complete heart block and is not associated with a widened QRS. Many drugs, such as β-blockers and calcium-channel blockers, commonly cause first-degree AV block and should be considered a potential cause of any degree of AV block. Mobitz type II block (see Fig. 51-7) signifies that the level of AV block is below the AV node in the His-Purkinje system, which is not sensitive to autonomic tone; the resulting QRS is widened, and there is a high likelihood of progression to complete heart block (third-degree AV block; see Figs. 51-8 and 51-9). Idiopathic paroxysmal AV block, detected by continuous ECG monitoring, can also cause syncope. Intermittent complete heart block, which can result in drop attacks or Stokes-Adams attacks, is usually preceded by abnormal baseline findings on the ECG, such as a bundle branch block or second-degree AV block.

Tachyarrhythmias

Tachyarrhythmias can arise from the atrium or AV node (supraventricular tachycardias) or from the ventricle (ventricular tachycardias). Supraventricular tachyarrhythmias that may be associated with palpitations, presyncope, or syncope include atrial tachycardia (see Fig. 52-11), AV nodal re-entrant tachycardia (see Fig. 52-8), AV junctional tachycardia (see Fig. 52-9), atrial flutter (see Fig. 52-12), atrial fibrillation (see Fig. 52-13), or sometimes in association with accessory conduction pathways that facilitate the re-entry needed to sustain the arrhythmia (AV reciprocating tachycardia). Ventricular tachyarrhythmias include the various forms of ventricular tachycardia (see Figs. 53-1 through 53-6).

TABLE 49-3 SUMMARY OF CLINICAL RECOMMENDATIONS FOR TRANSIENT LOSS OF CONSCIOUSNESS

TOPIC	RECOMMENDATIONS
Initial assessment	Detailed history, especially from witnesses Full clinical examination 12-lead ECG
Uncomplicated faints	Suggestive features include: Posture: occurrence during prolonged standing or similar previous episodes avoided by lying down Provoking factors, such as pain or a medical procedure Prodromal symptoms, such as sweating or feeling warm or hot before TLoC Further investigation and specialist referral are not needed.
Epilepsy	Suggestive features are a bitten tongue; head turning to one side during TLoC; no memory of abnormal behavior that occurred before, during, or after TLoC; unusual posturing; prolonged limb jerking (brief seizure-like activity often occurs during syncope, including uncomplicated faints); confusion after the event; or prodromal déjà vu or jamais vu. If features of epilepsy are present, arrange for early review by an epilepsy specialist. Do not arrange for EEG before neurologic assessment. Note that brief seizure-like activity often occurs during syncope, including uncomplicated faints. Do not suspect epilepsy unless suggestive features are present. Arrange for cardiovascular assessment if the cause of TLoC is unclear.
Urgent specialist referral	Give immediate treatment for clinically urgent problems (such as complete AV block or severe bleeding). Arrange for urgent specialist cardiovascular assessment for patients at risk for a severe adverse event (such as those with long QT interval, cardiac arrhythmia, or structural heart disease).
Further cardiovascular assessment	Focus on specific disorders that may cause TLoC, such as orthostatic hypotension, the carotid sinus syndrome, structural heart disease, or cardiac arrhythmia. Assessment should include repeated history, clinical examination, and 12-lead ECG. For suspected cardiac arrhythmia or unexplained TLoC, use ambulatory ECG for further assessment: Very frequent episodes: use 24- to 48-hour Holter monitoring. Moderately frequent episodes: use external event monitoring. Infrequent episodes: use an implantable event recorder. In patients who are sick or worrisome enough for hospital admission and do not have both a low Wells score (see Chapter 68) and a negative D-dimer assay, evaluate for possible pulmonary embolism (computed tomographic pulmonary angiography or ventilation-perfusion lung scanning).

AV = atrioventricular; ECG = electrocardiography; EEG = electroencephalogram; TLoC = transient loss of consciousness.

Neurocardiogenic Syncope and Related Syndromes

Neurocardiogenic syncope is the sudden onset of lightheadedness or loss of consciousness as a result of autonomic reflexes and is more common in younger patients (teenage to third decade of life). It is sometimes called a vasovagal episode, a common faint, or situational syncope if it is clearly induced by a particular activity (e.g., micturition syncope). Some families have autosomal dominant vasovagal syncope, which is genetically heterogeneous but seems to be linked to chromosome 15q26.

In neurocardiogenic syncope, heightened parasympathetic output, either due to direct stimulation (e.g., micturition, defecation, abdominal pain, or other gastrointestinal conditions) or as a reflex in response to sympathetic stimulation (e.g., seeing blood, abrupt cessation of exercise), results in arterial dilation (called the vasodilatory response) and an inhibition of sinus and

AV node activity (the cardioinhibitory response). The result is a transient decrease in blood pressure, often manifested as lightheadedness or syncope. Because they are associated with parasympathetic (vagal) output, episodes are frequently accompanied by nausea, diaphoresis, and salivation. Twin analyses provide strong evidence for genetic factors in vasovagal syncope.

Rarely, situational syncope is associated with swallowing or coughing. Swallowing can trigger brain stem reflexes that lead to vagally induced bradyarrhythmias, with resultant syncope. This phenomenon may or may not be associated with severe pain in the tonsillar pillar, which may radiate to the ear (i.e., glossopharyngeal neuralgia; Chapter 367). Cough-related syncope can occur with severe, repeated coughing, which may increase thoracic pressure and result in increased vagal tone or a transient reduction in outflow from the intracranial veins, followed by a transient increase in intracranial pressure and impaired blood flow.

A related cause of syncope is carotid body hypersensitivity, in which vagal tone is increased by direct stimulation of the carotid body. This condition is frequently seen in older patients (particularly men older than 60 years), in whom episodes are associated with mechanical stimulation of the neck (e.g., turning the head, shaving, wearing a tight collar or necktie). Use of β-blockers, calcium-channel blockers, and digitalis can exacerbate or predispose to this condition. This form of syncope is diagnosed by documenting pauses longer than 3 seconds in response to carotid sinus massage.

Postural or orthostatic hypotension can result in recurrent syncope. The history confirms that the patient is in the upright posture during spells, that the prodromal symptoms are those of cerebral hypoperfusion, and that the symptoms are relieved with recumbency. The diagnosis is supported by detecting a decrease of 30 mm Hg or greater in systolic blood pressure or a decrease of 10 mm Hg or greater in diastolic blood pressure between recumbent and upright postures. The many causes include drugs, polyneuropathies (Chapter 388), postural orthostatic tachycardia syndrome (a ≥30 beat per minute increase in heart rate when standing),[6] and neurodegenerative disorders (Chapter 378).

Cerebrovascular syncope results from cerebral hypoperfusion due to vascular phenomena, as opposed to generalized hypotension caused by arrhythmias or neurocardiogenic reflexes. Loss of consciousness can be a component of a basilar artery transient ischemic attack, but other brain stem symptoms nearly always precede or accompany the unconsciousness. Vertigo is most frequent, but diplopia or visual field disturbances, hemifacial or perioral numbness, and dysarthria or ataxia are also common. Recovery of consciousness may require 30 to 60 minutes. Although the diagnosis is suggested by the history and clinical presentation, imaging studies can be useful to confirm the diagnosis. Carotid Doppler studies may show various degrees of stenosis, especially in older patients. However, unconsciousness requires bihemispheric dysfunction; thus, unilateral carotid stenosis alone does not cause syncope. Transcranial Doppler studies or magnetic resonance angiography of the basilar artery is indicated only if brain stem ischemic symptoms are present in addition to loss of consciousness; false-positive tests are common, especially with increasing age.

Other syndromes that can cause syncope include subclavian artery stenosis, which may result in retrograde blood flow from the vertebral artery to one arm, with resultant brain stem hypoperfusion (i.e., subclavian steal syndrome). Asymmetry in upper extremity systolic blood pressure, typically averaging 45 mm Hg, is nearly always present. Brain stem symptoms are similar to those in basilar transient ischemic attacks, including loss of consciousness, but a subsequent stroke from subclavian steal is rare. Syncope may also occur in up to 10% of patients with basilar artery migraine (Chapter 367). It can have a postural (orthostatic) manifestation or be associated with other basilar artery symptoms.

Neuropsychiatric syncope is a diagnosis of exclusion but is suggested by young age, frequent spells, multiple symptoms (e.g., dizziness, vertigo, lightheadedness, numbness), and duplication of the patient's symptoms by hyperventilation with the mouth open for 2 to 3 minutes. Whereas syncope and seizures occur with the eyes open, often with gaze deviation, psychogenic events frequently begin with eye closing.

Seizures (Chapter 372) can cause loss of consciousness and occasionally present clinically as syncope. However, seizures usually have a characteristic presentation and include a postictal phase, whereas most patients experiencing a syncopal episode quickly regain consciousness, except when cerebral perfusion is so compromised as to cause a secondary seizure or persistent anoxia and brain damage.

Diagnostic Tests

Electrocardiography

The baseline ECG is critical in the evaluation of a patient with palpitations or syncope. The presence of ventricular preexcitation, as manifested by a short PR interval and a delta wave (see Fig. 52-10), establishes the likely diagnosis of Wolff-Parkinson-White syndrome in a patient with palpitations and AV reciprocating tachycardia (Chapter 52); a 12-lead ECG can also be used to determine the location of the responsible accessory pathway. The baseline ECG provides useful predictive information about the likelihood of conduction system abnormalities being responsible for bradyarrhythmias (e.g., sinus bradycardia suggests sinus node dysfunction, a prolonged PR interval suggests AV nodal disease, and a widened QRS suggests disease below the AV node). The ECG is also useful in diagnosing prior myocardial infarction (i.e., pathologic Q waves), which raises the likelihood of ventricular tachycardia as a potential cause of syncope or palpitations. Abnormalities such as a prolonged QT interval in a patient with syncope and a family history of syncope or sudden death suggest one of the congenital long QT syndromes (Chapter 50). An incomplete right bundle branch block with coved ST segment elevation in ECG lead V_1 or V_2 in a patient with syncope or palpitations suggests Brugada syndrome, whereas an epsilon wave, incomplete right bundle branch block, and inverted T waves in V_1 are suggestive of right ventricular dysplasia (Chapter 47). All these syndromes carry an increased risk for recurrent syncope and sudden death if untreated (Chapters 50 and 53). The short QT syndrome (QTc ≤330 msec or QTc ≤360 plus a family history of sudden death) also predisposes to ventricular arrhythmias. Since some of these ECG findings (especially those suggestive of Brugada syndrome and even long QT syndrome) may be transient or episodic, lack of these findings does not exclude these syndromes in patients with syncope and a strong family history.

In one study, electrocardiographic screening for 14 days increased the detection of atrial fibrillation in older adults and led to a small reduction in adverse events.[A1] However the U.S. Preventive Services Task Force found evidence to be insufficient to recommend such screening.[7]

Performing an ECG during an episode of palpitations is extremely useful in making a definitive diagnosis. For narrow–QRS complex tachycardias, the specific supraventricular tachycardia can often be surmised from the 12-lead ECG obtained during symptoms (Fig. 49-2). Moreover, for wide–QRS complex tachycardias, the 12-lead ECG is useful in distinguishing a supraventricular tachycardia (with aberrancy) from a ventricular tachycardia (Fig. 49-3). The presence of fusion beats or AV dissociation during a wide–QRS complex tachycardia leads to the diagnosis of ventricular tachycardia. For ventricular tachycardias, the morphology of the QRS complex is useful in determining the location of the ventricular tachycardia focus and in identifying idiopathic ventricular tachycardia (right ventricular outflow tract or fascicular), which has a much more benign course than ventricular tachycardia in the setting of coronary disease (Chapter 53).

The effect of carotid sinus massage, vagal maneuvers, or adenosine (given as a rapid intravenous bolus of 6 mg and repeated at a dose of 12 mg if the initial dose is ineffective) is also useful in narrowing the differential diagnosis of a tachycardia. These maneuvers slow conduction through the AV node. Therefore, tachycardias that terminate with either maneuver are likely to involve the AV node as a critical component of the re-entrant circuit (AV nodal re-entrant tachycardia or AV re-entrant tachycardia). If the maneuver induces AV block but does not immediately terminate the arrhythmia, likely causes are atrial fibrillation, atrial flutter, and atrial tachycardias (or occasionally ventricular tachycardia if the QRS is wide). On rare occasions, atrial tachycardias and some idiopathic ventricular tachycardias terminate in response to adenosine (but usually not at precisely the same time as AV block). Important clues to the specific mechanism can be obtained at the onset or termination of tachycardia, so obtaining a continuous 12-lead ECG during carotid sinus massage or the administration of adenosine is very useful.

During bradycardias, the ECG is useful in determining the level of the conduction system (sinus node, AV node, or His bundle) responsible for the bradycardia. Sinus bradycardia is diagnosed when a slow (<50/minute at rest) atrial rate (P wave) conducts to the ventricle. Sinus arrest or sinus pauses are diagnosed by absent or dropped P waves. First-degree AV block (see Fig. 51-5) is defined as a prolonged PR interval (>200 msec), and second-degree AV block is defined by P waves that occasionally do not conduct to the ventricle (P wave without an ensuing QRS); Mobitz type I second-degree AV block (also known as Wenckebach block; see Fig. 51-6) is characterized by progressive lengthening of the PR interval until one P wave does not conduct to the ventricle. This form of AV block is often seen in younger patients, is usually benign, and rarely progresses to complete AV (third-degree) block. Mobitz type II second-degree AV block (see Fig. 51-7), which is characterized by the sudden, unexpected loss of conduction of a P wave to the ventricle (dropped QRS), signifies disease of the His-Purkinje system and often progresses to complete heart block. Complete heart block or third-degree AV block (see Figs. 51-8 and 51-9) is diagnosed by the dissociation of P waves from QRS complexes, with an atrial rate faster than the ventricular rate.

Ambulatory Monitoring

For intermittent symptoms such as palpitations, dizziness, or syncope, it is often difficult to obtain a 12-lead ECG while the symptoms are occurring.

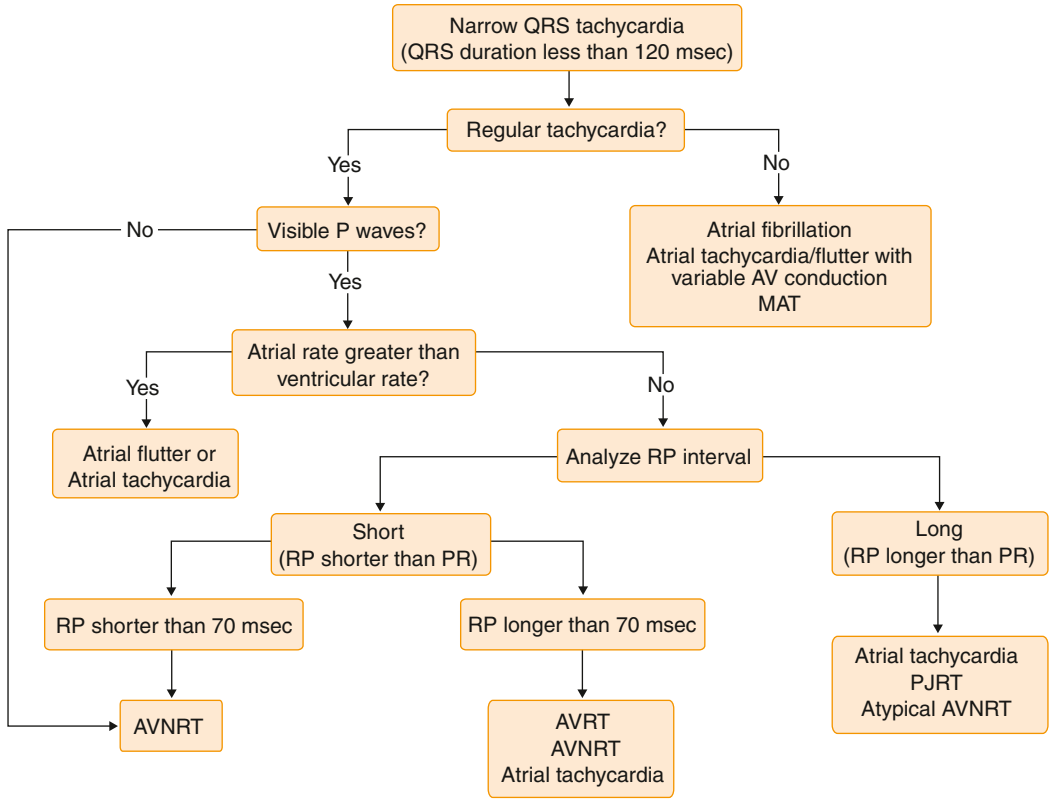

FIGURE 49-2. ECG algorithm for diagnosis of narrow-complex tachycardias. AVNRT = atrioventricular nodal reciprocating tachycardia; AVRT = atrioventricular reciprocating tachycardia; MAT = multifocal atrial tachycardia; PJRT = permanent form of junctional reciprocating tachycardia. (From Blomstrom-Lundqvist C, Scheinman MM, Aliot EM, et al. ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias—executive summary. *Circulation*. 2003;108:1871-1909.)

Therefore, ambulatory monitoring, which allows ECG monitoring over long periods, is a vital diagnostic tool. There are currently four general types of ambulatory monitors: Holter monitors, which continuously record the ECG for 24 to 48 hours (or extended monitors that can record continuously for longer); event recorders, which are wearable loop recorders that record only during specific events (when the patient activates the recorder because of symptoms or the recorder detects a heart rate above or below a specified threshold) and can be worn for 1 month or more; mobile cardiac outpatient telemetry that functions similarly to external event recorders but transmits data in real time through a wireless network to a central monitoring center and can be worn for up to 1 month; and implantable loop recorders, which function similarly to event recorders but can be used for up to 3 years. More recently, consumer-directed smartphone ECGs attach to a smartphone and can record an on-demand single-lead ECG rhythm strip or can use light-sensing photoplethysmography to detect irregular heart rhythms (such as atrial fibrillation) and heart rates. The choice among ambulatory monitoring methods is largely determined by the frequency and severity of the symptoms and the likelihood of capturing an episode during a given monitoring period.

Ambulatory monitoring is diagnostic only if abnormalities occur during symptoms or if the patient has typical symptoms without any concurrent abnormalities. A "normal" monitoring record is nondiagnostic if the patient does not have symptoms during the period.

Holter Monitors

Holter monitors use either a tape (in older devices) or digital media (in newer devices) to record a 3-, 5-, or 12-lead surface ECG continuously, usually for 24 to 48 hours but for 3 weeks or more when indicated. Processing, printing, and analysis of the recordings are performed offline with commercial systems. In addition to recording the rhythm, analyses of heart rate variability and ST segment changes and accurate counts of PACs and PVCs can be automated. Some systems allow extrapolation to produce a "virtual" 12-lead recording at any time during the monitoring period. Holter monitoring is useful for detecting symptoms that are frequent (multiple times daily) and for diagnosing sinus node dysfunction (sinus node arrest, sick sinus syndrome) or intermittent AV block. It can also be useful to assess the adequacy of ventricular rate control in a patient with atrial fibrillation or burden of PVCs. New form factors have enabled longer, more comfortable monitors (such as a self-contained patch) that can record for several weeks.

Traditional Holter monitors have largely been replaced by the more convenient and longer-lasting extended monitors using a single-lead patch. Traditional Holters remain useful, however, for situations in which having more than one simultaneous lead is helpful, for example, in differentiating supraventricular tachycardia (SVT) with aberrancy from ventricular tachycardia (VT) or localizing the source of a PVC or VT.

Event Monitors

Event monitors, also known as loop recorders, are designed to record intermittent episodes during long periods (weeks to months) and are thus useful for patients with less frequent symptoms. The system records the ECG into a loop buffer that is continuously updated and overwritten. The duration of memory varies from a few seconds to a few minutes and is usually programmable. When activated, the information is "locked" into memory and continues to record forward for a preprogrammed amount of time. Newer systems allow both patient-activated (when symptoms occur) and event-triggered (when the heart rate is above or below a preset threshold) recording.[8] Some recorders have algorithms to detect and record atrial fibrillation automatically, regardless of the heart rate. After episodes have been recorded, the patient transmits the recording over the telephone to centralized receivers. Some event monitors require leads similar to Holter monitors, whereas others are worn on the wrist or are put into small credit card–sized devices that are placed on the chest during symptoms. The latter type is useful only in patients whose symptoms last for several minutes and who do not have syncope.

Mobile Cardiac Outpatient Telemetry

Mobile cardiac outpatient telemetry units are similar to external event monitors, except that data are transmitted wirelessly in real time to a monitoring center. These devices are useful for patients in whom intermittent symptoms are severe or the differential diagnosis includes potentially dangerous arrhythmias that should be diagnosed expeditiously. For example, a wearable ECG sensor patch can expedite the diagnosis of atrial fibrillation in patients at high risk for it.[A2] The monitoring center also has the ability to dispatch emergency medical services if necessary.

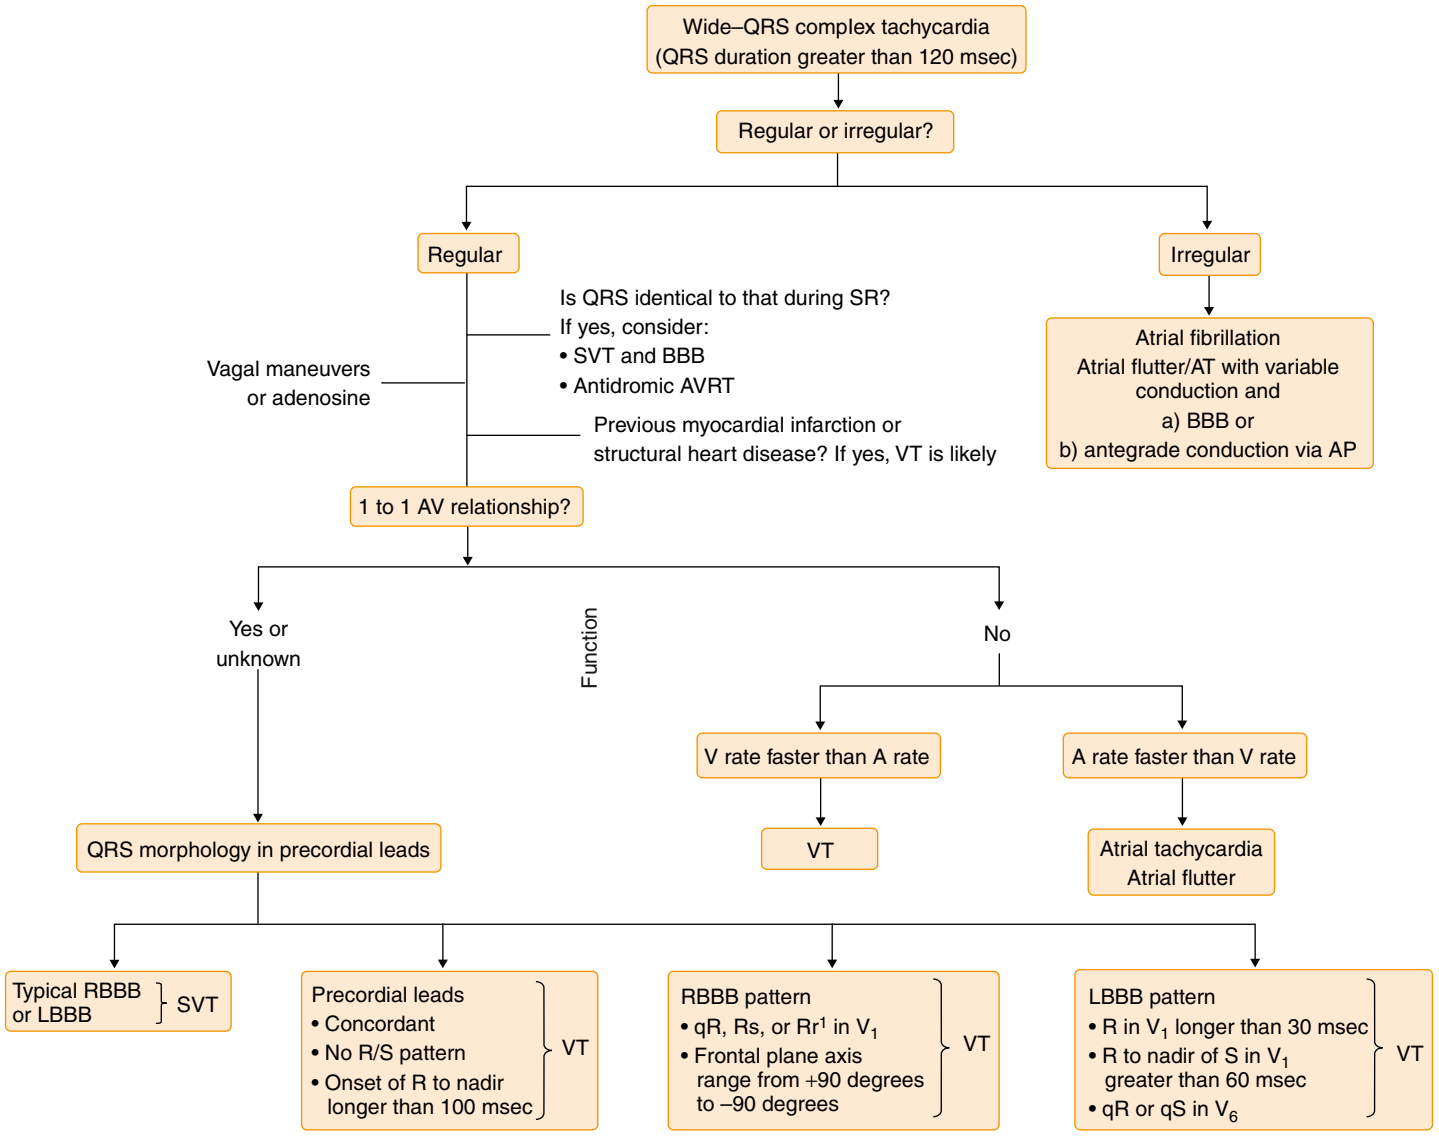

FIGURE 49-3. ECG algorithm for diagnosis of wide-complex tachycardias. A = atrial; AP = accessory pathway; AT = atrial tachycardia; AV = atrioventricular; AVRT = atrioventricular reciprocating tachycardia; BBB = bundle branch block; LBBB = left bundle branch block; RBBB = right bundle branch block; SR = sinus rhythm; SVT = supraventricular tachycardia; V = ventricular; VT = ventricular tachycardia. ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias—executive summary. *Circulation*. 2003;108:1871-1909.)

Implantable Loop Recorders

Implantable loop recorders are small devices with integrated leads that are placed in a small subcutaneous pocket during a simple surgery, usually performed in the electrophysiology laboratory. They function similarly to event recorders in terms of recording ECGs. Patients can activate the device with a small transmitter, or the device can be autotriggered on the basis of preprogrammed heart rates. The device can be interrogated by a computer, similar to the way pacemakers are interrogated to program the device's parameters and to retrieve ECGs that have been recorded. Newer devices can wirelessly communicate with a telephone-connected base station in the home to upload data after an event. In patients with recurrent, difficult-to-diagnose syncope, an implantable loop recorder is better than the combination of tilt testing, an external loop recorder, and electrophysiologic testing for establishing an arrhythmic diagnosis. In patients ages 70 to 79 years or with a history of ischemic stroke, implantable loop recorders are significantly more likely than prolonged external monitoring to detect paroxysmal atrial fibrillation,[A3-A5] but the clinical benefits of better diagnosis appear to be negligible.

Consumer-Based Rhythm Monitors

With the growth of smartphones and wearable devices, patients can purchase consumer-grade devices to monitor their heart rate and heart rhythm. These devices use one of two general approaches[9,10]: use of the light sensor on the back of a smartwatch to measure *pulse* rate and rhythm using photoplethysmography or single-lead ECG devices that connect to a smartphone or are integrated into a smartwatch. Both of these devices use internal algorithms to provide automated simple interpretations of the heart rhythm (e.g., normal, possible atrial fibrillation or undetermined) and heart rate to the user. The ECG devices also record a single-lead ECG, which may be useful for a physician to interpret for possible arrhythmias. Currently, these devices are designed and approved to screen for atrial fibrillation but not other abnormal rhythms. These devices should not generally substitute for other, more established types of ambulatory monitoring to diagnose patients with suspected arrhythmias, with the possible exception of screening for atrial fibrillation.

Tilt Table Testing

Tilt table testing is used to confirm the diagnosis of neurocardiogenic syncope.[11] The test involves continuous heart rate and blood pressure monitoring during head-up tilting. After baseline measurements in the supine position, the patient is tilted head-up at 60 to 80 degrees for 60 minutes. Some laboratories use isoproterenol or nitroglycerin as additional provocation. A positive result is a sudden and precipitous fall in blood pressure and heart rate, with concurrent reproducibility of symptoms (syncope). Because there is an appreciable false-positive rate, the test is best used as a confirmatory test in patients with a history suggestive of neurocardiogenic syncope or in patients with syncope in whom structural heart disease and other causes of syncope have been excluded.

Electrophysiologic Studies

Electrophysiologic studies involve the placement of several transvenous catheters in the heart to make temporary measurements of intracardiac electrograms and to perform pacing. Electrophysiologic studies are useful to identify the

precise mechanism of tachyarrhythmias and are a necessary prelude to curative ablation (Chapter 54). Most arrhythmias, especially those with re-entrant mechanisms, can be readily induced during electrophysiologic studies. In addition, the existence and characteristics of accessory AV pathways (i.e., those responsible for Wolff-Parkinson-White syndrome or other re-entrant tachyarrhythmias) can be readily assessed by an electrophysiologic study. In patients with previous myocardial infarction, electrophysiologic studies are useful in determining the existence of a substrate for ventricular arrhythmias (Chapter 53), which may be treated with ablation or implantable defibrillators (Chapter 54). Electrophysiologic studies are also useful to determine the integrity of the conduction system and the precise mechanism of bradyarrhythmias that may be causing syncope. Therefore, electrophysiologic studies may be indicated in patients with documented or suspected tachyarrhythmias as a prelude to curative ablation in patients with documented or suspected supraventricular tachycardia or idiopathic ventricular tachycardia; in patients with a previous myocardial infarction (but left ventricular ejection fraction >30 to 35%) and syncope, presyncope, or palpitations to exclude ventricular tachycardia; and in patients with severe or prolonged symptoms and no apparent diagnosis by history or ambulatory monitoring in the setting of an abnormal ECG. However, with the advent of implantable loop recorders capable of prolonged electrocardiographic monitoring and the known benefit of implantable cardioverter-defibrillator therapy in many patients with depressed left ventricular function, the role of invasive diagnostic cardiac electrophysiologic studies has been substantially reduced in patients with unexplained syncope in patients with reduced left ventricular function.

Other Tests

Echocardiography

Echocardiography (Chapter 43) can be useful to ensure that a patient does not have underlying structural heart disease, which can be an important prognostic factor in patients with ventricular tachycardia or syncope. Echocardiography should be performed in patients who present with near-syncope or syncope that is not obviously neurocardiogenic to ensure that there is no valvular or myocardial cause.

Exercise Testing

Exercise testing (Chapters 39 and 56) can be useful to assess arrhythmias, particularly in patients whose symptoms are exercise related. Exercise testing can also be useful in the evaluation of patients with bradyarrhythmias to diagnose chronotropic incompetence, and it can differentiate AV block due to autonomic tone (improves with exercise) from intrinsic conduction disease (generally worsens with an increasing rate).

Neurologic Testing

Routine electroencephalography (Chapter 366) is not helpful because a single study may be normal, even in epileptic patients. Structural brain diseases rarely cause episodic loss of consciousness, and routine brain imaging studies are indicated only in patients with focal neurologic findings. Carotid Doppler (Chapter 376) studies can document stenosis, but unconsciousness requires bihemispheric dysfunction. Transcranial Doppler or magnetic resonance angiography of the basilar artery is indicated only in patients with symptoms suggestive of brain stem ischemia.

TREATMENT

Treatment of syncope depends on the underlying cause (Chapters 52 and 53),[12,13] as well as the risk of recurrence. One approach to risk stratification is the Canadian Syncope Risk Score (Tables 49-4 and 49-5).[14] Immediate hospital admission (e.g., observation in a chest pain unit, syncope unit, or the equivalent) is recommended when the patient has a Canadian Syncope Risk Score of greater than 3 or high-risk characteristics (see Table 49-6); the cause of syncope is unclear (especially in elderly patients, otherwise fragile, or worrisome patients); the syncope resulted in significant injury; the patient is suspected of having a cardiac or cerebrovascular cause of syncope; or the patient meets criteria established by professional societies (Table 49-7). Patients at highest risk have a systolic blood pressure below 90 mm Hg, a history of myocardial infarction or heart failure, a complaint of shortness of breath, an abnormal initial ECG, or a hematocrit less than 30%.

Until the cause of the syncope is determined and treated, patients should be instructed to avoid situations that may cause injury as a result of the syncope, especially if there is no prodrome and episodes are frequent. Careful consideration should be given to driving restrictions, which may be mandatory depending on local laws, and restrictions on dangerous work-related activity (e.g., for pilots, heavy machine operators, bus drivers) until definitive therapy is given.

TABLE 49-4 THE CANADIAN SYNCOPE RISK SCORE

	POINTS
History and physical examination	
Vasovagal characteristics*	−1
History of heart disease†	1

Cardiac Syncope

In patients with a cardiac cause of syncope, targeted treatments include valve replacement for aortic stenosis (Chapter 60); medications for hypertrophic cardiomyopathy (Chapter 47); a pacemaker for bradyarrhythmias (Chapters 52 and 54) and for carotid body hypersensitivity; cardioversion, an implantable cardioverter-defibrillator, ablation, or medications for tachyarrhythmias (Table 49-8; Chapters 50 through 53); and fluid repletion for orthostatic hypotension. Even when a pacemaker is implanted in a patient with syncope attributed to bradycardia, the 5-year incidence of recurrent syncope approaches 20%.[15]

Neurocardiogenic Syncope

In patients with neurocardiogenic syncope, the most effective therapies are behavioral: avoidance of triggers, wearing of compression stockings, and maintenance of adequate hydration and salt intake. Lying down with the feet elevated and performing isometric hand exercises may abort an acute episode. Patients should specifically be taught how to tense their arms and legs and grip their hands during prodromal symptoms to increase peripheral resistance and systemic blood pressure.

If neurocardiogenic syncope recurs despite education and lifestyle changes, fludrocortisone (0.1 mg/day, starting dose, increasing to 0.2 mg daily if tolerated or decreasing to 0.05 mg daily if not) can expand intravascular volume and reduce syncopal episodes[A6] but has not been definitively proven to prevent syncope. Midodrine (usually 5 to 10 mg three times daily), an α_1-receptor agonist and vasoconstrictor, has shown benefit,[A7] but other α-agonists have not. Fluoxetine (10 to 40 mg daily) may be useful in patients with recurrent neurocardiogenic syncope triggered by anxiety.[A8] β-blockers (e.g., pindolol 5 to 15 mg twice daily) can be of limited benefit. High dietary sodium intake is useful for reducing the change in heart rate in the postural tachycardia syndrome.[A9]

Pacemakers reduce recurrent neurocardiogenic syncope in selected patients with primarily a cardioinhibitory component or with severely asystolic neurally mediated syncope. For example, in patients older than 40 years with frequent syncopal episodes (at least three episodes in 2 years) and either (a) demonstrated bradycardia (asystole or AV block) during an event (≥3 seconds during a

ETIOLOGY	SPECIFIC ARRHYTHMIA	SYMPTOMS			TREATMENT	COMMENTS
		PALPITATIONS	DIZZINESS	SYNCOPE		
TACHYARRHYTHMIAS						
SVT	Atrial tachycardia	Yes	Occasional	Rare	Ablation β-Blockers (e.g., metoprolol, atenolol)* Calcium-channel blockers (e.g., diltiazem)*	
	Atrial flutter	Yes	Occasional	Rare	Ablation Antiarrhythmic drugs (e.g., amiodarone)* Cardioversion (acute episode)	Often difficult to control rate
	Atrial fibrillation	Yes	Occasional	Rare	Ventricular rate control Warfarin Antiarrhythmic drugs (e.g., amiodarone)* Cardioversion (acute episode) Ablation	
	AV nodal re-entrant tachycardia	Yes	Yes	Rare	Ablation β-Blockers (e.g., metoprolol, atenolol)* Calcium-channel blockers (e.g., diltiazem)*	
	AV re-entrant tachycardia (WPW)	Yes	Yes	Rare	Ablation Antiarrhythmic drugs*	
VT	Idiopathic (RV outflow tract, fascicular)	Yes	Yes	Occasional	Ablation	Absence of structural heart disease Low risk for sudden death
	VT secondary to CAD, cardiomyopathy	Yes	Yes	Yes	ICD Amiodarone (400 mg qd)* Ablation	Increased incidence of sudden death
	Bundle branch re-entry	Yes	Yes	Yes	Ablation	Usually in the setting of LV dysfunction and baseline intraventricular conduction delay
	Genetic syndromes (e.g., long QT syndrome, Brugada, arrhythmic right ventricular dysplasia)	Occasional	Yes	Yes	ICD	Not always a clear family history Increased incidence of sudden death
Ectopy	PACs	Occasional	No	No	None β-Blockers (e.g., atenolol, metoprolol) if symptomatic*	
	PVCs	Occasional	No	No	None β-Blockers (e.g., atenolol, metoprolol) if symptomatic*	Benign in absence of structural heart disease
NEUROCARDIOGENIC SYNCOPE		No	Yes	Yes	Behavioral (hydration, avoid triggers, abort episodes) Midodrine (10 mg tid)	

*See Table 52-2 for drug doses.

AV = atrioventricular; CAD = coronary artery disease; ICD = implantable cardioverter-defibrillator; LV = left ventricle; PACs = premature atrial contractions; PVCs = premature ventricular contractions; RV = right ventricle; SVT = supraventricular tachycardia; VT = ventricular tachycardia; WPW = Wolff-Parkinson-White syndrome.

syncopal episode or ≥6 seconds during a presyncopal episode) or (b) a positive tilt test, dual-chamber pacing reduces subsequent syncope significantly.[A10, A11]

In syncope related to glossopharyngeal neuralgia (Chapter 367), the pain can usually be prevented by carbamazepine (400 to 1000 mg/day total in divided doses of 2 to 3 times per day orally). In refractory cases, 300 mg/day in divided doses of 1 to 4 times per day of phenytoin can be added.

Neurological Syncope

Patients who are at risk for basilar artery stroke should be treated with aspirin and should be considered for other treatments (e.g., surgery, stent placement) appropriate for their symptoms and anatomy (Chapter 376). For subclavian stenosis, repair of the stenosis is the treatment of choice. For other patients with cerebrovascular disease, the potential value of antithrombotic therapy and cerebral revascularization procedures must be considered according to standard criteria (Chapter 376). Seizures require anti-epileptic medications (Chapter 372). Basilar artery migraine requires careful medical therapy (Chapter 367).

PROGNOSIS

One syncopal event predicts a substantial risk for recurrent syncope. Although a history of syncope itself does not appear to increase the risk for a motor vehicle crash,[16] patients with cardiac or cerebrovascular causes have higher mortality rates than patients with definable noncardiac causes or those without a definable cause. For otherwise healthy individuals discharged with a primary diagnosis of syncope, the subsequent risk for all-cause mortality is increased by 6%, with stroke increased by 35%, and a cardiovascular hospitalization by 75%. Among patients who come to an emergency department, the overall death rate is about 7.5% at 1 year. In patients with inherited arrhythmias, such as long QT syndrome (Chapter 53), syncope worsens prognosis. Compared with other patients with supraventricular tachycardia, syncope per se does not increase mortality but does increase the likelihood of needing medical or ablation therapy (Chapter 54).

TABLE 49-9 DRIVING IN PATIENTS WITH ARRHYTHMIAS

CARDIOVASCULAR DISORDER	DRIVING RESTRICTION
SVT: atrial fibrillation, atrial flutter, narrow-complex SVT, wide-complex SVT	No driving if symptomatic Can drive if asymptomatic for 1 month (3-6 months for wide-complex SVT)
VT, VF	No driving for 6 months
Bradyarrhythmias	No restriction if asymptomatic; no driving if syncope occurs
After successful catheter ablation	Can drive after recovery from procedure
After pacemaker implantation	No driving for 1 week (4 weeks for commercial drivers)
After ICD implantation	No driving for 6 months (barred from commercial driving)

ICD = implantable cardioverter-defibrillator; SVT = supraventricular tachycardia; VF = ventricular fibrillator; VT = ventricular tachycardia.

Adapted from Banning AS, Ng GA. Driving and arrhythmia: a review of scientific basis for international guidelines. *Eur Heart J*. 2013;34:236-244.

In patients with arrhythmias, a key issue is whether they should be allowed to drive a motor vehicle. Consensus recommendations vary depending on the arrhythmia and its treatment (Table 49-9).

50 CARDIAC ARREST AND LIFE-THREATENING ARRHYTHMIAS

ROBERT J. MYERBURG AND RACHEL LAMPERT

Sudden cardiac arrest is characterized by an abrupt loss of consciousness because of absence of cerebral blood flow owing to loss of cardiac pumping action. If not treated promptly, it will lead to central nervous system injury within minutes and a progressively increasing risk of death. Sudden cardiac arrest is often forewarned by a change in cardiovascular status, as indicated by the onset or worsening of symptoms related to transient arrhythmias, such as palpitations, lightheadedness, or near-syncope or syncope (Chapter 49). Other forewarnings may include new or worsening chest pain, dyspnea, or weakness. In individual patients, however, these warning symptoms have limited sensitivity and predictive power for sudden cardiac arrest because they also predict acute coronary syndromes (Chapter 57) and acute myocardial infarction (MI) (Chapter 58) in the absence of expressed arrhythmia. Further, sudden cardiac arrest is often the first manifestation of cardiac disease.

EPIDEMIOLOGY

The population burden of sudden cardiac arrest leading to sudden cardiac death is described by the rule of 50 s—specifically, sudden cardiac death accounts for about 50% of all cardiovascular deaths, about 50% of which are first cardiac events in apparently healthy individuals with unrecognized disease, and resulting in 50% of the loss of years of productivity owing to cardiovascular diseases.[1] The incidence in the general population over the age of 35 years is 1 to 2 per 1000 per year. Among adolescents and young adults, it is 1 per 100,000 per year. Most sudden cardiac arrests occur out of hospital (>375,000/year in the United States, with an average survival rate of 10%), and an additional 200,000 or so occur in hospital, with about a 25% survival rate.

Coronary artery disease is the most common cause of sudden cardiac arrest, either during acute events or as a consequence of chronic disease. Patients with advanced ischemic and nonischemic cardiomyopathies (Chapter 47) and with heart failure (Chapters 45 and 46) are at higher risk, although the incidence in heart failure appears to be decreasing as a result of improved long-term therapies. Patients with either common or rare acquired and inherited arrhythmia syndromes (Chapters 52 and 53) are also at increased risk for sudden cardiac arrest. In addition, both competitive athletes and individuals participating in high-intensity recreational athletic activities have a low but finite increase in risk for sudden cardiac arrest. Risk is higher in males and in association with specific sports, such as basketball and football in the United States and cycling, jogging, and soccer in Europe. In adolescents and young adults in the United States, hypertrophic cardiomyopathy (Chapter 47) is the most commonly identified structural cause in competitive athletes.[2] In individuals under 35 years, 40% of patients have no structural cardiac abnormalities at autopsy ("sudden unexplained death"), among whom about 25% have a clinically relevant variant in postmortem genetic testing.[3] Beyond the age of 30 to 35 years, coronary artery disease is more common (Chapter 58). Offspring in families in which sudden cardiac arrest was the initial manifestation of heart disease are themselves at increased risk for arrest as the initial manifestation of heart disease, thereby emphasizing the importance of a careful family history for assessing risk.[4]

PATHOBIOLOGY

In the past, ventricular fibrillation (VF) and pulseless ventricular tachycardia (VT) were the most common initially identified electrical mechanisms of sudden cardiac arrest (Chapter 53), largely in association with acute MI. However, asystole and pulseless electrical activity are now the first recorded rhythm in the majority of both in-hospital and out-of-hospital cases. Asystole may be primary or may follow deterioration or active termination of VF by electrical cardioversion. Pulseless electrical activity is defined as primary when it is the initial rhythm noted in patients with predisposing cardiac disorders and as secondary when it occurs in the setting of noncardiac predisposing factors, such as hypoxemia, metabolic disorders, massive pulmonary embolism, or blood loss.

Premature ventricular contractions (PVCs) and short runs of nonsustained VT may forewarn a long-term risk for sudden cardiac arrest, primarily when associated with advanced structural heart disease, but there is no evidence that suppression of chronic PVCs is protective. In contrast, sustained wide-QRS tachycardias are of greater concern and should be considered of ventricular origin, because of their potentially high immediate risk, until determined otherwise (Chapter 49).

It is important to recognize that not all out-of-hospital sudden deaths are cardiac in origin. Other causes include pulmonary embolism (Chapter 68), ruptured aortic aneurysm (Chapter 63), aortic dissection (Chapter 63), and acute neurologic events such as intracerebral or subarachnoid hemorrhage (Chapter 377).[5,6]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

TABLE 49-9 DRIVING IN PATIENTS WITH ARRHYTHMIAS

CARDIOVASCULAR DISORDER	DRIVING RESTRICTION
SVT: atrial fibrillation, atrial flutter, narrow-complex SVT, wide-complex SVT	No driving if symptomatic Can drive if asymptomatic for 1 month (3-6 months for wide-complex SVT)
VT, VF	No driving for 6 months
Bradyarrhythmias	No restriction if asymptomatic; no driving if syncope occurs
After successful catheter ablation	Can drive after recovery from procedure
After pacemaker implantation	No driving for 1 week (4 weeks for commercial drivers)
After ICD implantation	No driving for 6 months (barred from commercial driving)

ICD = implantable cardioverter-defibrillator; SVT = supraventricular tachycardia; VF = ventricular fibrillator; VT = ventricular tachycardia.

Adapted from Banning AS, Ng GA. Driving and arrhythmia: a review of scientific basis for international guidelines. *Eur Heart J*. 2013;34:236-244.

In patients with arrhythmias, a key issue is whether they should be allowed to drive a motor vehicle. Consensus recommendations vary depending on the arrhythmia and its treatment (Table 49-9).

50 CARDIAC ARREST AND LIFE-THREATENING ARRHYTHMIAS

ROBERT J. MYERBURG AND RACHEL LAMPERT

Sudden cardiac arrest is characterized by an abrupt loss of consciousness because of absence of cerebral blood flow owing to loss of cardiac pumping action. If not treated promptly, it will lead to central nervous system injury within minutes and a progressively increasing risk of death. Sudden cardiac arrest is often forewarned by a change in cardiovascular status, as indicated by the onset or worsening of symptoms related to transient arrhythmias, such as palpitations, lightheadedness, or near-syncope or syncope (Chapter 49). Other forewarnings may include new or worsening chest pain, dyspnea, or weakness. In individual patients, however, these warning symptoms have limited sensitivity and predictive power for sudden cardiac arrest because they also predict acute coronary syndromes (Chapter 57) and acute myocardial infarction (MI) (Chapter 58) in the absence of expressed arrhythmia. Further, sudden cardiac arrest is often the first manifestation of cardiac disease.

EPIDEMIOLOGY

The population burden of sudden cardiac arrest leading to sudden cardiac death is described by the rule of 50 s—specifically, sudden cardiac death accounts for about 50% of all cardiovascular deaths, about 50% of which are first cardiac events in apparently healthy individuals with unrecognized disease, and resulting in 50% of the loss of years of productivity owing to cardiovascular diseases.[1] The incidence in the general population over the age of 35 years is 1 to 2 per 1000 per year. Among adolescents and young adults, it is 1 per 100,000 per year. Most sudden cardiac arrests occur out of hospital (>375,000/year in the United States, with an average survival rate of 10%), and an additional 200,000 or so occur in hospital, with about a 25% survival rate.

Coronary artery disease is the most common cause of sudden cardiac arrest, either during acute events or as a consequence of chronic disease. Patients with advanced ischemic and nonischemic cardiomyopathies (Chapter 47) and with heart failure (Chapters 45 and 46) are at higher risk, although the incidence in heart failure appears to be decreasing as a result of improved long-term therapies. Patients with either common or rare acquired and inherited arrhythmia syndromes (Chapters 52 and 53) are also at increased risk for sudden cardiac arrest. In addition, both competitive athletes and individuals participating in high-intensity recreational athletic activities have a low but finite increase in risk for sudden cardiac arrest. Risk is higher in males and in association with specific sports, such as basketball and football in the United States and cycling, jogging, and soccer in Europe. In adolescents and young adults in the United States, hypertrophic cardiomyopathy (Chapter 47) is the most commonly identified structural cause in competitive athletes.[2] In individuals under 35 years, 40% of patients have no structural cardiac abnormalities at autopsy ("sudden unexplained death"), among whom about 25% have a clinically relevant variant in postmortem genetic testing.[3] Beyond the age of 30 to 35 years, coronary artery disease is more common (Chapter 58). Offspring in families in which sudden cardiac arrest was the initial manifestation of heart disease are themselves at increased risk for arrest as the initial manifestation of heart disease, thereby emphasizing the importance of a careful family history for assessing risk.[4]

PATHOBIOLOGY

In the past, ventricular fibrillation (VF) and pulseless ventricular tachycardia (VT) were the most common initially identified electrical mechanisms of sudden cardiac arrest (Chapter 53), largely in association with acute MI. However, asystole and pulseless electrical activity are now the first recorded rhythm in the majority of both in-hospital and out-of-hospital cases. Asystole may be primary or may follow deterioration or active termination of VF by electrical cardioversion. Pulseless electrical activity is defined as primary when it is the initial rhythm noted in patients with predisposing cardiac disorders and as secondary when it occurs in the setting of noncardiac predisposing factors, such as hypoxemia, metabolic disorders, massive pulmonary embolism, or blood loss.

Premature ventricular contractions (PVCs) and short runs of nonsustained VT may forewarn a long-term risk for sudden cardiac arrest, primarily when associated with advanced structural heart disease, but there is no evidence that suppression of chronic PVCs is protective. In contrast, sustained wide-QRS tachycardias are of greater concern and should be considered of ventricular origin, because of their potentially high immediate risk, until determined otherwise (Chapter 49).

It is important to recognize that not all out-of-hospital sudden deaths are cardiac in origin. Other causes include pulmonary embolism (Chapter 68), ruptured aortic aneurysm (Chapter 63), aortic dissection (Chapter 63), and acute neurologic events such as intracerebral or subarachnoid hemorrhage (Chapter 377).[5,6]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Pulselessness, in conjunction with the absence of respiratory efforts or only gasping or agonal respirations and absence of responsiveness, is diagnostic of

ABSTRACT

Sudden cardiac arrest, as the mechanism for unexpected deaths, accounts for 50% of all cardiovascular deaths and is the first clinically recognized cardiovascular event in 50% of these victims. Electrical mechanisms of sudden cardiac arrest are shockable rhythms, including ventricular fibrillation (VF) and pulseless ventricular tachycardia (pulseless VT), and nonshockable rhythms, such as pulseless electrical activity and asystole. Shockable rhythms provide a better opportunity for return of spontaneous circulation and survival. The most common causes of cardiac arrest are consequences of coronary artery disease, such as acute ischemia and ischemic cardiomyopathy. The various nonischemic cardiomyopathies, and other acquired or inherited disorders, account for a smaller proportion of the events. Survival from sudden cardiac arrest free of neurologic dysfunction is dependent upon a rapid return of spontaneous circulation. Cardiopulmonary resuscitation (CPR) initiated by bystanders immediately after summoning emergency rescue and rapid defibrillation with community-based automated defibrillators improve survival. Advanced life support includes activities—such as intubation, administration of antiarrhythmic drugs, and other therapies—that may restore circulation when return of spontaneous circulation is not immediate. An important consequence of sudden cardiac arrest is brain damage, due to ischemic encephalopathy and resulting coma. Among out-of-hospital cardiac arrest victims who are resuscitated and hospitalized, brain damage is the most important cause of subsequent in-hospital death and long-term disabilities. Outcomes can be improved by preventing hyperthermia in the comatose cardiac arrest victim. Among those whose sudden cardiac arrest is not secondary to reversible causes, implantable cardioverter-defibrillators provide long-term protection against death from recurrent sudden cardiac arrest.

cardiac arrest. Although the absence of a carotid or femoral pulse is a primary diagnostic criterion for health care professionals, palpation for a pulse is no longer recommended for lay responders. The absence of respiratory efforts or severe stridor with persistence of a pulse suggests a primary respiratory arrest that may lead to cardiac arrest in a short time.

In the out-of-hospital setting, the rhythm can be diagnosed by an automatic external defibrillator, when available. In the inpatient setting, electrocardiographic monitoring should be started immediately. The underlying arrhythmia can be VF, VT, supraventricular tachycardia, bradycardia, asystole, or pulseless electrical activity, with the latter implying electrical activity during which no pulse is generated (Fig. 50-1). VF is recognized by the disorganized electrical activity with no recognizable QRS. If the electrocardiogram (ECG) reveals pulseless electrical activity, potentially treatable causes include hypovolemia (Chapter 102), hypoxia (Chapter 90), cardiac tamponade (Chapter 62), tension pneumothorax (Chapter 86), drug overdose (Chapter 96), hypothermia (Chapter 95), and hyperkalemia (Chapter 103). For a wide-complex tachycardia, differentiating VT from a supraventricular tachycardia can be more challenging (see Fig. 49-3 and Table 53-2).

For at least 50% of survivors of a cardiac arrest, the arrest represents the first manifestation of cardiac disease, and diagnosing the underlying cause is critical for treatment to and prevent recurrence. The leading causes of out-of-hospital cardiac arrest are ischemic heart disease, structural heart disease, and primary arrhythmias (Table 50-1), but a variety of severe noncardiac conditions can also be responsible and are more frequent when a patient arrests in a hospital.

Systematic clinical testing should start with an ECG, blood testing for electrolytes and toxicology, echocardiography, and imaging for coronary artery disease or coronary artery anomalies. Cardiac magnetic resonance imaging (Chapter 44) is more sensitive than echocardiography and should also be performed if the diagnosis remains elusive. If the underlying diagnosis remains unclear after initial testing, provocative stress testing may reveal arrhythmic syndromes such as catecholaminergic ventricular tachycardia (Chapter 53) or a subclinical arrhythmogenic cardiomyopathy, and pharmacologic testing may unmask other rare arrhythmic syndromes. Genetic testing can reveal an underlying abnormality in about 10 to 30% of patients whose other tests have been unrevealing.[6]

TREATMENT

The management of a patient during cardiac arrest emphasizes actions to maintain blood flow to preserve the viability of the central nervous system, heart, and other vital organs, while striving to restore spontaneous circulation as quickly as possible. These goals are accomplished by assessing the patient and contacting an emergency response system (EMS), followed quickly by initiating basic life support (BLS), early defibrillation for patients with VF or pulseless VT, advanced life support (ACLS) as needed, and post–cardiac arrest care.

Cardiopulmonary resuscitation (CPR) performed by bystanders in the community or at sporting events before EMS arrival is associated with a 30-day

TABLE 50-1 CAUSES OF OUT-OF-HOSPITAL CARDIAC ARREST

CARDIAC CAUSES
- Ischemic heart disease with or without acute myocardial infarction
- Cardiomyopathy (e.g., myocarditis, hypertrophic, infiltrative, dilated), arrhythmogenic right ventricular cardiomyopathy
- Valvular heart disease
- Pericardial tamponade
- Congenital heart disease, including coronary artery anomalies
- Arrhythmia without ischemic or structural heart disease (e.g., Wolff-Parkinson-White syndrome, long QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia)

NONCARDIAC CAUSES
- Traumatic or nontraumatic bleeding
- Cerebrovascular accident
- Aortic dissection or rupture
- Hypoxia (e.g., pulmonary embolism, pneumonia, carbon monoxide poisoning, asthma, or chronic obstructive pulmonary disease)
- Drug overdose
- Hypoglycemia
- Hypothermia or hyperthermia
- Epilepsy
- Tension pneumothorax
- Septic shock
- Electrolyte abnormalities
- Severe dehydration

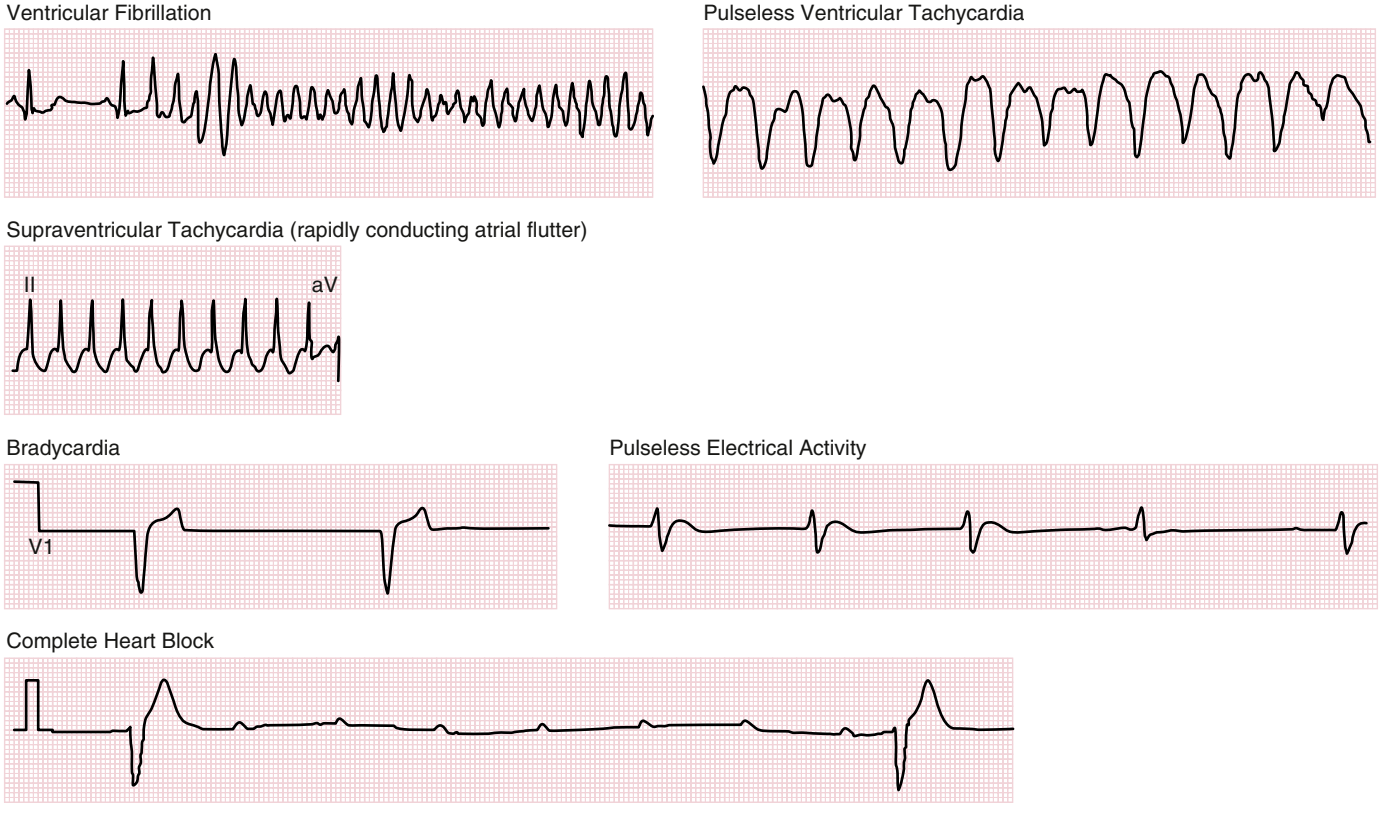

FIGURE 50-1. Electrical mechanisms associated with cardiac arrest. Shockable mechanisms include ventricular fibrillation and pulseless ventricular tachycardia. Pulseless electrical activity (as distinct from pulseless ventricular tachycardia) is a mechanical rather than an electrical disorder, and shocks are not indicated.

survival rate that is more than twice as high as that associated with no CPR before the arrival of EMS.[7,8] A mobile-phone system dispatch of lay volunteers trained in CPR and located within about one third of a mile of the victim can increase the rate of lay response by about 40%.[A1] In the United States, however, Black and Hispanic persons are 20 to 35% less likely to receive bystander CPR regardless of the location of their arrest.[9]

Basic Life Support

After an initial evaluation for response to voice or tactile stimulation, observation for respiratory movements and skin color, and simultaneous palpation of major arteries for the presence of a pulse, the determination that a life-threatening incident is in progress should prompt immediate contact with EMS (911).

When a cardiac arrest is confirmed, the goal of BLS is to establish perfusion as quickly as possible using CPR or the concept of cardiocerebral resuscitation (see later). The algorithm of BLS is compression-airway-breathing, based on the recognition that compression alone is the primary maneuver because the patient is better perfused by minimizing interruptions between compressions and can be harmed by excessive ventilation.

A precordial thump may be attempted by a trained rescuer as part of an initial response, although its added benefit is questionable. The technique involves one or two blows delivered firmly to the junction of the middle and lower thirds of the sternum from a height of 8 to 10 inches. It should not be used in an unmonitored patient with a perceptible rapid tachycardia or without complete loss of consciousness because of concern about converting organized electrical activity into VF.

Prompt initiation of CPR, which can be performed by professional and paraprofessional personnel, by emergency medical technicians, and by trained laypersons, is the key element for successful resuscitation. The delay between diagnosis and starting CPR should be minimal. If only one witness is present, the only activity that should precede BLS is telephone contact (911) of EMS. The untrained lay bystander can be prompted on how to perform CPR by the EMS telecommunicator.

Clearing the airway includes tilting the head backward and lifting the chin, in addition to exploring the airway for foreign bodies—including dentures—and removing them. The Heimlich maneuver, which entails wrapping the arms around the victim from the back and delivering a sharp thrust to the upper part of the abdomen with a closed fist, should be performed if there is reason to suspect a foreign body lodged in the oropharynx, as suggested by severe respiratory stridor, in contrast to slow agonal respirations or apnea, especially in a patient who is eating at the time of the arrest. When the person at the scene has insufficient physical strength to perform the maneuver, mechanical dislodgment of a foreign body can sometimes be achieved by abdominal thrusts with the unconscious patient in a supine position. If there is suspicion that respiratory arrest precipitated the cardiac arrest, particularly in the presence of a mechanical airway obstruction, a second precordial thump should be delivered after the airway has been cleared.

With the head properly positioned and the oropharynx clear, mouth-to-mouth respiration can be initiated. With the exception of Heimlich maneuvers, however, mechanical ventilation strategies are now reserved for EMS responders and medical professionals, rather than bystanders. Devices for establishing ventilation include plastic oropharyngeal airways, esophageal obturators for establishing ventilation, a masked Ambu bag, and endotracheal tubes. Intubation is the preferred procedure, but time should not be sacrificed, even in the in-hospital setting, while awaiting an endotracheal tube or a person trained to insert it. Temporary support with Ambu bag ventilation is the usual method in the hospital until endotracheal intubation can be accomplished. When ventilatory support is provided by EMS responders in the out-of-hospital setting, the lungs should be inflated twice in succession after every 30 chest compressions.

Circulatory support, which is the primary element of BLS, is intended to maintain blood flow until definitive steps can be taken to restore effective cardiac contractions. The rationale is based on the hypothesis that chest compression maintains an externally driven pump function by sequential emptying and filling of its chambers, with competent valves favoring forward flow. The palm of one hand is placed over the lower sternum while the heel of the other rests on the dorsum of the lower hand. The sternum is then depressed with the resuscitator's arms straight at the elbows to provide a less tiring and more forceful fulcrum at the junction of the shoulders and back. A force sufficient to depress the sternum at least 2 inches (>5cm) should be applied, with abrupt relaxation. The cycle is carried out at a rate of about 100 compressions per minute. Compression-only CPR is as good as, if not perhaps slightly better than, compression plus rescue breathing, in part because it may be more effective than compression-ventilation sequences, encourages more bystander CPR by untrained or remotely trained bystanders who lack confidence, and also allays concerns about mouth-to-mouth ventilation of unknown victims in the absence of mechanical airway devices.[A2,A3] An alternative is a compression-ventilation ratio of 30:2 for single responders to victims through adulthood and for two responders to adult victims. For two-rescuer CPR for infants and children, the recommended compression-ventilation ratio is 15 : 2. Another recently suggested modification is the "hands-only" (cardiac-only, compression-only) technique, which uses 200 successive compressions without interruption. In the prehospital setting, therapeutic hypothermia is not beneficial.[A4]

Intermediate Life Support: Automated External Defibrillators

Despite the benefit of BLS, time to defibrillation is the major determinant of survival for victims in VF or pulseless VT. Because ACLS strategies are generally implemented by in-hospital personnel or out-of-hospital EMS responders, an intermediate strategy is for nonconventional first responders to use automated external defibrillators. These devices prompt the user to deliver a defibrillation shock when deemed appropriate by a computerized rhythm detection system integrated into the device. The operators can be trained police officers, security guards, airline personnel, or trained or untrained lay bystanders (Table 50-2). A number of studies have suggested improved survival rates when such strategies are deployed in public sites,[A5] but an initial study of a home deployment strategy was disappointing. Further study is warranted because 70 to 80% of out-of-hospital cardiac arrests occur at home, with survival rates less than 6%. Automated external defibrillators, which serve as an intermediate supplement to the BLS-ACLS sequence, are intended to attempt earlier defibrillation while awaiting the arrival of ACLS-trained emergency personnel.

Advanced Cardiac Life Support

ACLS methods, other than those directly related to control of tachyarrhythmias, are guided by comprehensive protocols to aid responders over a broad expanse of clinical circumstances and mechanisms of cardiac arrest, ranging from transient clinical events to end-stage multisystem disease. The primary goals of ACLS are to restore a hemodynamically effective cardiac rhythm, optimize ventilation, and maintain and support the restored circulation. During ACLS, the first priority is prompt cardioversion or defibrillation of persisting pulseless VT or VF, if appropriate equipment is immediately available. If cardiac arrest has occurred for 4 to 5 minutes before the availability of a defibrillator, a short period of cardiac compressions immediately before defibrillation increases the probability of survival. The administration of epinephrine in this setting to all patients can increase 30-day overall survival but not survival with a favorable neurologic outcome.[A6] In the in-hospital setting, vasopressin (20 IU) plus methylprednisolone (40 mg) similarly can increase the likelihood of a return to spontaneous circulation but not of a favorable neurologic outcome.[A7] If the initial attempt to restore circulation is

TABLE 50-2 AUTOMATED EXTERNAL DEFIBRILLATOR STRATEGIES FOR RAPID RESPONSE TO CARDIAC ARRESTS CAUSED BY VENTRICULAR FIBRILLATION

unsuccessful, continued on-scene resuscitation may be preferred to immediate transfer to a hospital.[10] In patients who do not respond to standard defibrillation, either rapid sequential shocks from two defibrillators or switching the pads to an anterior-posterior position is preferable to repeated standard shocks.[A8]

After the initial attempt to restore a hemodynamically effective rhythm, the patient is intubated and oxygenated, if needed. Electrical pacing of the heart should be attempted if a severe bradyarrhythmia or asystole is present (Chapter 54). An intravenous line is established to deliver medications. After intubation, the goal of ventilation is to reverse hypoxemia and not merely to achieve a high alveolar P_{O_2}. When available, oxygen rather than room air should be used to ventilate the patient, and arterial O_2 saturation should be monitored, when possible. In the out-of-hospital setting, a face mask or an Ambu bag by means of an endotracheal tube is generally used.

Approach to Specific Arrhythmias

Tachyarrhythmic Cardiac Arrest

Slow, well-tolerated monomorphic VTs, especially in the absence of structural heart disease, can usually be treated with antiarrhythmic drugs or β-adrenergic blocking agents in some circumstances (see Tables 52-2 and 52-3 in Chapter 52). In contrast, when rapid VT or VF is identified on a monitor or by telemetry, immediate cardioversion or defibrillation should be performed (Fig. 50-2). When a reversible cause, such as an acute ischemic syndrome or electrolyte disturbance, is the apparent mechanism, normal rhythm can be successfully restored in up to 90% of VF victims weighing up to 90 kg with a direct current (DC) biphasic shock of up to 200 joules delivered within 2 to 3 minutes, or if such equipment is not available, a monophasic shock of up to 360 joules. Failure of the initial shock to restore an effective rhythm is a poor prognostic sign.

After a single shock, the patient should be checked immediately for restoration of a spontaneous pulse; CPR should be continued for five cycles if a pulse remains absent. Subsequently, a second shock should be delivered, followed by epinephrine 1 mg intravenously (IV). If a pulse is still absent, CPR is repeated for five cycles before the next shock. Epinephrine may be repeated at 3- to 5-minute intervals with defibrillator shocks in between, but high-dose epinephrine does not appear to provide added benefit. Vasopressin (40 U given IV once) is an equally good alternative to epinephrine,[A8] but the combination does not appear to be better than either alone.

SVTs can precipitate cardiac arrest in two circumstances. One is in patients with high-grade coronary artery disease, in whom rapid heart rates can cause myocardial ischemia because of the dependence of coronary blood flow on the diastolic interval. In this setting, the arrhythmia should be treated urgently by restoring sinus rhythm or slowing the heart rate, either by medical therapy (e.g., intravenous adenosine, β-blockers, or calcium channel blockers) (Chapter 52) or by electrical DC cardioversion (Chapter 54). The second mechanism of concern is atrial fibrillation in patients with Wolff-Parkinson-White syndrome, who may have ventricular rates greater than 240 beats per minute when the accessory pathway has a short refractory period (see Fig. 52-10 in Chapter 52). This abnormality, which can trigger VF or cause hypotensive VT, requires prompt slowing or termination of the SVT (Chapter 52).

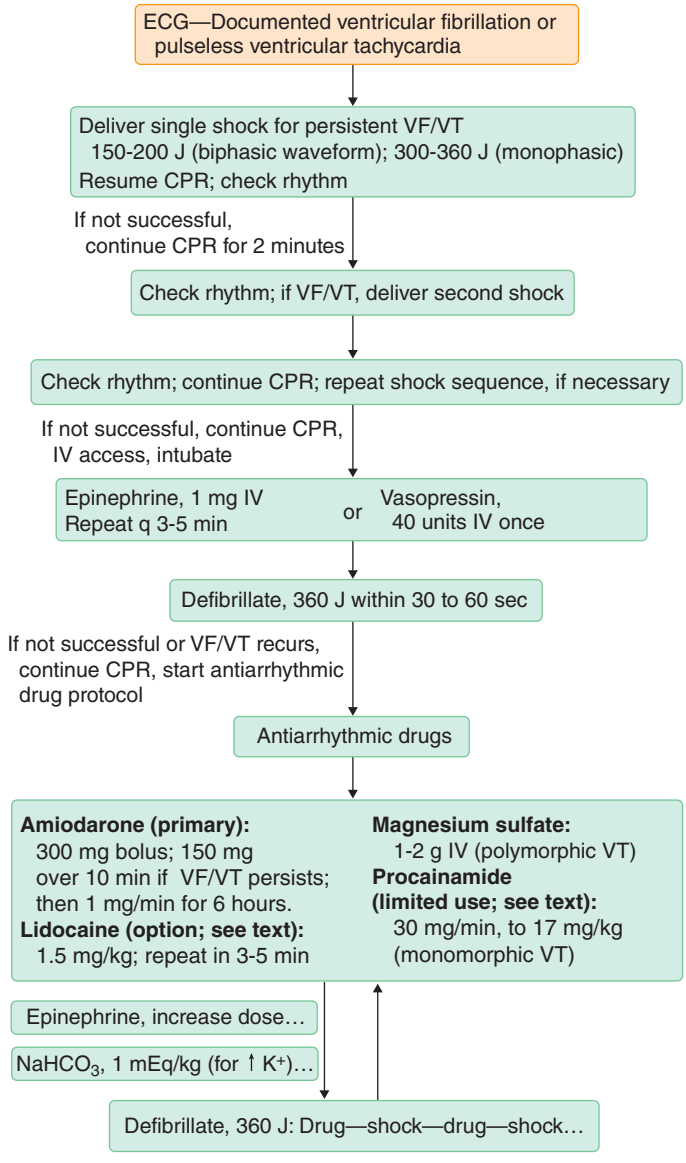

FIGURE 50-2. General algorithm for advanced cardiac life support (ACLS) response to ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT). For more detail, see the ACLS guidelines in the Grade A References. *Note:* In a 2008 advisory, 200 compression-only sequences were suggested as an alternative to standard cardiopulmonary resuscitation (CPR) cycles between shocks, and this approach is under consideration for future guidelines. ECG = electrocardiogram; IV = intravenous; K^+ = potassium; $NaHCO_3$ = sodium bicarbonate.

Pharmacotherapy for Resistant Arrhythmias

For a patient who continues in VF or pulseless VT despite multiple attempts at DC cardioversion after epinephrine, or who has recurrent episodes of VF or VT after cardioversion, the likelihood of return of spontaneous circulation and survival to hospitalization may be increased by administering intravenous antiarrhythmic agents while continuing resuscitative efforts (see Fig. 50-2). Amiodarone and lidocaine are equivalent to each other and better than placebo when the cardiac arrest is witnessed by bystanders or EMS, but neither is better than placebo for patients who suffer unwitnessed arrests.[A9]

Amiodarone is given as a 150-mg intravenous bolus over a 10-minute period, followed by 1 mg/minute for up to 6 hours and 0.5 mg/minute thereafter. Additional bolus dosing, to a maximum of 500 mg, can be tried if the initial bolus is unsuccessful. The lidocaine dose is a 1.0- to 1.5-mg/kg intravenous bolus, with the dose repeated in 2 minutes. Neither drug needs to be given as a routine to individuals who respond to initial defibrillation with a persistently stable rhythm. For patients who remain electrically unstable or have recurrent episodes of VT or VF after initial defibrillation and oxygenation, continued antiarrhythmic therapy is indicated.

If there is sufficient clinical evidence that the cardiac arrest was associated with an acute coronary syndrome or that recurrent arrhythmias are precipitated by ischemia, lidocaine may be used in preference to amiodarone. Under other circumstances, intravenous amiodarone may be the preferred initial drug. Under all circumstances, the alternative drug may be tried if the initial choice fails. Intravenous procainamide (loading infusion of 100 mg/5 minutes to a total dose of 500 to 800 mg, followed by a continuous infusion at 2 to 5 mg/minute) is now rarely used but may be tried in those with persisting, hemodynamically unstable arrhythmias.

In patients with acute hyperkalemia as the triggering event for resistant VF, hypocalcemia, or arrest potentially caused by excess doses of calcium-blocking drugs, 10% calcium gluconate (5 to 20 mL infused at a rate of 2 to 4 mL/minute) may be helpful. Otherwise, calcium should not be used routinely during resuscitation, even though ionized Ca^{2+} levels may be low during resuscitation from cardiac arrest.

Resistant forms of polymorphic VT (*torsades de pointes*), rapid monomorphic VT, ventricular flutter (rate >260/minute), or resistant VF may respond to magnesium sulfate ($MgSO_4$) (1 to 2 g given IV over a 1- to 2-minute period) or to β-blocker therapy (propranolol, 1-mg boluses IV to a total dose of up to 15 to 20 mg or metoprolol 5 mg IV, up to 20 mg). $MgSO_4$ is specifically indicated for polymorphic VTs due to inherited or acquired (drug-induced) long QT patterns (Chapter 53). This VT pattern also occurs with marked hypokalemia. Potassium chloride (20 mEq/hour intravenously) should be included in the treatment of patients with these arrhythmias if their serum potassium level is less than 3 mEq/L. However, hypokalemia also may follow the acid-base and electrolyte shifts associated with prolonged arrests and should not be considered a primary cause of the cardiac arrest in that circumstance.

Asystole, Bradyarrhythmias, and Pulseless Electrical Activity

The approach to a patient with symptomatic bradyarrhythmia, asystolic arrest, or pulseless electrical activity differs from the approach to patients with tachyarrhythmic events (pulseless VT or VF). Effective CPR is critical because no electrical strategies are effective for restoring circulation. As soon as this mechanism of cardiac arrest is recognized, efforts should focus on continuous CPR, intubation, and establishing intravenous access. Possible reversible causes, including hypovolemia, hypoxia, cardiac tamponade, tension pneumothorax, preexisting

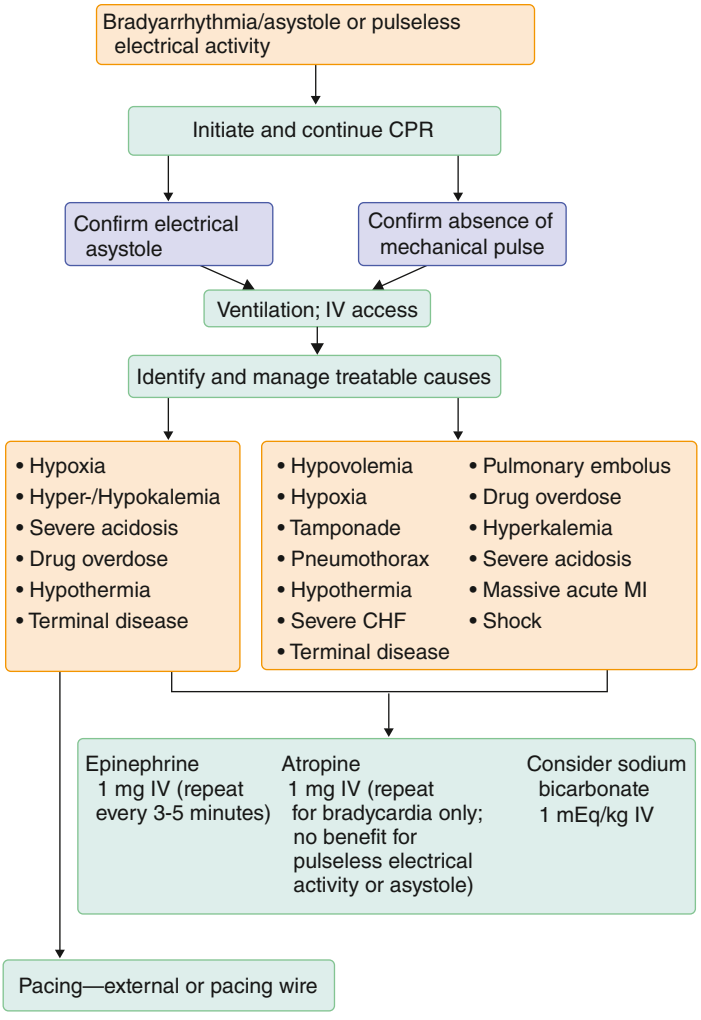

FIGURE 50-3. General algorithm for advanced cardiac life support response to bradycardic or asystolic cardiac arrest or pulseless electrical activity. For more detail, see the Grade A References. CHF = congestive heart failure; CPR = cardiopulmonary resuscitation; IV = intravenous; MI = myocardial infarction.

acidosis, drug overdose, hypothermia, and hyperkalemia, must be identified and treated immediately (Fig. 50-3). Respiratory causes of pulseless electrical activity or asystole may respond promptly to appropriate interventions, as do tamponade and hypovolemic causes. Epinephrine (1.0 mg IV every 3 to 5 minutes) or isoproterenol (up to 15 to 20 μg/minute IV), which are commonly used in an attempt to elicit spontaneous electrical activity or increase the rate of a bradycardia, have only limited success. However, one randomized trial of patients with cardiac arrest requiring vasopressors showed that combined vasopressin-epinephrine plus methylprednisolone during CPR and stress-dose hydrocortisone in postresuscitation shock improved survival to hospital discharge with favorable neurologic status compared with epinephrine-saline placebo. In the absence of an intravenous line, epinephrine (1 mg, i.e., 10 mL of a 1 : 10,000 solution) may be given by the intracardiac route, despite the danger of coronary artery or myocardial laceration. Sodium bicarbonate (1 mEq/kg) may be tried for known or strongly suspected preexisting hyperkalemia or bicarbonate-responsive acidosis but is no longer recommended for routine use. Atropine is no longer recommended for management of bradyarrhythmic cardiac arrests because of lack of efficacy.

External pacing (Chapter 54) should be tried for out-of-hospital bradycardic or asystolic cardiac arrests, although existing data suggest little effect on outcome. In-hospital, external pacing is generally used during the initial response to a bradycardic or asystolic arrest, but it should be superseded by transvenous pacing if the arrest is prolonged, if continuous pacing is needed, or if the external device fails to pace. Unfortunately, an *asystolic* patient continues to have a very poor prognosis.

Postresuscitation Care

After return of spontaneous circulation, particularly following a prolonged resuscitation, attention shifts to the elements of injury caused by cardiac arrest. The four components of the post–cardiac arrest syndrome include brain injury,[11] myocardial dysfunction, systemic ischemia-reperfusion responses, and control of persistent precipitating factors. The therapeutic goal is to maintain a stable electrical, hemodynamic, and central nervous system status. Specific therapy is determined by the clinical circumstances. The most pressing issue is the presence of anoxic encephalopathy, which is a strong predictor of in-hospital death and postarrest disability. To prevent postarrest encephalopathy, therapeutic cooling to prevent hyperthermia improves neurologic outcomes, but a target of 36°C appears to be as good as targeted hypothermia.[A10,A11] After 24 to 48 hours of cooling, patients should be gradually rewarmed to 37°C. For patients who suffer in-hospital cardiac arrest, therapeutic hypothermia does not appear to be beneficial.

During or after therapy targeted to restoration of an electrically stable cardiac rhythm, the patient's general metabolic state should be addressed by improving oxygenation and reversing acidosis. Intravenous sodium bicarbonate (1 mEq/kg), with up to 50% of this dose repeated every 10 to 15 minutes during the course of CPR, is recommended for patients with known or suspected preexisting bicarbonate-responsive causes of acidosis, for certain drug overdoses (Chapter 96), and after prolonged and unsuccessful attempts at resuscitation. Caution must be exercised, however, because excessive quantities of sodium bicarbonate can be deleterious by causing alkalosis, hypernatremia, and hyperosmolality. Furthermore, goal-directed optimization of oxygenation does not improve neurologic outcomes.[A12] When possible, arterial pH, P_{O_2}, and P_{CO_2} should be monitored during the resuscitation. Myocardial injury (Chapter 58) and hemodynamic dysfunction (Chapter 93) are managed by standard techniques, and a mean arterial blood pressure target of 63 mm Hg is as good as a target of 77 mg Hg.[A13]

In parallel with postarrest therapeutic support, diagnostic actions are also indicated, especially when the arrest is suspected to be due to an acute coronary syndrome (Chapter 57). The most pressing is cardiac catheterization followed by coronary interventions (Chapter 59) to help control unstable rhythms associated with persisting ischemia and to preserve myocardium in survivors.[12] However, in patients without ST elevation, immediate angiography is no better than delaying angiography until after neurologic recovery.[A14,A15] These activities require EMS transport to hospitals capable of advanced care on a 24-7 basis. An added transport time of less than 15 minutes to achieve prompt advanced care has been suggested as an appropriate tradeoff. A 2-day course of amoxicillin-clavulanate (1 g, 200 mg) can reduce the risk of ventilator-associated pneumonia but not mortality at 28 days.[A16]

PREVENTION

Prevention of sudden cardiac arrest should focus on preventing the underlying diseases whenever possible. Since coronary artery disease is the most common cause of sudden cardiac arrest, treatment of the modifiable risk factors of atherosclerosis (e.g., serum lipids, blood pressure, smoking, and exercise; see Chapter 40) is the cornerstone of prevention. In addition, patients who have known cardiac diseases, such as patients with a history of myocardial infarction or heart failure, and clinical characteristics indicative of a high risk of ventricular arrhythmias, can benefit from insertion of an implantable cardioverter defibrillator (Chapters 46 and 53). Screening of highly competitive and professional athletes with a history and physical examination is recommended to detect undiagnosed cardiac disease, and an ECG adds further diagnostic sensitivity.[13]

Public health initiatives can improve survival after cardiac arrest by increasing the number of people trained in CPR and in how to use automated external defibrillators, as well as by increasing the availability of defibrillators in public places. Innovative strategies, such as the use of drones to deliver automated external defibrillators when needed, may further improve survival.

PROGNOSIS

The probability of survival after a prompt intervention is about 25 to 30% for VF/pulseless VT compared with about 10 to 15% for pulseless electrical activity and less than 5% for asystole. In the hospital, the probability of survival is determined by the specific patient category (acute syndromes better than end-stage diseases), the mechanism of cardiac arrest (better for tachyarrhythmias than for bradyarrhythmias, asystole, or pulseless electrical activity), and the hospital site (better in intensive care units or other monitored settings than on an unmonitored general care unit).[14] Immediate defibrillation in highly protected settings, such as a cardiac catheterization laboratory where response times of less than 60 seconds are the norm, is associated with greater than a 90% survival rate for VF in the absence of pathophysiologic conditions that tend to perpetuate the potentially fatal arrhythmia. In many acute care settings, including patients with acute

coronary syndromes (Chapters 57 and 58), outcomes also can be excellent. For other in-hospital settings and most out-of-hospital settings, the absolute number and proportion of survivors remain low.

The most important determinant of survival from sudden cardiac arrest is time to CPR and defibrillation. Some public locations amenable to very rapid response times achieve survival rates of 50% or higher. If, however, 3 to 4 minutes elapse from the onset of sudden cardiac arrest to attempted defibrillation, the survival rate falls below 50% in most in-hospital and out-of-hospital circumstances. Survival rates continue to fall rapidly thereafter, decreasing to 25% or less by 4 to 6 minutes and to less than 10% by 10 minutes. Although immediate defibrillation is preferred within the first few minutes after the onset, a brief period of CPR improves survivability when the time to defibrillation exceeds 4 to 5 minutes.

The 10-year survival among patients who are discharged alive is about 60%.[15] Long-term prognosis after discharge is determined by a number of factors, including pre-event ventricular function, history of heart failure, and the severity of residual neurologic injury. Bystander resuscitation and defibrillation not only improve survival but also reduce the rate of brain damage and nursing home admission.

Overall, about 40% of patients who survive out-of-hospital cardiac arrest have good quality of life and functional status. Patients whose sudden cardiac arrests are due to a transient arrythmia, who have preserved left ventricular function, and who have minimal, if any, neurologic defects, have a good prognosis. In contrast, patients with advanced heart disease have annual mortality rates that range from 10 to 50%. Most patients who survive but who do not have a predictably reversible cause will receive an implantable cardioverter defibrillator for secondary prevention (Chapter 54). Survivors who receive an implantable defibrillator after a sudden cardiac arrest not due to transient factors (Chapter 54) achieve a relative risk reduction of 25 to 30%, with absolute risk decreasing from 21 to 25% to 15 to 18% over a 2-year follow-up.[A17]

BRADYCARDIAS AND CONDUCTION SYSTEM DELAYS

PETER ZIMETBAUM AND LEE GOLDMAN

BRADYCARDIAS

DEFINITION

The normal human heart rate is typically defined as 60 to 100 beats per minute, and rates below 60 per minute are defined as bradycardia. Bradycardias can be a result of sinus node dysfunction or of atrioventricular (AV) block (Table 51-1). However, many individuals have heart rates below 60 per minute at rest and especially during sleep without any symptoms or signs of hypoperfusion. A bradyarrhythmia is best defined as a heart rate below 60 per minute associated with signs or symptoms, or an awake non–sinus rhythm rate below 60 per minute even in the absence of symptoms.

EPIDEMIOLOGY

Bradycardia (heart rate below 60 beats per minute) is very common, with an estimated prevalence of about 15% in adult males and 7% in adult females.[1] It is even more common (50 to 80% prevalence) in endurance athletes.[2] The prevalence of bradycardia actually diminishes with age, presumably because of age-related declines in parasympathetic activity. During sleep, bradycardia is even more common, with studies of healthy adults showing sinus bradycardia below 40 beats per minute in 20 to 25% of individuals, sinus pauses of two seconds or more in 5 to 10%, first-degree AV block in 8 to 12%, and second-degree Wenckebach block in about 5 to 10%.

However, an overwhelming majority of bradycardias are asymptomatic in individuals who can raise their heart rates to meet increased cardiac demands when needed. As a result, only an estimated 0.26% of U.S. adults have a cardiac pacemaker implanted for any indication, including bradycardia.

PATHOBIOLOGY

The normal cardiac impulse begins in the sinus node complex, which is located at the junction of the right atrium and the superior vena cava. It then travels through the right atrium and primarily activates the left atrium through the coronary sinus. The time it takes to activate the atria is represented by the P wave on the electrocardiogram (ECG). After depolarizing the atria, the impulse enters the AV node, which is located in the inferior septal region of the right atrium, where a delay occurs. This delay allows time for the atria to contract and fill the ventricles. In most individuals, the impulse travels through the AV node over a uniform functional pathway or route. Some people have two or more functional pathways called dual AV nodal pathways (fast and slow pathways). The delay in the AV node represents most of the isoelectric portion of the PR interval on the ECG (E-Fig. 51-1). The usual duration

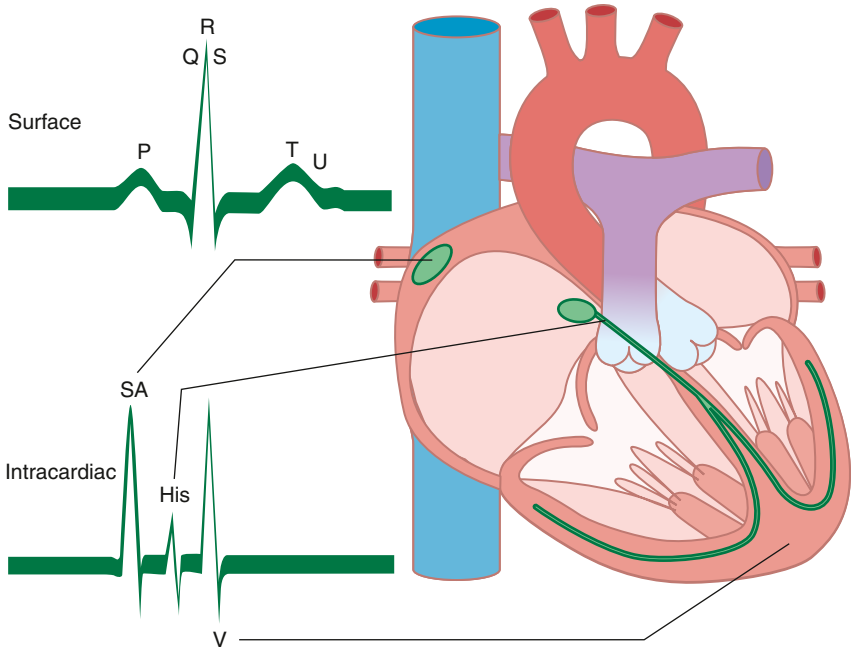
ABSTRACT

Bradyarrhythmias can be a result of sinus node dysfunction or blocked conduction of a sinus impulse, usually at or below the level of the atrioventricular node. Causes include intrinsic disease within the conducting system, medications, iatrogenic injury, and occasionally infiltrative or infectious cause. Except for cases that respond to the elimination of precipitating medications, symptomatic patients nearly always require a cardiac pacemaker. Delays in intraventricular conduction are usually asymptomatic but can be markers of underlying coronary or myocardial disease and can progress to higher degrees of conduction block.

KEYWORDS

complete heart block
sick sinus syndrome
bradycardia



E-FIGURE 51-1. Diagram of the surface electrocardiogram (P, QRS, T, and U waves) and the related intracardiac electrograms (SA, His, and V). The atrial (SA) electrogram represents intra-atrial conduction. The His bundle electrogram (His) represents the recording of a His potential, and the ventricular (V) electrogram represents activation of the ventricles. The SA-His interval corresponds to intra-atrial conduction and delay in the atrioventricular node. The His-V interval represents conduction between the His bundle and the ventricles (infranodal conduction).

of atrial activation including delay in the AV node is up to 140 msec and can be measured directly as the atrial-His interval. The impulse then travels into the specialized infranodal conducting system, that is, through the His bundle, then right and left bundle branches, and into the Purkinje network. The Purkinje network extends or fans out throughout the ventricular endocardium. Impulses conduct rapidly through the Purkinje network, thereby allowing nearly simultaneous activation of the ventricles. A small portion of the isoelectric segment of the PR interval represents infranodal conduction. This infranodal conduction through the His-Purkinje system (HPS) also can be measured directly (His-ventricle interval) and should take between 40 and 60 msec. Once out of the Purkinje network, the impulse proceeds relatively slowly from the endocardial to epicardial surface of the ventricles. The QRS complex on ECG represents depolarization of the bundle branches and ventricular myocardium.

The normal heart rate is generated by tissues or pacemaker cells with intrinsic automaticity. The sinus node cells produce the greatest rate (60 to 100 beats per minute) of automaticity and suppress other potentially automatic (AV junctional, 40 to 55 beats per minute; His-Purkinje cells, 15 to 40 beats per minute) tissues with slower rates of depolarization. The sinus node and AV node are heavily influenced by the parasympathetic (vagal) and sympathetic (adrenergic) nervous systems. At rest, the parasympathetic system controls sinus node automaticity. With exertion or emotional or physical stress, a withdrawal of parasympathetic tone and an increase in heart rate, which is then perpetuated by sympathetic tone, further increase heart rate. Sinus arrhythmia refers to the normal variation in heart rate with inspiration and expiration. With inspiration, a withdrawal of vagal tone increases heart rate; by comparison, expiration is associated with a drop in heart rate (Fig. 51-1). During sleep, a dominance of vagal tone slows heart rate.

Most bradyarrhythmias are caused by intrinsic idiopathic fibrocalcific degeneration of the cardiac conduction system (Table 51-2). Some patients have congenital heart block,[3] and familial bradycardia can occur. The conduction system also can be damaged by ischemia and myocardial infarction, especially below the AV node. Infiltrative diseases, such as amyloidosis (Chapter 174). Sarcoidosis (Chapter 83)[4] and collagen vascular diseases, such as scleroderma (Chapter 246) or advanced rheumatoid arthritis (Chapter 243), can affect any part of the conduction system. Hypothyroidism (Chapter 207) is also commonly associated with sinus bradycardia.

Systemic infections such as Lyme disease (Chapter 296) can affect the cardiac conduction system. A myocardial abscess in bacterial endocarditis (Chapter 61) can present with acute conduction delays. Iatrogenic causes include medications (Table 51-3),[5] valve replacement surgery (whether open or catheter-based), and intracardiac procedures.[6] Even percutaneous placement of a pulmonary artery catheter can precipitate transient heart block.

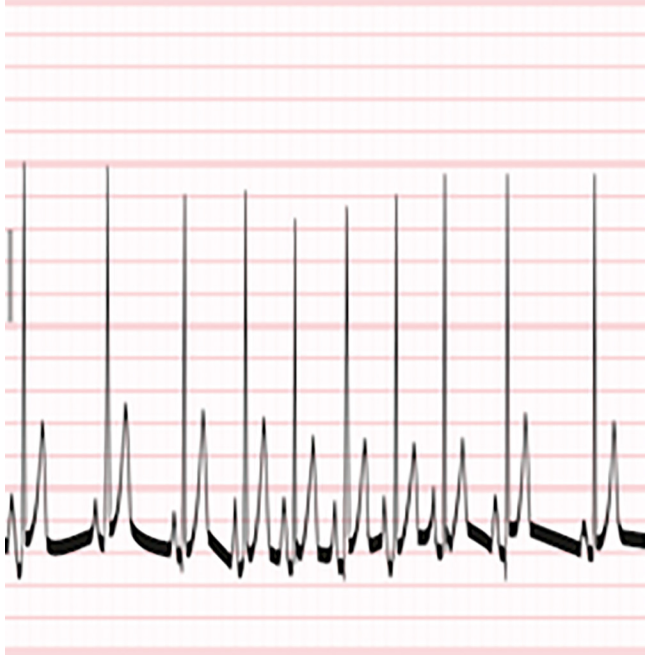


FIGURE 51-1. Sinus arrhythmia. Note the variation in sinus rates, which fluctuate with normal variations in autonomic tone.

BRADYARRHYTHMIAS

Bradyarrhythmias may be caused by dysfunction of the sinus node, AV node, or His-Purkinje system (see Table 51-1).

CLINICAL MANIFESTATIONS

Sinus bradycardia and various degrees of AV nodal blocks can occur asymptomatically during sleep in healthy individuals. Asymptomatic first- and second-degree AV block, particularly when partially or completely reversed by exercise, is usually benign. Persistent second-degree and third-degree AV nodal block is abnormal and is often associated with dizziness, fatigue, exertional dyspnea, worsening of heart failure, near-syncope, or syncope. Third-degree AV block with a good junctional escape mechanism that accelerates during exercise, as often noted in patients with congenital AV block, may remain asymptomatic. Patients with congenital heart block may not appreciate their potential for a more active lifestyle because of the lack of a reference point but often feel much better when an appropriate heart rate acceleration can be achieved after pacemaker therapy.

DIAGNOSIS

Bradycardias are typically diagnosed by the ECG. In symptomatic patients with symptoms suggestive of bradyarrhythmia, 24-hour Holter monitoring or prolonged loop monitoring usually can make the diagnosis, but some patients may require formal electrophysiologic testing (Chapter 49). Any bradycardias,

including sinus node dysfunction and AV nodal block, can be caused at least in part by vagal influences, such as vasovagal episodes, vomiting, abdominal surgery, and upper and lower gastrointestinal invasive procedures. Syncope, sometimes caused by the bradycardia and sometimes by vasodepression with hypotension, may result (Chapters 39 and 49). Medications, infiltrative diseases, fibrocalcific degeneration, and a variety of other causes must be considered. Lyme disease also is a common cause of reversible complete heart block, usually localized to the AV node.

The evaluation should also include echocardiography (Chapter 43) to evaluate for structural heart disease and cardiac function. If myocardial ischemia is suspected, exercise testing (Chapters 44 and 56) should be performed. If an underlying endocarditis (Chapter 61), an infiltrative or inflammatory cardiomyopathy (Chapter 47), or adult congenital heart disease (Chapter 55) is suspected, either cardiac computed tomography or cardiac magnetic imaging should be performed (Chapter 44).

SPECIFIC BRADYARRHYTHMIAS

SINUS BRADYCARDIA AND SINUS NODE DYSFUNCTION

Sinus bradycardia (Fig. 51-2) is generally defined as a sinus rate of less than 60 beats per minute. It should be noted, however, that sinus rates as low as 45 to 50 beats per minute, particularly at rest, can be physiologically normal. Sinus node dysfunction[7] encompasses a group of disorders including sinus bradycardia, sinoatrial exit block, sinus arrest (pause of >2 to 3 seconds) during sinus rhythm, chronotropic incompetence, and tachycardia-bradycardia (tachy-brady) syndrome.[8] Sinus node dysfunction in combination with symptoms such as fatigue, dizziness, near or complete syncope (Chapters 39 and 49), or worsening of heart failure (Chapter 45) is called sick sinus syndrome. The tachy-brady syndrome is often identified by a prolonged delay in sinus node recovery following the termination of atrial fibrillation (AF) (Fig. 51-3). Sinoatrial exit block refers to the electrophysiologic phenomenon of sinus node firing with delay or block of the impulse as it travels from the sinus node to the surrounding atrial tissue (Fig. 51-4). Sinoatrial exit block can be first degree, second degree (type 1 or 2), and third degree. First-degree sinoatrial block is difficult to diagnose from the surface ECG. Second-degree sinoatrial exit block type 1 is manifest by progressive PP shortening preceding the sinus pause. The PP interval following the pause must be greater than twice the PP interval that preceded the pause. Second-degree sinoatrial exit block type 2 is characterized by a pause equaling an exact multiple of the sinus rate (i.e., constant PP interval before and after the pause). High-degree sinoatrial exit block refers to the absence of multiple P waves with a pause still corresponding to an absolute multiple of the underlying PP intervals, and third-degree AV block results in a complete absence of sinus P waves.

Chronotropic incompetence refers to the inability to increase the sinus rate appropriately in response to exercise or other physiologic demand. In most patients, chronotropic incompetence is manifest by a maximal heart rate of less than 100 beats per minute.

ATRIOVENTRICULAR CONDUCTION DISTURBANCES

AV conduction disturbances refer to abnormal conduction in the AV node or in the HPS below the AV node. Electrical transmission through the AV conduction system is primarily limited by the AV node, which conducts in a decremental fashion to prevent excessively rapid conduction to the ventricles. The normal AV node rarely conducts faster than 200 beats per minute and

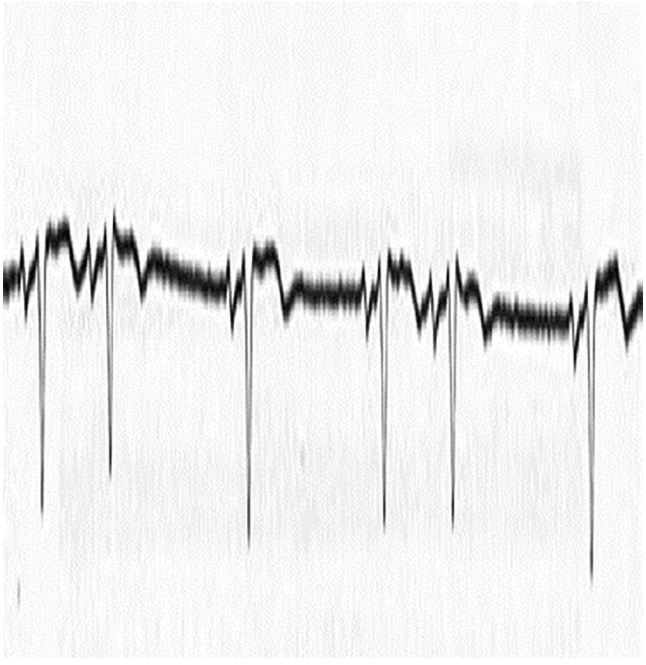

FIGURE 51-4. Sinoatrial block. Sinoatrial exit block, probably type 2, is characterized by a pause equaling an exact multiple of the sinus rate.

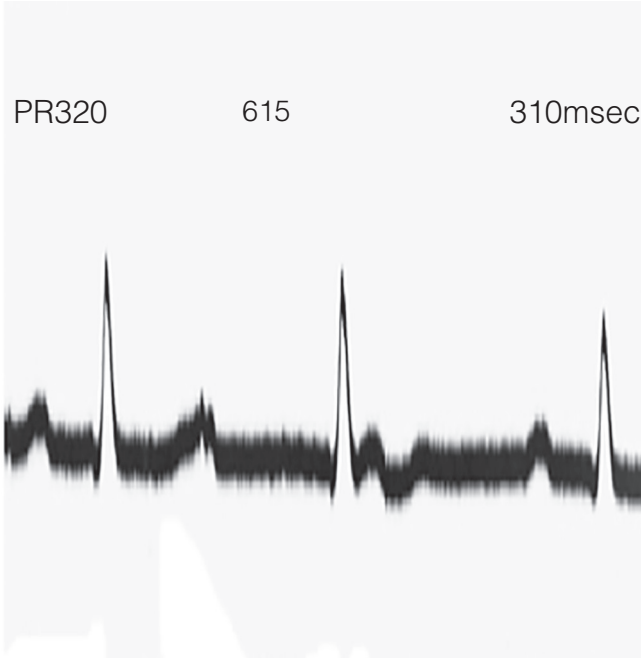

FIGURE 51-6. Mobitz I block. Progressive PR prolongation from 320 to 615 msec, followed by a blocked P wave. The subsequent conducted PR interval is less than the PR interval before the dropped P wave.

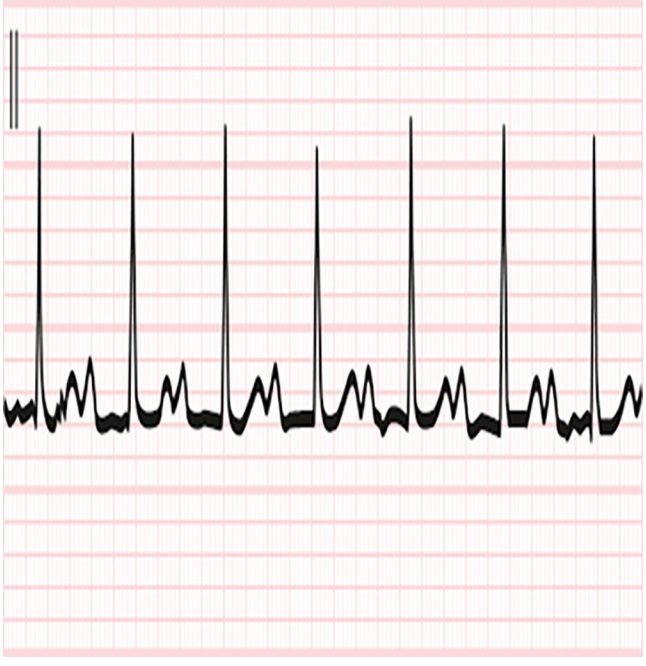

FIGURE 51-5. First-degree atrioventricular (AV) block. Note the prolonged (>200 msec) AV conduction.

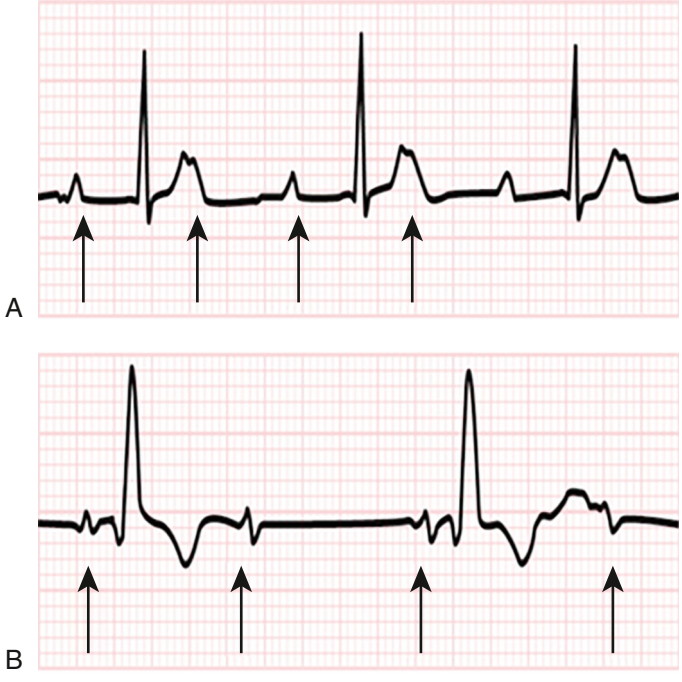

FIGURE 51-7. Two-to-one conduction in the atrioventricular (AV) node and below the AV node. A, Two-to-one conduction, with the conducted beats demonstrating a prolonged PR interval (>300 msec) and a narrow QRS, indicating Mobitz I block in the AV node. **B,** Normal-duration conducted PR interval and a wide QRS duration favoring Mobitz II block into an infranodal site of block.

slows with aging. The AV node is heavily influenced by autonomic tone and may conduct more than 200 beats per minute in the presence of heightened sympathetic and withdrawal of parasympathetic tone. Conduction through the HPS is faster and nondecremental.

The AV blocks are classified as first, second, high, and third degree.[9] First-degree AV block is a misnomer because nothing is actually blocked; rather, there is delay, usually in the AV node, manifest by a prolonged PR interval (Fig. 51-5). However, 50% or more of patients who have first-degree AV block either have detectable higher-degree AV block on prolonged monitoring or develop higher-grade block within about a year after the detection of asymptomatic first-degree AV block.[10] Second-degree AV block is divided into Mobitz type I (Wenckebach) or Mobitz type II. Mobitz type I is defined by progressive PR prolongation with eventual block after a P wave (Fig. 51-6). The initial PR prolongation is longest, the subsequent RR intervals shorten, and the PR interval following the blocked P wave is shorter than the last conducted PR interval before the blocked P wave. Mobitz type I usually occurs in the AV node. Mobitz type II, which is characterized by the abrupt failure of conduction after a P wave without preceding PR prolongation, usually represents conduction disease below the AV node. In patients with 2 : 1 block (two P waves for every QRS), it can be difficult to determine whether the block is Mobitz I in the AV node or Mobitz II below the AV node. Clues to conduction disease in the AV node include a prolonged PR interval (i.e., >300 msec) and a narrow QRS duration. Clues to conduction disease below the node include a normal PR interval but with bundle branch block (Fig. 51-7).

FIGURE 51-8. High-degree atrioventricular block. Periods of complete heart block with three nonconducted P waves (the first of which is buried in the first QRS complex) followed by two P waves, the second of which is conducted to the ventricle with a long PR interval. The subsequent three P waves are once again nonconducted, with the last P wave buried in the last QRS complex.

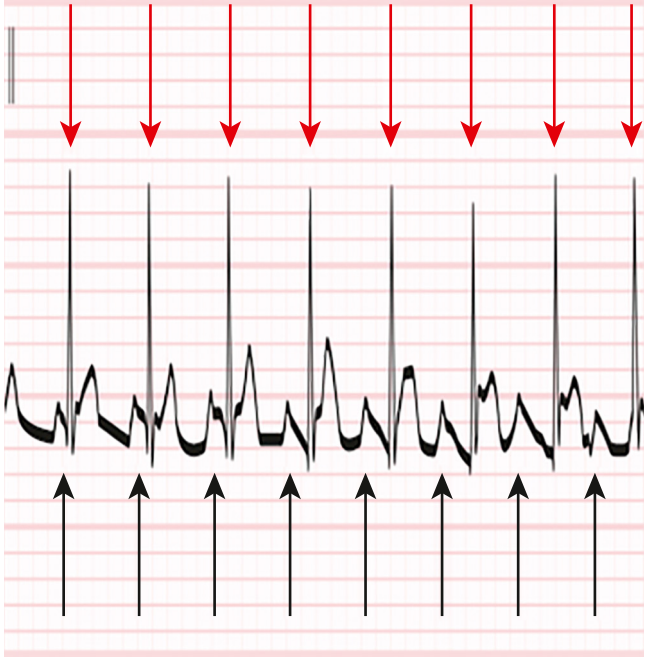

FIGURE 51-9. Complete heart block with the atrial beats *(black arrows)* dissociated from the ventricular beats *(red arrows)*. Note the ST elevation in leads III and aVF indicating acute inferior myocardial infarction as the cause of complete heart block.

High-degree or advanced AV block, which is a form of second-degree block with multiple or successive nonconducted P waves, or both (Fig. 51-8), frequently recurs or persists. Third-degree block (or complete heart block) refers to a rhythm in which the atrial and ventricular activity occurs independently, and the atrial rate usually exceeds the ventricular rate.[11] Third-degree heart block can be seen with sinus rhythm or any atrial tachyarrhythmia with a regular escape rhythm in the AV junction or below (Fig. 51-9). Sometimes there is no escape rhythm, and heart block results in asystole. Complete heart block, particularly when it is acute and accompanied by an escape rhythm, can be associated with marked QT prolongation, which signifies a risk for torsades de pointes (Chapter 53). For this reason, patients who undergo AV node ablation have their pacemakers set at 80 beats per minute for at least 6 weeks after the procedure to prevent QT prolongation and torsades de pointes. Eventually, the pacing rate can be reduced to more physiologic levels without the ongoing risk for ventricular arrhythmia. Complete heart block and other types of severe bradyarrhythmia may present with syncope if there is a prolonged pause before an escape rhythm develops. More often, these rhythms present with fatigue and dyspnea. The blood pressure is often elevated owing to peripheral vasoconstriction, and there may be renal insufficiency secondary to reduced cardiac output.

The term AV dissociation refers to any rhythm in which the atria and ventricles beat independently of one another. If the atrial rate is faster than the ventricular rate, it is called complete heart block or third-degree AV block. AV dissociation with an atrial rate slower than the subsidiary pacemaker is usually seen with junctional or ventricular tachycardias.

TREATMENT

The treatment of sinus node dysfunction and AV blocks consists of first removing any medications that may precipitate dysfunction (see Table 51-3).[12] Although some patients will recover normal conduction, the susceptibility to medications usually indicates an underlying conduction abnormality that may worsen over time. For example, asymptomatic sinus bradycardia (<50 per minute) in middle-aged or older adults does not appear to be associated with incident cardiovascular disease or mortality except in patients who take heart rate–modifying drugs.

Asymptomatic sinus node dysfunction requires no therapy. Asymptomatic AV nodal block, particularly if the QRS escape complex is narrow, also can be managed without intervention unless the QT interval is markedly prolonged, in which case a pacemaker should be considered.

For acutely symptomatic sinus node dysfunction and second- and third-degree AV block, urgent management includes intravenous atropine (1 mg) or isoproterenol (usually 1 to 2 µg/minute infusion) to increase the heart rate. Temporary cardiac pacing (Chapter 54) may be required. If sinus node dysfunction or AV block is due to transient abnormalities, such as drug-induced or acute ischemic syndromes, temporary pacing is usually sufficient; however, when intra-His or infra-His block is suspected (e.g., exercise-induced AV block or asymptomatic Mobitz type II block) and the site can be documented with His bundle recording, permanent pacing (see Tables 54-1 and 54-2) is the only effective long-term therapy, and consensus recommendations for pacemaker implantation should guide its use (Chapter 54).

For all forms of persistent symptomatic sinus node dysfunction or second- or third-degree AV block, permanent pacing is the therapy of choice (Chapter 54). However, recurrent syncope occurs despite a pacemaker in about 20% of patients over the subsequent 5 years.[13] In patients who have the tachy-brady syndrome, permanent pacing is usually required to prevent symptomatic bradycardia if medications are required to treat the tachycardia (Chapter 52).[14] In patients with AV block and systolic dysfunction, biventricular pacing is preferred. The only exception is Lyme disease, in which most cases of heart block resolve within a week of antibiotic therapy (Chapter 296). A newer form of physiologic pacing paces the His or left bundle branch region of the right ventricle (Chapter 54). This type of pacing stimulates the native conduction system and results in more synchronous contraction of the left and right ventricles than occurs with placement of a pacemaker into the apex or wall of the right ventricle. Cardiac neural ablation attempts to improve sinus node and AV node conduction by ablating the parasympathetic ganglia that innervate the sinus and AV nodes. This therapy has been used to treat neurocardiogenic syncope (Chapter 49) and is also being investigated for patients with sinus node dysfunction and varying degrees of AV nodal block.

INTRAVENTRICULAR BLOCKS

Given the anatomy of the intraventricular cardiac conduction system, patients can have conduction blocks or delays in either of the two fascicles (anterior or posterior) of the left bundle branch, a block or delay in the right bundle branch, or any combination of these three. As long as any one of the three conducts adequately, the patient's ECG will show the delays in the other(s): left anterior block (see Fig. 42-5A), with an axis of −45° or more negative; left posterior fascicular block (see Fig. 42-5D), with an axis of +120° or more positive; complete left bundle branch block (see Fig. 42-5E); or right bundle branch block (see Fig. 42-5B). Right bundle branch block also can occur in combination with either left anterior or left posterior fascicular block (see Fig. 42-5C). If all are delayed but at least one conducts, the patient will also have Mobitz type II block as described earlier. If all three are blocked, the patient has complete heart block (as described earlier). These intraventricular conduction delays or blocks can be caused by any of the structural (non-neurogenic, nonmedication) causes of AV block. However, by far the most common causes are ischemic heart disease, especially for the left bundle, and intrinsic degenerative changes.

In aggregate, about 1% of individuals have a bundle branch block at age 50 years, but the prevalence increases to about 17% by age 80 years. Left posterior

fascicular block[15] is unusual and nearly always associated with right bundle branch block; it must be distinguished from much more common causes of right axis deviation, such as right ventricular hypertrophy, pulmonary embolism, and lateral wall myocardial infarction. Left anterior fascicular block, defined as an axis of −45° to −90°, is found in about 1% of otherwise healthy adults. However, it can be associated with degenerative disease of the conduction system, myocardial fibrosis, coronary artery disease, and structural heart diseases.

Complete left bundle branch block[16] is seen in fewer than 0.1 to 0.5% of healthy individuals but up to 25% of patients with heart failure. About 50 to 60% of patients have underlying coronary or structural heart disease.

Right bundle branch block is present in about 0.5 to 1% of the normal adult population.[17] Potential underlying causes include degenerative or infiltrative or inflammatory heart diseases, prior myocardial infarction, or severe lung disease. Transient right bundle branch block can be precipitated by the passage of pulmonary artery catheter.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Intraventricular conduction delays themselves are typically asymptomatic. However, left bundle branch block causes ventricular dyssynchrony, whereby the right ventricle contracts before the left ventricle. In some patients, this dyssynchrony also leads to mitral regurgitation. The result can be the precipitation or worsening of heart failure.

The evaluation centers on determining the risk for progression to complete heart block and determining cause, especially otherwise undiagnosed ischemic heart disease. When an intraventricular conduction delay is found on an ECG, the first task is to seek any prior ECGs to determine if the abnormality is new, whether the abnormality is or is not associated with hitherto undiagnosed underlying heart disease.[18] In patients who are presenting with suspected myocardial ischemia, a new left bundle branch block is the equivalent of ischemic ECG changes and warrants appropriate evaluation for a possible acute myocardial infarction (Chapters 57 and 58). In the setting of a possible pulmonary embolism (Chapter 68), a new right bundle branch block suggests right ventricular strain and severe pulmonary hypertension. Symptoms of syncope or presyncope suggest that the intraventricular blocks may be associated with high-degree heart block.

The routine evaluation should include echocardiography and a stress test (using echocardiography or radionuclides). Cardiac magnetic resonance imaging is recommended if there is any suspicion of an infiltrative cardiomyopathy. Rhythm monitoring (Chapter 49) is indicated if the intraventricular conduction abnormality is associated with prolongation of the PR interval, evidence of alternating right and left intraventricular blocks, or any symptoms of light-headedness or presyncope.

TREATMENT

Treatment for intraventricular conduction delays is targeted at any underlying cause. However, rhythm-specific treatments are sometimes indicated. In patients with heart failure (Chapter 46), for example, left bundle branch block is often an indication for biventricular pacing (Chapter 54). For patients with bifascicular block and syncope, pacemaker implantation is preferable to an implantable cardiac monitor,[A1] regardless of the morphology of the block or the PR interval.[19] For patients with new bifascicular block (either left bundle branch block alone or right branch block plus a left fascicular block) in combination with PR prolongation, a pacemaker is often placed prophylactically because of the high risk for progression to complete heart block, especially in the setting of an acute myocardial infarction (Chapter 47).

PROGNOSIS

The risk of all-cause mortality is increased by about two- to three-fold in individuals with left bundle branch block, about six-fold higher in the presence of underlying heart disease, and probably only minimally if exercise testing and cardiac magnetic resonance imaging show no evidence of underlying heart disease.[20] For right bundle branch block, mortality is increased in the presence of underlying heart disease; for idiopathic cases, the risk of mortality is not increased, but the long-term risk of requiring a cardiac pacemaker may be higher. The combination of right bundle branch block with either left anterior or left posterior fascicular block portends a high risk for needing a pacemaker, but prophylactic pacing is not indicated in the absence of symptoms such as syncope.

52 SUPRAVENTRICULAR ECTOPY AND TACHYARRHYTHMIAS

PETER ZIMETBAUM AND LEE GOLDMAN

SUPRAVENTRICULAR ARRHYTHMIAS WITH A NORMAL RATE

Atrial premature beats (APBs) can arise from the right or left atrium or the pulmonary veins. The P wave, which differs from the P wave of sinus rhythm unless the APB originates near the sinus node, always precedes the QRS complex (Fig. 52-1). If the P wave is blocked, however, it is not followed by a QRS complex. A blocked premature atrial contraction may be confused with second-degree atrioventricular (AV) block, unless its prematurity is recognized, or with sinus node dysfunction, if it is inconspicuous. Altered appearance of the ST-T segment is often a clue to the presence of a P wave. A premature QRS complex with the morphology of the underlying sinus rhythm in the absence of a premature P wave represents an AV junctional beat (Fig. 52-2).

An ectopic atrial rhythm refers to a nonsinus atrial rhythm from a single focus with a single P wave morphology (Fig. 52-3). Wandering atrial pacemaker refers to an ectopic atrial rhythm with at least three distinct P wave morphologies at rates between 50 and 100 beats per minute (Fig. 52-4).

CLINICAL MANIFESTATIONS

APBs are most often asymptomatic but can occasionally be experienced as palpitations (Chapter 49). Similarly, ectopic atrial rhythms, including a wandering atrial pacemaker, are virtually always asymptomatic. Rarely, ectopic atrial rhythm can be very slow and associated with symptoms of fatigue.

DIAGNOSIS

The diagnoses of APBs, ectopic atrial rhythms, and wandering atrial pacemakers are all made by an electrocardiogram (ECG), an ambulatory Holter monitor, or an event recorder (Chapter 49).

FIGURE 52-1. Atrial premature beat. Sinus rhythm with an atrial premature beat as the third complex in the rhythm strip. The P wave is buried in the preceding T wave.

FIGURE 52-2. Junctional premature beat. The premature beat is narrow but slightly different in morphology compared with the surrounding sinus beats. This premature beat is from the atrioventricular junction or slightly more distal in the fascicles. The inverted P wave following the QRS represents retrograde activation of the atria.

fascicular block[15] is unusual and nearly always associated with right bundle branch block; it must be distinguished from much more common causes of right axis deviation, such as right ventricular hypertrophy, pulmonary embolism, and lateral wall myocardial infarction. Left anterior fascicular block, defined as an axis of −45° to −90°, is found in about 1% of otherwise healthy adults. However, it can be associated with degenerative disease of the conduction system, myocardial fibrosis, coronary artery disease, and structural heart diseases.

Complete left bundle branch block[16] is seen in fewer than 0.1 to 0.5% of healthy individuals but up to 25% of patients with heart failure. About 50 to 60% of patients have underlying coronary or structural heart disease.

Right bundle branch block is present in about 0.5 to 1% of the normal adult population.[17] Potential underlying causes include degenerative or infiltrative or inflammatory heart diseases, prior myocardial infarction, or severe lung disease. Transient right bundle branch block can be precipitated by the passage of pulmonary artery catheter.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Intraventricular conduction delays themselves are typically asymptomatic. However, left bundle branch block causes ventricular dyssynchrony, whereby the right ventricle contracts before the left ventricle. In some patients, this dyssynchrony also leads to mitral regurgitation. The result can be the precipitation or worsening of heart failure.

The evaluation centers on determining the risk for progression to complete heart block and determining cause, especially otherwise undiagnosed ischemic heart disease. When an intraventricular conduction delay is found on an ECG, the first task is to seek any prior ECGs to determine if the abnormality is new, whether the abnormality is or is not associated with hitherto undiagnosed underlying heart disease.[18] In patients who are presenting with suspected myocardial ischemia, a new left bundle branch block is the equivalent of ischemic ECG changes and warrants appropriate evaluation for a possible acute myocardial infarction (Chapters 57 and 58). In the setting of a possible pulmonary embolism (Chapter 68), a new right bundle branch block suggests right ventricular strain and severe pulmonary hypertension. Symptoms of syncope or presyncope suggest that the intraventricular blocks may be associated with high-degree heart block.

The routine evaluation should include echocardiography and a stress test (using echocardiography or radionuclides). Cardiac magnetic resonance imaging is recommended if there is any suspicion of an infiltrative cardiomyopathy. Rhythm monitoring (Chapter 49) is indicated if the intraventricular conduction abnormality is associated with prolongation of the PR interval, evidence of alternating right and left intraventricular blocks, or any symptoms of light-headedness or presyncope.

TREATMENT

Treatment for intraventricular conduction delays is targeted at any underlying cause. However, rhythm-specific treatments are sometimes indicated. In patients with heart failure (Chapter 46), for example, left bundle branch block is often an indication for biventricular pacing (Chapter 54). For patients with bifascicular block and syncope, pacemaker implantation is preferable to an implantable cardiac monitor,[A1] regardless of the morphology of the block or the PR interval.[19] For patients with new bifascicular block (either left bundle branch block alone or right branch block plus a left fascicular block) in combination with PR prolongation, a pacemaker is often placed prophylactically because of the high risk for progression to complete heart block, especially in the setting of an acute myocardial infarction (Chapter 47).

PROGNOSIS

The risk of all-cause mortality is increased by about two- to three-fold in individuals with left bundle branch block, about six-fold higher in the presence of underlying heart disease, and probably only minimally if exercise testing and cardiac magnetic resonance imaging show no evidence of underlying heart disease.[20] For right bundle branch block, mortality is increased in the presence of underlying heart disease; for idiopathic cases, the risk of mortality is not increased, but the long-term risk of requiring a cardiac pacemaker may be higher. The combination of right bundle branch block with either left anterior or left posterior fascicular block portends a high risk for needing a pacemaker, but prophylactic pacing is not indicated in the absence of symptoms such as syncope.

52 SUPRAVENTRICULAR ECTOPY AND TACHYARRHYTHMIAS

PETER ZIMETBAUM AND LEE GOLDMAN

SUPRAVENTRICULAR ARRHYTHMIAS WITH A NORMAL RATE

Atrial premature beats (APBs) can arise from the right or left atrium or the pulmonary veins. The P wave, which differs from the P wave of sinus rhythm unless the APB originates near the sinus node, always precedes the QRS complex (Fig. 52-1). If the P wave is blocked, however, it is not followed by a QRS complex. A blocked premature atrial contraction may be confused with second-degree atrioventricular (AV) block, unless its prematurity is recognized, or with sinus node dysfunction, if it is inconspicuous. Altered appearance of the ST-T segment is often a clue to the presence of a P wave. A premature QRS complex with the morphology of the underlying sinus rhythm in the absence of a premature P wave represents an AV junctional beat (Fig. 52-2).

An ectopic atrial rhythm refers to a nonsinus atrial rhythm from a single focus with a single P wave morphology (Fig. 52-3). Wandering atrial pacemaker refers to an ectopic atrial rhythm with at least three distinct P wave morphologies at rates between 50 and 100 beats per minute (Fig. 52-4).

CLINICAL MANIFESTATIONS

APBs are most often asymptomatic but can occasionally be experienced as palpitations (Chapter 49). Similarly, ectopic atrial rhythms, including a wandering atrial pacemaker, are virtually always asymptomatic. Rarely, ectopic atrial rhythm can be very slow and associated with symptoms of fatigue.

DIAGNOSIS

The diagnoses of APBs, ectopic atrial rhythms, and wandering atrial pacemakers are all made by an electrocardiogram (ECG), an ambulatory Holter monitor, or an event recorder (Chapter 49).

FIGURE 52-1. Atrial premature beat. Sinus rhythm with an atrial premature beat as the third complex in the rhythm strip. The P wave is buried in the preceding T wave.

FIGURE 52-2. Junctional premature beat. The premature beat is narrow but slightly different in morphology compared with the surrounding sinus beats. This premature beat is from the atrioventricular junction or slightly more distal in the fascicles. The inverted P wave following the QRS represents retrograde activation of the atria.

ABSTRACT

Supraventricular arrhythmias include premature atrial contractions, sinus tachycardia, sinus node re-entry, atrial tachycardias, atrial flutter, and atrial fibrillation, as well as a variety of atrioventricular junctional tachycardias. These arrhythmias can be caused by intrinsic diseases of the conduction system but also may be triggered by alcohol, exercise, or stimulation of the sympathetic nervous system. Each can typically be diagnosed by a surface electrocardiogram, but electrophysiologic testing is sometimes required to distinguish among them or to exclude a ventricular arrhythmia. Treatment focuses on relieving symptoms, occasionally with medications and often with procedures. Because of the risk of systemic embolization, systemic anticoagulation is required for atrial fibrillation and atrial flutter.

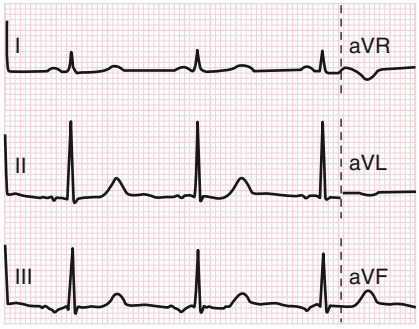

FIGURE 52-3. Ectopic atrial rhythm. The inverted P waves in leads II, III, and aVF indicate a nonsinus P wave originating in the low right atrium.

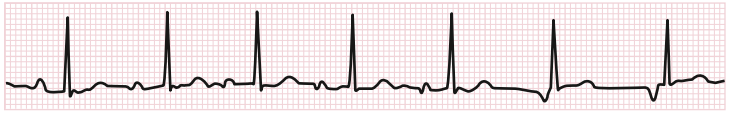

FIGURE 52-4. Wandering atrial pacemaker. Rhythm with three distinct P wave morphologies.

TREATMENT AND PROGNOSIS

Premature atrial contractions do not generally require treatment unless they are associated with significant symptoms. Treatment consists primarily of β-blockers (e.g., metoprolol XL, 25 to 100 mg daily) or calcium-channel blockers (e.g., long-acting diltiazem, 180 to 300 mg daily). Ectopic atrial rhythms and wandering atrial pacemakers are rarely symptomatic and are not treated with medications. Rarely, a slow ectopic rhythm associated with fatigue can be treated with atrial pacing at a rate faster than the ectopic atrial rhythm. Very frequent premature atrial contractions may portend a higher risk of atrial fibrillation (AF)[1] and other serious atrial arrhythmia, and they are associated with an increased long-term risk of stroke and clinical cardiovascular disease.

SUPRAVENTRICULAR TACHYARRHYTHMIAS

The supraventricular tachycardias (SVTs) are defined as arrhythmias with three or more beats at a rate of greater than 100 beats per minute (Table 52-1). In the United States, the incidence and prevalence of paroxysmal supraventricular tachycardias are estimated to be about 93 per 100,000 people and 480 per 100,000 people, respectively.[2]

The beats, which can be regular or irregular, are usually narrow complex but can be wide complex when associated with bundle branch block (aberration) or conduction over an accessory pathway. Atrial dilation, acute or chronic heart failure, pulmonary embolism, acute or chronic inflammatory states, or scars from prior surgery involving atrial myocardium or pericardium are among the causes of atrial tachyarrhythmias.

The most important clues for diagnosing the type of SVT include the ventricular response rate, regularity, and, if known, the suddenness of the onset of tachycardia. The QRS is regular during sinus tachycardia, atrial flutter, AV nodal re-entrant tachycardia, AV re-entrant tachycardia, and atrial tachycardia; it is irregular with AF, atrial flutter with variable AV block, multiple atrial premature contractions, and multifocal atrial tachycardia. Sudden onset and termination suggest acute AF, atrial flutter, AV nodal re-entrant tachycardia, AV reciprocating tachycardia, and atrial tachycardia. Gradual onset and recession are more suggestive of sinus tachycardia, nonparoxysmal junctional tachycardia and some forms of atrial tachycardia. The QRS complex during SVT is usually narrow but can be wide in the setting of aberrant conduction through the ventricles because of its very fast rate in the presence of coexisting disease in the bundle branches.[3]

SVTs can produce symptoms specifically related to the rhythm itself (Chapter 49), including fatigue, palpitations, dizziness, shortness of breath, chest discomfort, presyncope, and syncope. These symptoms are mostly related to the rapidity of the ventricular response and are most prevalent at the onset of the arrhythmia. In contrast to other forms of SVT, asymptomatic episodes of AF are common in patients who also have symptomatic AF.

TABLE 52-1 SUPRAVENTRICULAR TACHYCARDIAS

	R-R REGULARITY	P WAVE MORPHOLOGY
ATRIAL TACHYCARDIAS		
Sinus tachycardia	Regular	Positive in II, III, aVF; negative in aVR
Sinus node re-entry	Regular	Positive in II, III, aVF; negative in aVR
Atrial tachycardia, unifocal	Regular	P different from sinus
Atrial tachycardia, multifocal	Irregular	Three or more different P wave morphologies
Atrial flutter, common: Counterclockwise	Regular; irregular if variable AV block	Sawtooth flutter waves; regular waveform; negative in II, III, aVF, positive in V_1, negative in V_6
Clockwise		Positive in II, III, aVF; negative in V_1; positive in V_6
Atrial flutter: uncommon	Regular; irregular if variable AV block	Pattern different than common atrial flutter (counterclockwise or clockwise)
Atrial fibrillation	Irregularly irregular	Irregular fibrillation waves
AV JUNCTIONAL TACHYCARDIAS		
AV re-entry (using accessory pathways)		
Orthodromic	Regular	Retrograde P in ST-T wave
Antidromic	Regular preexcited, except in irregular preexcited atrial fibrillation	Retrograde P, short RP
Slow conducting	Regular	Retrograde P at end of T wave or later (long RP)
Atriofascicular (antidromic)	Regular preexcited	Retrograde P, short RP
AV nodal re-entry		
Common (slow-fast)	Regular	Retrograde P obscured by QRS or alters the end of QRS (short RP)
Uncommon (fast-slow)	Regular	Retrograde P at end of T wave or later (long RP)
Others (slow-slow)	Regular	PR-RP approximately equal
Nonparoxysmal junctional tachycardia*	Regular, slow rate	AV dissociation
Automatic junctional tachycardia*	Regular	AV dissociation

*Site of origin is usually infranodal.
AV = atrioventricular.

Incessant SVT and uncontrolled ventricular rates can cause tachycardia-related cardiomyopathy (Chapter 45), which is reversible with control of these arrhythmias. In some situations, however, the clinical presentation may be dominated by the underlying condition that precipitates the arrhythmia, such as fever, physical stress, hypovolemia, heart failure (Chapter 45), hypoxia, sympathomimetic or parasympatholytic medications, thyrotoxicosis (Chapter 207), and pheochromocytoma (Chapter 209).

The fundamental principle for the diagnosis of a supraventricular tachycardia is the identification of the rhythm on a 12-lead ECG, on a continuous ECG monitor, or on a wearable device such as a smart watch with ECG capability (Chapter 49). The latter two methods will also determine any correlation between an identified arrhythmia and a patient's symptoms. Chronically implanted devices such as pacemakers and an implantable cardioverter-defibrillator (ICD) also allow identification of SVTs.

SINUS TACHYCARDIA

Sinus tachycardia (Fig. 52-5) is an arrhythmia that is almost always a physiologic response to an emotional or physical stress such as anxiety, exercise, anemia, hypotension, hypoxemia, fever, thyrotoxicosis, or heart failure. It is

FIGURE 52-5. Sinus tachycardia at 120 beats/minute.

characterized by a gradual increase and decrease in heart rate and rarely exceeds 180 beats per minute. In rare cases, it may be a nonphysiologic condition called inappropriate sinus tachycardia, which is characterized by sinus tachycardia that develops in response to minimal stress and that continues beyond the time when the normal response would have slowed.

Sinus node re-entry is a rare form of SVT caused by re-entry in the sinus node. As opposed to physiologic sinus tachycardia, sinus node re-entry begins abruptly, is often triggered by a premature atrial beat, and ends abruptly. The P wave morphology is identical to sinus rhythm.

TREATMENT AND PROGNOSIS

Sinus tachycardia rarely should be treated directly. Instead, treatment should focus on identifying and treating any precipitating underlying conditions, especially heart failure (Chapter 46), pulmonary disease (Chapters 75 and 76), fever, anemia, thyroid disease (Chapter 207), or pheochromocytoma (Chapter 209). In the occasional patients who require treatment for symptoms that are associated with inappropriate sinus tachycardia, β-blockers (e.g., metoprolol succinate starting at 25 mg daily and titrating upward as needed) are generally chosen as first-line therapy. Alternatively, ivabradine (5 mg twice daily) provides significant improvement and can completely eliminate symptoms in approximately 50% of patients.[4] Rarely, catheter-based sinus node modification can be performed when medications are ineffective and symptoms are intractable. The prognosis is poorly understood and likely highly variable.

ATRIAL TACHYCARDIA

The term atrial tachycardia refers to a group of SVTs that originate from focal anatomic locations in the atria and propagate in a centrifugal pattern (Fig. 52-6). These locations include the pulmonary veins, crista terminalis in the right atrium, tricuspid or mitral annulus, coronary sinus, atrial septa, left atrial appendage, aortomitral continuity, or regions of scar tissue from previous cardiac surgery. Atrial tachycardias, which are usually regular rhythms that rarely exceed 200 beats per minute, may present in young age but more often develop later in life. Atrial tachycardias can be re-entrant, triggered, or automatic in mechanism.

TREATMENT AND PROGNOSIS

Some forms of atrial tachycardia are paroxysmal and may remit spontaneously without treatment. When they do not, electrical mapping and ablation (Chapter 54) of atrial tachycardia are highly effective and are increasingly offered as first-line therapy.[5] Alternatively, atrial tachycardias can be managed with medications such as β-blockers (e.g., metoprolol starting at 25 mg twice daily), calcium-channel blockers (e.g., diltiazem starting at 180 mg long-acting daily), or other antiarrhythmic drugs (see Table 52-2). Some forms of atrial tachycardia are incessant and can predispose to a tachycardia-related cardiomyopathy (Chapter 47).

MULTIFOCAL ATRIAL TACHYCARDIA

Multifocal atrial tachycardia (Fig. 52-7), which is a unique form of atrial tachycardia characterized by three or more P wave morphologies, is distinguished from wandering atrial pacemaker when the rate is 100 beats per minute or more, rather than less than 100 beats per minute. It is an irregular rhythm and occurs almost exclusively in patients with advanced pulmonary disease.

TREATMENT AND PROGNOSIS

Multifocal atrial tachycardia is relatively unresponsive to medical therapy, is very difficult to ablate, and is best treated by management of the underlying pulmonary or cardiac disorder. If absolutely required for acute symptoms, options include intravenous diltiazem, verapamil, or metoprolol (see Table 52-2). Cardioversion can restore normal sinus rhythm, but multifocal atrial tachycardia generally recurs quickly. Prognosis is largely determined by the underlying pulmonary disease.

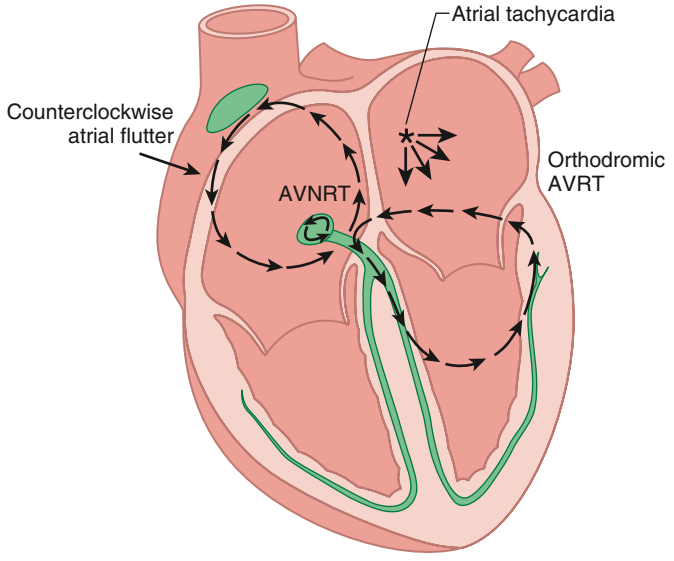

FIGURE 52-6. Diagram of the site and mechanism of common forms of supraventricular tachycardia. AVNRT = atrioventricular nodal re-entrant tachycardia; AVRT = atrioventricular re-entrant tachycardia.

ATRIOVENTRICULAR NODAL RE-ENTRANT TACHYCARDIA

AV nodal re-entrant tachycardia (also called AVNRT) is a common form of SVT in all age groups, but it presents most often in young adulthood and frequently occurs after a change in position. It is more common in women than men and may develop or be exacerbated by pregnancy or certain phases of the menstrual cycle. Patients with AV nodal re-entrant tachycardia have two functional AV nodal pathways (dual pathways). Typically, an APB blocks in one pathway (fast pathway) and conducts slowly over the other pathway (slow pathway). If this beat conducts back up the fast pathway and then re-enters the slow pathway, AV nodal re-entry occurs (Fig. 52-8). This re-entrant circuit is confined to the AV node, and the result is that both the atria and ventricles are activated nearly simultaneously. P waves may not be visible on the ECG because they are buried in the QRS complex. When P waves are present, they usually are seen just after the QRS and have a negative or superior axis (negative in leads II, III, and aVF; short RP tachycardia) (see Fig. 52-6). Atypical AV nodal re-entrant tachycardia is rare and occurs with conduction down the fast pathway and up the slow pathway, with a long interval between the preceding R wave and subsequent negative P wave (e.g., long RP tachycardia).

Symptoms associated with AV nodal re-entrant tachycardia most often include palpitations, occasionally include a sense of fullness in the neck, and may include a beat-to-beat distention of the neck veins, known as a "frog sign" and associated with contraction of the atria while the tricuspid and mitral valves are closed (cannon a waves; see Chapter 39).

TREATMENT AND PROGNOSIS

Carotid sinus massage, which has a vagal effect on the AV node, can terminate SVTs such as AV nodal re-entrant tachycardia that depend on the AV node as part of the circuit. For documented intermittent episodes of atrial tachycardia, the patient also can be instructed to try a Valsalva maneuver to terminate the arrhythmia, with higher response rates if performed in a semi-recumbent position and combined with supine repositioning and straight leg raising immediately afterward.[AT] Longer-term preventive pharmacologic management typically includes daily β-blocker or calcium channel blocker therapy (see Table 52-2). Unfortunately, use of these agents once the arrhythmia has started is usually unsuccessful. Radiofrequency ablation is the definitive approach to manage AV nodal re-entrant tachycardia and can cure more than 95% of cases, but with about a 0.5 to 1% risk of causing complete heart block that will require a pacemaker.

JUNCTIONAL TACHYCARDIA

Primary junctional tachycardia refers to a focal (non-re-entrant) tachycardia originating in the AV junction (Fig. 52-9). A number of different forms of junctional tachycardia have differing clinical patterns. Digitalis toxicity was a leading cause when it was a commonly prescribed drug.

TABLE 52-2 ANTIARRHYTHMIC DRUGS: DOSES AND SIDE EFFECTS

ANTIARRHYTHMIC DRUG AND COMMON USE	DOSE/METABOLISM	SIDE EFFECTS AND REQUIRED MONITORING	SELECTED DRUG INTERACTIONS
RATE CONTROL			
β-Blockers (selected)	Hepatic, renal Only renal (atenolol, nadolol) IV: esmolol, 250-500 µg over 1 min, then 50-300 µg/kg/min over 4 min; metoprolol, 2.5- to 5-mg bolus over 2 min, up to 3 doses 10 min apart Oral: acebutolol, 200-600 mg bid; atenolol, 25-100 mg qd; carvedilol, 3.125-50 mg bid; metoprolol, 25-150 mg bid; nadolol, 20-120 mg qd; nebivolol, 5-40 mg qd; propranolol, 10-120 mg bid	Fatigue, depression, bronchospasm, impotence	Minimal, except for carvedilol and metoprolol, whose levels may be increased by amiodarone, propafenone, quinidine, fluoxetine, haloperidol, paroxetine, and cimetidine
Calcium-channel blocker (nondihydropyridine)	Hepatic Inhibit CYP 3A4 IV: diltiazem, 20-mg bolus over 2 min, then 5-15 mg per hour maintenance infusion; verapamil, 5- to 10-mg bolus over 2 min (if no response, an additional 10 mg after 30 min and then a 0.005-mg/kg/min infusion) Oral: verapamil long-acting 120-480 mg qd Diltiazem long-acting 180-300 mg qd	Constipation, rash, peripheral edema	Inhibits CYP 3A4—will increase levels of alprazolam, carbamazepine, dihydropyridine, cyclosporine, HMG-CoA inhibitors. Verapamil (but not diltiazem) increases digoxin levels
Digoxin	Renal, hepatic, gastrointestinal, 0.125-375 mg/day orally	Anorexia, nausea, fatigue, confusion, altered vision with green-yellow halos	Levels of or sensitivity to digoxin increased by hypokalemia, quinidine, verapamil, amiodarone, propafenone, renal failure, hypoxia, decreased muscle mass Levels of or sensitivity to digoxin decreased by malabsorption, hyperkalemia, hypocalcemia
RHYTHM CONTROL			
Adenosine	Erythrocyte, endothelial cell 6-mg IV push, followed if necessary by 12 mg after 1-2 min	Nausea, headache, flushing, chest pain, bronchospasm (contraindicated if asthma)	Methylxanthines compete for adenosine receptors with adenosine Dipyridamole decreases the metabolism of adenosine
Amiodarone	Hepatic half-life 50 days PO load 10 g over 7-10 days, then 400 mg for 3 wk, then 200 mg/day for atrial fibrillation Maintenance dose of 400 mg/day for VT Dose reduce load for bradycardia or QT prolongation IV: 150- to 300-mg bolus, then 1 mg/min infusion for 6 hr, followed by 0.5 mg/min thereafter	Pulmonary (acute hypersensitivity pneumonitis, chronic interstitial infiltrates), hepatitis Thyroid (hypothyroidism or hyperthyroidism) Photosensitivity, blue-gray discoloration with chronic high dose, nausea, ataxia, tremor, alopecia Avoid if identified thyroid nodule LFTs two to three times a year, TFTs twice yearly, PFTs and CXR at initiation and CXR yearly thereafter QT prolongation expected; reduce dose if exceeds 500 msec	Inhibits CYP 450 enzymes—increases concentrations of warfarin, digoxin, cyclosporine, alprazolam, carbamazepine, HMG-CoA inhibitors, phenytoin, and quinidine
Sotalol	Renal: 80-120 mg bid orally Max dose, 240 mg bid orally	Bronchospasm QT prolongation/torsades de pointes	No significant interactions
Ibutilide	Hepatic CYP 3A4 1 mg IV over 10 min, repeat after 10 min if necessary	Nausea QT prolongation and torsades de pointes Must monitor for 4 hr after drug initiation	None
Propafenone	Hepatic 150-300 mg q8h or sustained release 225-425 mg bid orally	Metallic taste, dizziness, SIADH Atrial flutter, ventricular tachycardia	May decrease the metabolism of warfarin Increase digoxin levels
Flecainide	Renal, hepatic CYP 2D6 50-100 mg bid orally; max dose, 300-400 mg/day	Dizziness, headache, visual blurring Atrial flutter, ventricular tachycardia	May increase digoxin levels Flecainide levels increased by amiodarone, haloperidol, quinidine, cimetidine, and fluoxetine
Disopyramide	Renal, hepatic (CYP 3A4) Dose: 100-400 mg q8-12h orally; max dose, 800 mg/24 hr Reduce dose for renal or hepatic dysfunction	Anticholinergic (contraindicated for narrow-angle glaucoma): dry mouth, urinary retention, constipation, blurry vision QT prolongation/torsades de pointes	None
Procainamide	Mostly hepatic—rapid acetylators produce more NAPA; NAPA renally cleared PO dose: 50 mg/kg/24 hr IV dose: 1 g over 25 min, then 20-60 µg/kg/min infusion Reduce dose for renal dysfunction or low cardiac output	Rash, fever, arthralgias, drug-induced lupus, particularly in slow acetylators Agranulocytosis QT prolongation/torsades de pointes	Procainamide clearance reduced by trimethoprim, cimetidine, and ranitidine

TABLE 52-2 ANTIARRHYTHMIC DRUGS: DOSES AND SIDE EFFECTS—cont'd

ANTIARRHYTHMIC DRUG AND COMMON USE	DOSE/METABOLISM	SIDE EFFECTS AND REQUIRED MONITORING	SELECTED DRUG INTERACTIONS
Quinidine	Hepatic CYP 3A4 (70%), renal (30%) Dose: sulfate—600 mg tid orally, gluconate—324 to 648 mg q8h orally Dose reduced for renal failure	Thrombocytopenia, cinchonism Pruritus, rash QT prolongation/torsades de pointes	↑ Digoxin and amiodarone concentrations Quinidine inhibits CYP 2D6 and may increase drugs metabolized by this enzyme (e.g., ↑ effect of tricyclic antidepressants, haloperidol, some β-blockers, fluoxetine, opioids) Quinidine metabolism inhibited by cimetidine Quinidine metabolism increased by phenobarbital, phenytoin, and rifampicin
Dofetilide	Renal, hepatic CYP 3A4 CrCl >60 mL/min (500 µg bid orally), CrCl 40-60 (250 µg bid orally), CrCl 20-39 mL/min (125 µg bid orally)	QT prolongation and torsades de pointes Three days of in-hospital monitoring is required during drug initiation	Contraindicated with verapamil, ketoconazole, cimetidine, megestrol, prochlorperazine, and trimethoprim Hydrochlorothiazide increases dofetilide levels Must discontinue amiodarone at least 3 mo before dofetilide initiation
Ivabradine	2.5 mg starting dose, 5 mg bid orally for 1 mo followed by increase to 7.5 bid if needed	Sinus bradycardia Headaches Visual brightness	Azole antifungals, macrolide antibiotics, nefazodone, nelfinavir, ritonavir
Dronedarone	Hepatic CYP 3A4 half-life 30 hr PO 400 mg bid orally Improved absorption with food	Reduces the secretion of creatinine without a reduction in GFR Hepatic failure Avoid in heart failure	Increases digoxin levels (dose reduce digoxin by half) May increase myositis with simvastatin Avoid grapefruit

bid = twice daily; CrCl = creatinine clearance; CXR = chest radiograph; CYP = cytochrome P-450; GFR = glomerular filtration rate; HMG-CoA = 3-hydroxy-3-methylglutaryl coenzyme A; IV = intravenous administration; LFT = liver function test; max = maximum; NAPA = *N*-acetyl procainamide; PFT = pulmonary function test; PO = oral administration; qd = daily; SIADH = syndrome of inappropriate diuretic hormone; TFT = thyroid function test; VT = ventricular tachycardia.

FIGURE 52-7. Multifocal atrial tachycardia. An atrial tachycardia with three different P wave morphologies.

Nonparoxysmal junctional tachycardia is a benign arrhythmia that rarely exceeds 120 beats per minute and typically exhibits a "warm-up" and "cool-down" pattern. A more rapid paroxysmal form of junctional tachycardia occurs in young adults and is often associated with exercise. Congenital junctional ectopic tachycardia, which occurs in the pediatric population, is associated with very rapid rates and a risk for tachycardia-related cardiomyopathy.

TREATMENT AND PROGNOSIS

When junctional tachycardia is not a re-entrant arrhythmia, treatment is either medically, with amiodarone or ivabradine (see Table 52-2),[A2] or with radiofrequency catheter ablation. Reported efficacies are in the 90% range.

ACCESSORY PATHWAY TACHYCARDIAS

Tachycardias associated with an accessory pathway or bypass tract are called AV re-entrant tachycardia (also called AVRT). These tachycardias most often conduct down the normal AV conducting system and back up the accessory pathway (orthodromic AV re-entrant tachycardia) (see Fig. 52-6). Antidromic tachycardia is rare and represents conduction down the accessory pathway and back up the normal conducting system or, less commonly, a second accessory pathway. Wolff-Parkinson-White syndrome is defined by the presence of delta waves or preexcitation on the ECG in sinus rhythm (Fig. 52-10), in combination with a history of AV re-entrant tachycardia. It is important to recognize, however, that many patients with ventricular preexcitation never get AV re-entrant tachycardia. In addition, up to 40% of patients with accessory pathways have AF. Because accessory pathway tissue, unlike the AV node, is usually nondecremental, a rapidly conducting accessory pathway may allow AF to conduct to the ventricles at excessive rates and precipitate ventricular fibrillation. Drugs such as digoxin, which accelerate accessory pathway conduction, should be avoided in these patients.

The ECG during orthodromic AV re-entrant tachycardia can have a narrow complex, but a wide QRS complex will be seen if there is aberration from a bundle branch block, especially at more rapid rates. The retrograde P wave is negative in leads I and aVL if it conducts over a left lateral accessory pathway and negative in leads II, III, and aVF if it conducts over a septal or posteroseptal accessory pathway (Fig. 52-11). The P wave occurs later (after the preceding R wave) compared with AV nodal re-entrant tachycardia because in AV re-entrant tachycardia, the impulse must conduct beyond the AV node and into the ventricle before returning to the atria over an accessory pathway. In antidromic AV re-entrant tachycardia, the QRS complex is wide with a slurred upstroke and resembles that seen with ventricular tachycardia as opposed to a bundle branch block. Antidromic conduction with AF is often fast, broad, and irregular (see Fig. 52-10).

Palpitations are the most common symptoms. If AF with rapid conduction occurs over the accessory pathway (preexcited AF), more significant symptoms such as light-headedness, syncope, or even cardiac arrest may occur.

TREATMENT

The acute management of AV re-entrant tachycardia, particularly if there is evidence of preexcitation, is intravenous adenosine (6 mg intravenous push, followed by another 12 mg after 1 to 2 minutes if needed). Intravenous procainamide (1 g over 25 minutes is an alternative, but direct electrical cardioversion is a safe, effective, and generally preferred option if adenosine is unsuccessful. Intravenous calcium channel blockers and β-blockers can potentially be used (see Table 52-2), but the risk of associated vasodilation and hypotension with a resultant reflex adrenergic response can cause a dangerous acceleration in conduction over the accessory pathway, so they require great caution and should be used only under expert supervision.

The longer term management of AV re-entrant tachycardia is best accomplished with an electrophysiologic study and ablation of the accessory pathway (Chapter 54). If an invasive approach is not available or preferred by the patient or if the accessory pathway is in a location that is difficult to access or associated with high risk of damage to the conduction system (i.e., risk of complete heart block), oral medications, including β-blockers (e.g., metoprolol 25 to 50 mg daily) or antiarrhythmic drugs (e.g., flecainide 100 to 150 mg twice daily) can be considered.

ATRIAL FLUTTER

Atrial flutter is an arrhythmia with an atrial rate of approximately 300 beats per minute and a ventricular response of 150 (2 : 1), 100 (3 : 1), or slower multiples. Typical atrial flutter is a macro-re-entrant circuit that circulates in the

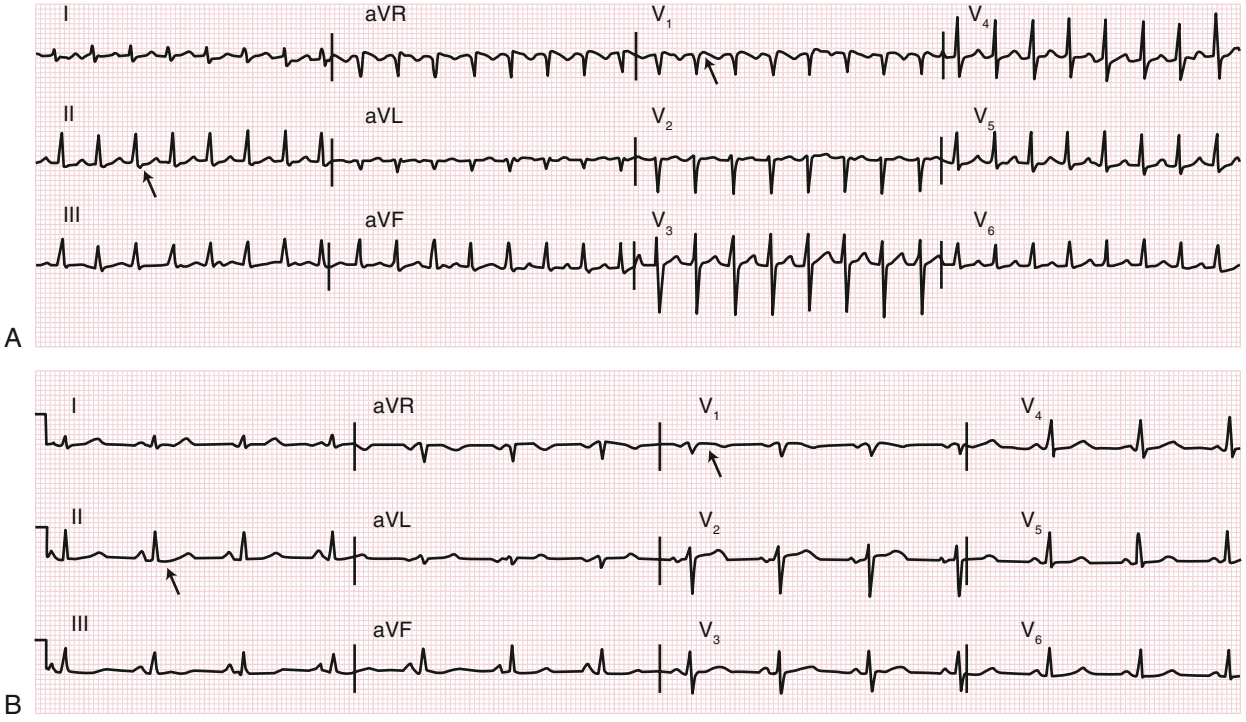

FIGURE 52-8. **Electrocardiograms demonstrating different rhythms in the same patient. A,** Atrioventricular nodal re-entrant tachycardia, with *arrows* indicating retrograde P waves (negative in lead II, positive in V_1). **B,** Same patient in sinus rhythm. The absence of a negative deflection at the end of the QRS in lead II and positive deflection in V_1 confirms that those findings in panel A were retrograde P waves.

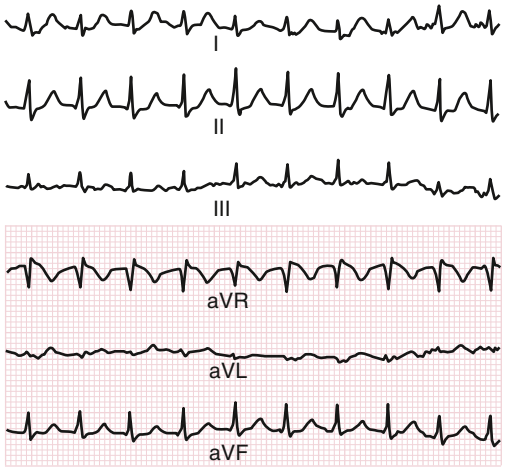

FIGURE 52-9. **Junctional tachycardia. A tachycardia without evident P waves. The negative deflections at the end of leads II, III, and aVF represent retrograde P waves. This rhythm is impossible to distinguish from atrioventricular nodal re-entrant tachycardia on the surface electrocardiogram.**

right atrium in a clockwise or counterclockwise loop (Fig. 52-12). The inferior portion of typical flutter uses the narrow region between the inferior vena cava and tricuspid annulus as a critical isthmus of conduction. Typical atrial flutter almost always occurs in patients with underlying cardiovascular or pulmonary disease. It can also develop in patients who receive antiarrhythmic drugs (e.g., sodium-channel blocking drugs) for AF. Atypical atrial flutter refers to macro-re-entrant atrial circuits that do not use this critical cavotricuspid isthmus of tissue. These atypical forms of atrial flutter often occur in the left atrium after mitral valve surgery or catheter ablation of AF. Typical atrial flutter can be recognized by a "sawtooth" P wave morphology, which is predominantly negative in leads II, III, and aVF and positive in V_1 (counterclockwise atrial flutter) or positive in leads II, III, and aVF and negative in V_1 (clockwise atrial flutter).

If the rate of atrial flutter is well controlled by effective atrioventricular block, patients may be asymptomatic. More rapid ventricular rates are associated with palpitations, light-headedness, syncope, or shortness of breath. Atrial flutter also can precipitate heart failure or myocardial ischemia in patients with underlying heart disease. If high-grade atrioventricular block develops, light-headedness and even syncope can be seen as with other bradycardias (see Chapter 51).

TREATMENT AND PROGNOSIS

It can be very difficult to control the ventricular rate of acute atrial flutter, which generally must be treated by restoring sinus rhythm. In some cases, successful treatment of precipitating problems such as hypoxia, fever, and electrolyte abnormalities will lead to spontaneous conversion, and such treatment is often required to sustain sinus rhythm once it is achieved.

Intravenous ibutilide (1 g over 10 minutes, repeated after 10 minutes if needed) is approximately 60% effective for converting atrial flutter to sinus rhythm, but direct current electrical cardioversion (Chapter 54) is the preferred approach and is highly (>95%) effective for restoring sinus rhythm. As is true of AF (see later), electrical or pharmacologic cardioversion should not be performed unless the episode of atrial flutter is believed to be less than 48 hours in duration, a transesophageal echocardiogram has excluded clot in the left atrial appendage, or the risk for stroke has been minimized by achieving a therapeutic level of anticoagulation, preferably with a direct-acting oral anticoagulant (e.g., dabigatran, rivaroxaban, apixaban, or edoxaban; see Table 70-6) or with a therapeutic international normalized ratio (INR) of 2 to 3 with warfarin (see Table 70-4), for the prior 4 weeks. Since the effective ventricular rate in atrial flutter depends on the degree of atrioventricular block, a titrated β-blocker (e.g., metoprolol starting at 25 to 50 mg daily) or calcium channel blocker (e.g., diltiazem starting at 180 to 240 mg daily) can provide temporary rate control while awaiting cardioversion. However, very careful follow-up is critical because of the challenge of balancing the degree of atrioventricular block.

As with AF, atrial flutter is rarely an isolated occurrence and can be expected to recur. Even if patients are minimally symptomatic because atrioventricular block results in a physiologic heart rate, patients are likely to have variable block, and hence an unstable heart rate, over time. For these reasons, radiofrequency ablation of the cavotricuspid isthmus is 95% curative for the typical form of atrial flutter and is the preferred choice for most patients (Chapter 54). The first-line therapy for atypical atrial flutter is also often catheter ablation, but the likelihood of success is lower,[6] so either antiarrhythmic drug therapy or simply recurrent cardioversion for infrequent recurrences are also reasonable approaches. Because patients with atrial flutter have a 3% per year risk for thromboembolism, patients at risk for recurrence should also receive long-term anticoagulation similar to what is recommended for AF (see later). If atrial flutter ablation is successful, however, the risk for recurrence is very small, and long-term anticoagulation is not necessary. Prognosis is generally related to any underlying comorbid conditions that may have precipitated the atrial flutter.

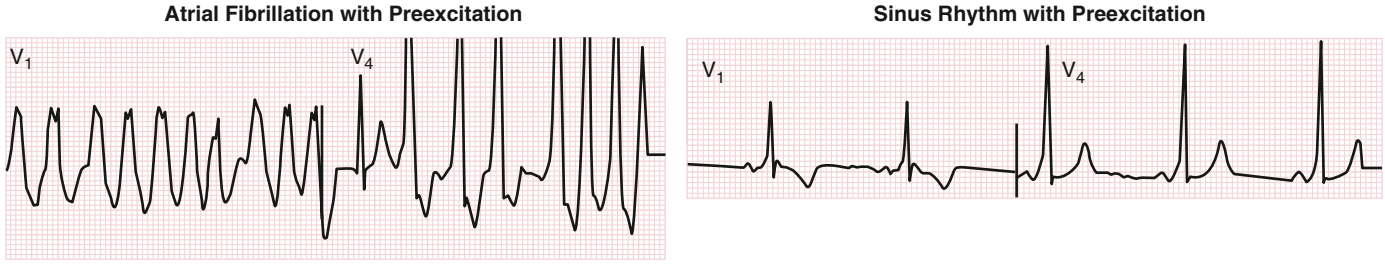

FIGURE 52-10. Two panels of the same patient with ventricular preexcitation. The rhythm on the left is fast, broad, and irregular, indicating atrial fibrillation with conduction over an accessory pathway. The rhythm on the right is sinus with conduction over an accessory pathway.

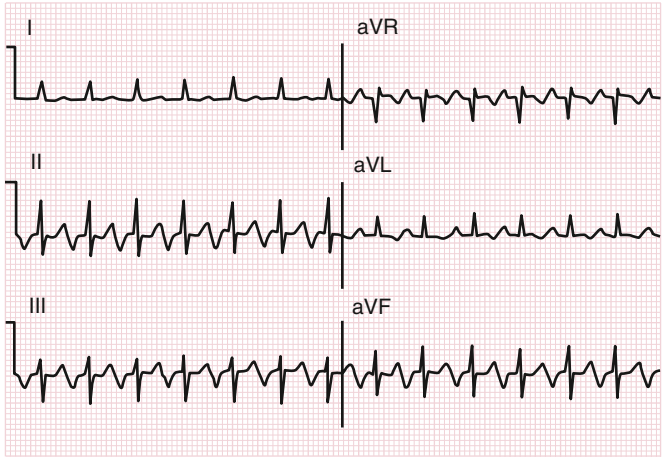

FIGURE 52-11. Atrioventricular re-entrant tachycardia. Negative P waves are seen in leads II, III, and aVF indicative of retrograde conduction to the atria over a septal accessory pathway.

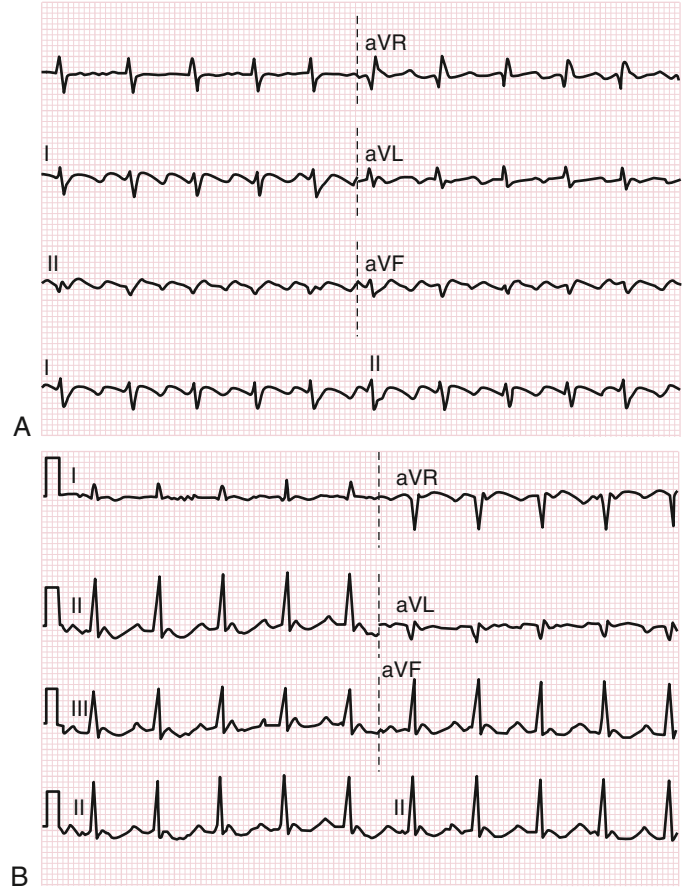

FIGURE 52-12. Two examples of atrial flutter. A, Typical counterclockwise right atrial flutter with classic sawtooth flutter waves seen in leads II, III, and aVF. **B,** Clockwise right atrial flutter.

FIGURE 52-13. Coarse atrial fibrillation. The wavy baseline is suggestive of atrial activity and can be misinterpreted as P waves or flutter waves. The irregularity of the QRS complexes indicates that this is atrial fibrillation.

ATRIAL FIBRILLATION

AF is identified by the absence of P waves and the presence of an irregularly irregular ventricular rate. Coarse AF, which describes the presence of residual atrial activity on the ECG, is generally best seen in lead V_1 with the absence of P wave–like activity in other leads (Fig. 52-13). AF can be present with a regular ventricular rate when there is concomitant AV dissociation (e.g., complete heart block or ventricular tachycardia).

AF, which is the most common arrhythmia in clinical practice,[7] afflicts more than 2 million Americans. The likelihood of developing AF increases with aging, with an anticipated three-fold increase in prevalence as the U.S. population ages in the next 20 years. AF is almost always a recurrent disorder, with the possible exception of AF that develops in association with hyperthyroidism (Chapter 207) and surgery (Chapter 401). AF can be paroxysmal (terminates spontaneously) or persistent (persists for at least 7 days or until cardioverted).

In addition to its association with aging, AF frequently occurs in association with hypertension (Chapter 64) or other comorbid conditions such as diabetes mellitus (Chapter 210), thyrotoxicosis (Chapter 207), heart failure (Chapter 45), coronary artery disease (Chapter 56), valvular heart disease (Chapter 60), or lung disease such as chronic obstructive pulmonary disease (Chapter 76)[8] or obstructive sleep apnea (Chapter 374). About 20% of patients have no associated comorbidity. Some patients develop AF after binges of alcohol use ("holiday heart")[9] or after parasympathetic surges, such as occur after vigorous exercise or a large meal (vagally induced AF). Long-term significant alcohol use can also result in an increased risk of AF. Excessive caffeine intake is an often cited but very rare cause of AF.

AF requires a trigger in the form of atrial premature depolarizations, which often originate in the pulmonary veins and which, in the susceptible individual, result in AF. The susceptibility to AF may relate to changes in the electrical function of the left atrium. Prolonged periods of AF can lead to electrical and structural remodeling of the atria and promote the further perpetuation of AF.

AF results in the loss of the atrial contribution to ventricular filling. This so-called loss of atrial kick is generally well tolerated in normal individuals, in whom only about 15% of ventricular filling is the result of atrial contraction. In patients who have stiff, noncompliant ventricles (e.g., patients with aortic stenosis, hypertrophic or restrictive cardiomyopathy, or long-standing hypertension), however, up to 40% of ventricular filling may be related to atrial contraction, so stroke volume may fall noticeably in such patients.

Silent or asymptomatic AF may be identified on a permanently placed device such as a pacemaker or implantable defibrillator or on a wearable device.[A3] By convention, at least 2 minutes of a sustained arrhythmia consistent with AF must be present to make the diagnosis of AF. Currently, the U.S. Preventive Services Task Force concludes that evidence is insufficient to determine whether screening for AF should be recommended.[10]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common symptoms associated with AF include palpitations, dyspnea, chest pain, and fatigue.[11] Most patients have symptoms with the new onset of AF, but it is common for these symptoms to dissipate over time with recurrent or persistent AF, especially if the heart rate is in the physiologic range. Syncope (Chapter 49) can occasionally occur and is usually a consequence of a conversion pause that occurs when AF terminates and a delay ensues before the resumption of sinus rhythm.

The primary morbidity associated with AF is thromboembolism. Thromboembolism in patients with nonvalvular AF typically results from thrombus that forms in the left atrial appendage and later dislodges from it. The risk for thromboembolism is related to the presence of underlying vascular disease but not to the pattern of AF (paroxysmal or persistent). For example, even subclinical ("silent") AF is associated with a 2.5-fold increased risk for ischemic stroke or systemic embolism. However, the risk for embolization is further increased in the first 3 to 4 weeks after cardioversion, when the gradual return of atrial mechanical function can result in a particularly high risk for thromboembolism. The risk for thromboembolism in AF increases with age, diabetes mellitus, hypertension, previous embolic episodes, vascular disease, and heart failure. The lowest incidence (<1% annually) is in patients younger than 65 years with lone AF. AF is associated with about a 1.4-fold higher risk for cognitive impairment and dementia, with or without a history of clinical stroke. About 12% of clinical embolic events are extracranial, about 70% of which affect the extremities, with most of the remainder affecting the visceral mesenteric circulation.

AF with a rapid ventricular response can also result in biventricular dysfunction, termed tachycardia-induced cardiomyopathy (Chapter 45). This complication is generally associated with ventricular rates over 120 beats per minute for at least a few weeks. In many instances, patients with this complication are relatively asymptomatic while in AF and, as such, do not seek medical attention until evidence of heart failure develops.

The initial diagnostic evaluation of AF should include blood work (hematocrit and blood levels of potassium, creatinine, and thyroid-stimulating hormone at a minimum), as well as an echocardiogram to evaluate for possible underlying ventricular dysfunction or valvular disease. A stress test to exclude ischemia is not required as a routine part of the evaluation unless the patient otherwise has clinical evidence of atherosclerosis or coronary artery disease from the history, physical examination, ECG, or echocardiogram.

TREATMENT

Recent-Onset Atrial Fibrillation

In the presence of hypotension, acute myocardial ischemia, or new or worsening heart failure, prompt cardioversion is generally indicated. However, precipitating conditions such as hypoxia, fever, and electrolyte abnormalities also should be addressed to increase the likelihood that cardioversion will be successful and the patient will remain in sinus rhythm.

For acute AF without hypotension, hemodynamic compromise, or acute ischemia, at least one attempt to restore normal sinus rhythm is almost always warranted. However, a short period of rate control is appropriate because about 50% of patients with acute-onset AF will spontaneously revert to sinus rhythm within the first 48 to 96 hours. Therefore, even in patients with mildly symptomatic recent-onset AF, a "wait-and-see" approach with delayed cardioversion if the AF does not resolve within 48hours is as good as early cardioversion in achieving a return to sinus rhythm at 1 month.[A4] Rate control is crucial and can be accomplished with esmolol, metoprolol, verapamil, or diltiazem (see Table 52-2); digoxin is usually a third-line agent (Fig. 52-14).

Before cardioversion, either pharmacologic or electrical (Chapter 54), however, the risk for clot formation must be mitigated in all patients who have AF of more than 48 hours' duration.[12] The first step generally is to perform transesophageal echocardiography (Chapter 43). If the transesophageal echocardiogram shows no evidence of a left atrial clot, cardioversion can be undertaken without systemic anticoagulation. If the patient has risk factors for stroke in association with AF, however, most clinicians administer anticoagulation during the cardioversion and for the subsequent 4 weeks. If the transesophageal echocardiogram shows evidence of clot, 4 consecutive weeks of pre-cardioversion anticoagulation is required, preferentially with therapeutic doses of dabigatran, rivaroxaban, apixaban, or edoxaban (see Table 70-6), rather than with heparin and warfarin. If warfarin is used (see Table 70-4), an international normalized ratio (INR) of at least 2.0 is required.

For a first episode of acute AF (<48 hours' duration), cardioversion can be attempted using electrical cardioversion (Chapter 54) or medications. Electrical cardioversion, which is performed with a minimum of 200 joules, is successful in more than 90% of cases.[A5] Medical options include procainamide (15mg/kg intravenously over 30 min), ibutilide (1 mg intravenously over 10 minutes, repeated after 10 minutes if necessary), or a single dose of propafenone (600 mg) or flecainide (300 mg). For recent-onset AF of less than 48 hours' duration, the success rate is approximately 50%. Approximately 3 hours of postadministration monitoring is required when these antiarrhythmic agents are used owing to a risk of proarrhythmia, including but not limited to QT prolongation and torsades de pointes. This limitation often makes this option impractical compared with treatment with immediate cardioversion.

Atrial Fibrillation of Uncertain Duration

Since the duration of AF may be hard to identify definitively, it is prudent to assume that the duration of AF has been greater than 48 hours when contemplating a cardioversion strategy (see Fig. 52-14) unless there is absolute certainty of the timing of onset. In this setting, a transesophageal echocardiogram should be performed to assess for possible clot in the left atrium. If negative, cardioversion (either medical or electrical) is as for recent-onset AF. If, however, clot is seen, then the patient must be anticoagulated for 1 month unless symptoms truly warrant urgent cardioversion. Anticoagulation also must be maintained for at least 3 to 4 weeks after successful cardioversion. Even in the absence of clot, long-term anticoagulation is commonly recommended for patients with paroxysmal or recurrent AF.

Chronic Rhythm and Rate Therapy

Catheter Ablation

After the treatment and hopefully resolution of a first episode of AF and the mandatory 1 month of anticoagulation, the strategy of rhythm control within the first year with catheter ablation to isolate the pulmonary veins electrically from the remainder of the atrium (see Chapter 54) and/or with an antiarrhythmic drug confers about a one-third lower rate of death (1.0 vs. 1.3 deaths/100 person years),[A6] due to the safety and efficacy of catheter ablation,[13] which is significantly superior to anti-arrhythmia medications,[A7–A10] and the widespread use of direct-acting oral anticoagulants. Early rhythm control with catheter ablation is especially beneficial in patients who have heart failure.[A11–A13]

Medical Rhythm Control

Rhythm control with medication alone is not superior to rate control in terms of major adverse events but may be chosen for bothersome symptoms. If catheter ablation is not selected, repeat electrical or pharmacologic cardioversion can be attempted with the same medications used for an initial episode or with oral amiodarone (typically a 10-g loading dose given in equal daily amounts over 1 to 2 weeks, followed by 400 to 600 mg a day for the remainder of a month).

To prevent recurrent AF, the pharmacologic options work by blocking sodium channels, potassium channels, or a combination of ion channels, thereby slowing cardiac conduction (sodium channels) and/or prolonging cardiac repolarization (potassium channels), as well as modulating the autonomic nervous system. The choice of antiarrhythmic drug is based on the patient's underlying clinical condition (Table 52-3).[14]

Amiodarone (usually 200 mg daily), which is the most widely used medication for the prevention of recurrent AF, has an efficacy of 60 to 70% at 1 year and is significantly more effective than propafenone, flecainide, dofetilide, or sotalol, which are the recommended alternatives. It is associated with a number of drug interactions, most notably with warfarin and digoxin. Its associated risk for thyroid, liver, and lung toxicities, related in part to the iodine moieties on this compound, necessitate careful monitoring. Dronedarone (400 mg twice daily), which is related to amiodarone but has no iodine and a shorter 15-hour half-life, is well tolerated in terms of non-cardiovascular side effects but carries an increased risk for heart failure, stroke, and death in patients with permanent AF. As a result, it should be discontinued in patients in whom sinus rhythm is not well maintained.

Quinidine, procainamide, and disopyramide are predominantly sodium-channel blocking drugs that also block potassium channels at slow heart rates. Each of these drugs is moderately successful in AF, with about 50% of treated patients in sinus rhythm at 1 year, but each also has idiosyncratic non-cardiovascular toxicities that can significantly limit their utility (see Table 52-2). Propafenone and flecainide are sodium-channel blockers that are also used for the maintenance of sinus rhythm. These drugs are moderately effective, with a 50% rate of sinus rhythm at 1 year, and are generally well tolerated, but they must be avoided in patients with structural heart disease, particularly with a history of prior myocardial infarction and impaired left ventricular function, because of a risk for drug-induced ventricular arrhythmia. Dofetilide is a potassium-channel blocking medication that is moderately effective for suppressing AF but carries a dose-dependent risk for QT prolongation and torsades de pointes.

Rate Control

If a strategy of rate control is chosen, it is important to confirm a heart rate of 70 to 100 beats per minute at rest and less than 140 beats per minute with exercise, preferably by monitoring the heart rate during exercise on an exercise treadmill test or with an ambulatory monitor. More strict rate control is not beneficial. Failure to confirm rate control can result in the development of tachycardia-induced cardiomyopathy. First-line therapy for rate control includes β-blockers (e.g., metoprolol 25 to 50 mg daily) or non-dihydropyridone calcium-channel

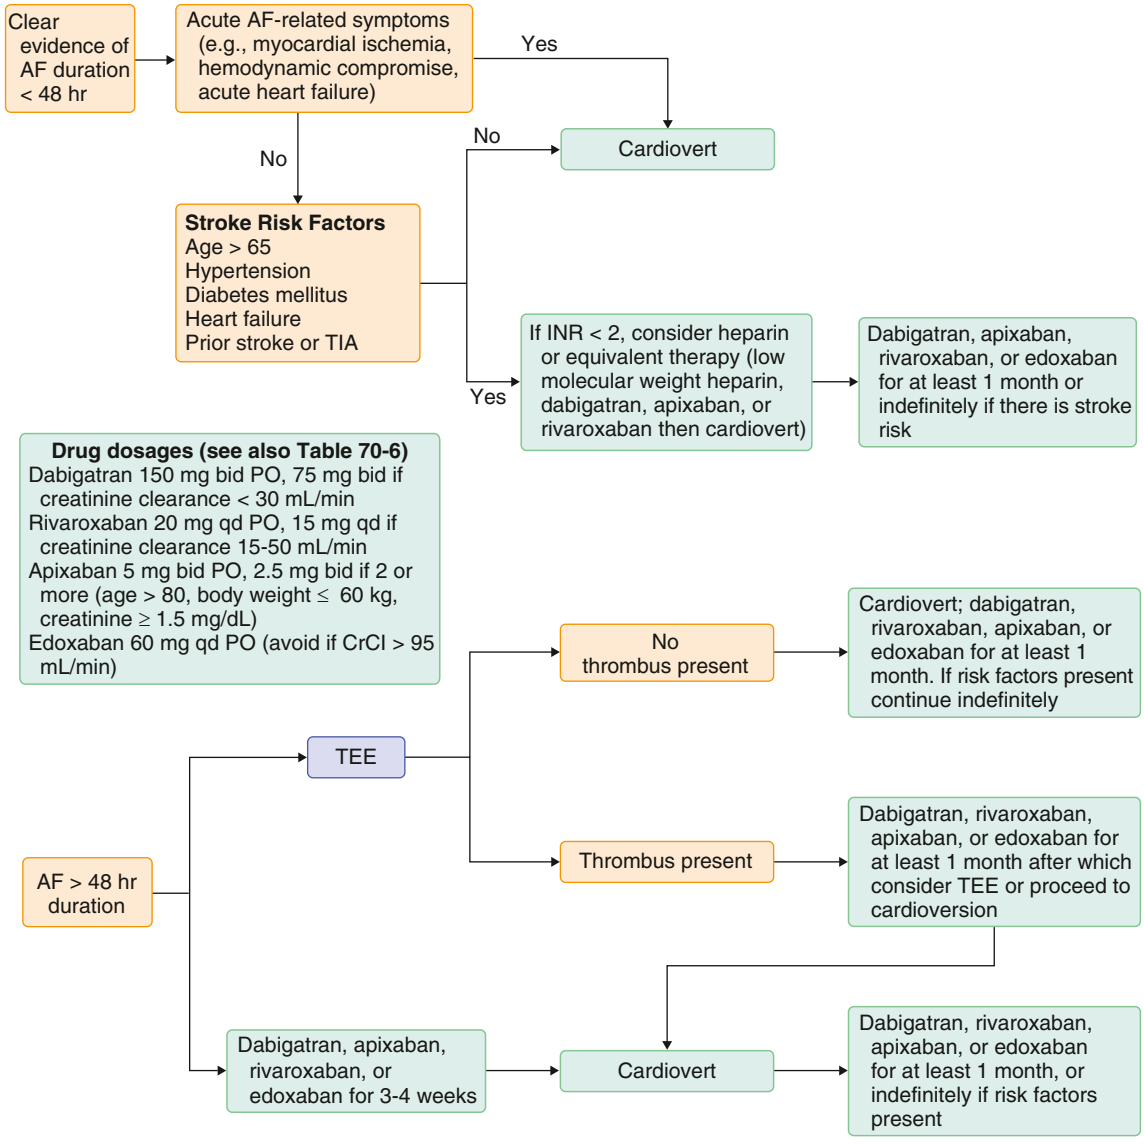

FIGURE 52-14. Management of recent-onset atrial fibrillation (AF). bid = twice daily; CrCl = creatinine clearance; INR = international normalized ratio; qd = daily; TEE = transesophageal echocardiography; TIA = transient ischemic attack.

TABLE 52-3 SELECTION OF ANTIARRHYTHMIC DRUGS

PATIENT'S CHARACTERISTICS	ANTIARRHYTHMIC DRUG CHOICES
No structural heart disease	*First line:* flecainide, propafenone, dronedarone, sotalol *Second line:* amiodarone, dofetilide
Depressed left ventricular ejection fraction with heart failure	*First line:* amiodarone, dofetilide *Avoid:* dronedarone, flecainide, propafenone
Coronary artery disease without heart failure	*First line:* sotalol, dronedarone, dofetilide, amiodarone *Avoid:* flecainide, propafenone
Hypertrophic cardiomyopathy	*First line:* amiodarone, sotalol *Second line:* disopyramide

blockers (e.g., diltiazem 180 to 240 mg daily); digoxin (usually 0.125 to 0.25 mg daily) can also be used but is generally less well tolerated.[A14] Interestingly, β-blockers do not appear to reduce all-cause mortality when used in patients whose AF is complicated by heart failure, but it is not clear whether digoxin is preferred in this setting. From a practical perspective, patients commonly require a combination of medications (e.g., metoprolol plus diltiazem) to achieve goal heart rates. In some patients, rate control is difficult to achieve because of inefficacy of or intolerance to medical therapy. In these patients, ablation of the AV junction can be performed with placement of a single chamber or biventricular pacemaker.[A15]

Chronic Persistent AF

In patients with chronic existing AF, catheter ablation is now recommended first-line therapy because of its efficacy of about 70% for preventing recurrent AF with an excellent safety profile.[A16] When available, the benefits of catheter ablation over medical therapy are even more striking in patients who have heart failure, in whom it provides a very clear survival advantage (Chapter 46). A second procedure typically is offered to patients who have recurrent AF following a first catheter-based procedure. Interestingly, continuing previously ineffective antiarrhythmic therapy after ablation can further reduce the risk of recurrent AF.[A17]

The surgical maze procedure is nearly always reserved for patients who have a concomitant reason for open heart surgery (e.g., coronary artery bypass grafting and/or a valve operation). The maze procedure is performed from an endocardial or epicardial approach with the same fundamental goal of electrical isolation of the pulmonary veins. In addition, a surgical maze procedure includes the clipping or resection of the left atrial appendage. The success rate for the procedure is comparable to or slightly better than that of catheter-based pulmonary vein isolation.

Paroxysmal AF

Paroxysmal AF refers to recurrent episodes of AF that resolve either spontaneously or with medical treatment. Paroxysmal AF may manifest as a breakthrough arrhythmia in patients who are on chronic medical therapy to suppress AF or in patients who are on no treatment or may be taking a medication (such as a β-blocker or diltiazem) to slow the rate of any future episode of AF. Unfortunately,

most behavioral efforts to limit the recurrence of AF have largely proven ineffective. One exception is in regular alcohol drinkers, for whom abstinence from alcohol can reduce the likelihood of recurrent paroxysmal AF by about one third.[A18] Prophylactic rhythm control can be tried, but outcomes are not as good as with ablation,[A19] and medication side effects often are limiting.

For paroxysmal AF, catheter ablation is preferred because it significantly reduces the risk of recurrent atrial arrhythmias and hospitalizations, significantly improves quality of life,[A20] and also results in about a one-third reduction in the risk of major adverse events.[A21] The success rate is improved if it is performed before patients with paroxysmal AF develop persistent AF.

The other option is prophylactic rate control, typically with low-dose metoprolol (25 to 50 mg daily, with the option for an additional dose at the onset of AF and again 6 hours later if rapid AF develops) or diltiazem (180 to 240 mg daily). Another option is so-called pill-in-the-pocket therapy with a single dose of propafenone (600 mg) or flecainide (300 mg) when the paroxysmal AF episode occurs (see Fig. 52-14).

Thromboembolic Prophylaxis

Long-term anticoagulation therapy (Fig. 52-15) is generally recommended in all patients who have persistent or paroxysmal AF and a CHADS VASC score of 2 or more (Table 52-4). When paroxysmal AF is detected by screening in asymptomatic individuals by intermittent electrocardiograms or an implantable loop recorder, prophylactic anticoagulation is of little or limited value in preventing major complications.[A22,A23]

For patients with a single risk factor for stroke in association with AF, the decision to anticoagulate can be at the preference of the patient and physician.[15,16] For thromboembolic prophylaxis in patients who have AF with a mechanical prosthetic valve or rheumatic heart disease, warfarin anticoagulation (Table 70-4) is the approach of choice.[A24] For other patients, however, direct-acting oral anticoagulant medications (Table 70-6 in Chapter 70) have replaced warfarin because of their ease of use, superior or equivalent efficacy, and excellent safety profile.[A25] Options include rivaroxaban (an oral factor Xa inhibitor at 20 mg per day), apixaban (an oral factor Xa inhibitor at 5 mg twice daily), dabigatran (a direct thrombin inhibitor at 150 mg twice daily), and edoxaban (30 or 60 mg once daily). All four drugs are eliminated by the kidney (apixaban 25%, edoxaban 50%, rivaroxaban 65%, and dabigatran 85%), so they are not recommended in patients with substantial renal dysfunction, and their doses should be reduced in patients with moderate renal dysfunction (see Chapter 70).[17] Even in patients older than 75 years, these agents appear to be at least as effective as warfarin with a lower risk of life-threatening bleeding.[18] In very elderly patients who are not considered candidates for full-dose anticoagulation, low-dose edoxaban (15 mg daily) is safe and efficacious.[A26] In patients who cannot take these agents because of renal failure, warfarin titrated to an INR of 2.0 (Chapter 70) is indicated.

Idarucizumab (4 to 5 g intravenously) can rapidly reverse dabigatran,[19] and andexanet alfa (400- to 800-mg bolus over 15 to 30 minutes followed by a 400- to 960-mg infusion) can reverse rivaroxaban or apixaban and achieve good to excellent hemostasis in about 75% of bleeding patients within 12 hours (Chapter 70).[20]

In patients with AF and stable coronary disease (Chapter 59), rivaroxaban (10 mg once daily for patients with a creatinine clearance of 15 to 49 mL/minute or 15 mg once daily for patients with a creatinine clearance of ≥50 mL/minute) alone is safer and as efficacious as combining it with an anti-platelet agent.[A27] In patients with AF after an acute coronary syndrome (Chapter 57) or a coronary stent, standard-dose apixaban (5 mg twice daily or 2.5 mg twice daily for patients who meet two or more of the following dose-reduction criteria: are at least 80

TABLE 52-4 CURRENT RECOMMENDATIONS FOR THROMBOEMBOLIC PROPHYLAXIS FOR PATIENTS WITH ATRIAL FIBRILLATION BASED ON RISK FACTORS FOR STROKE

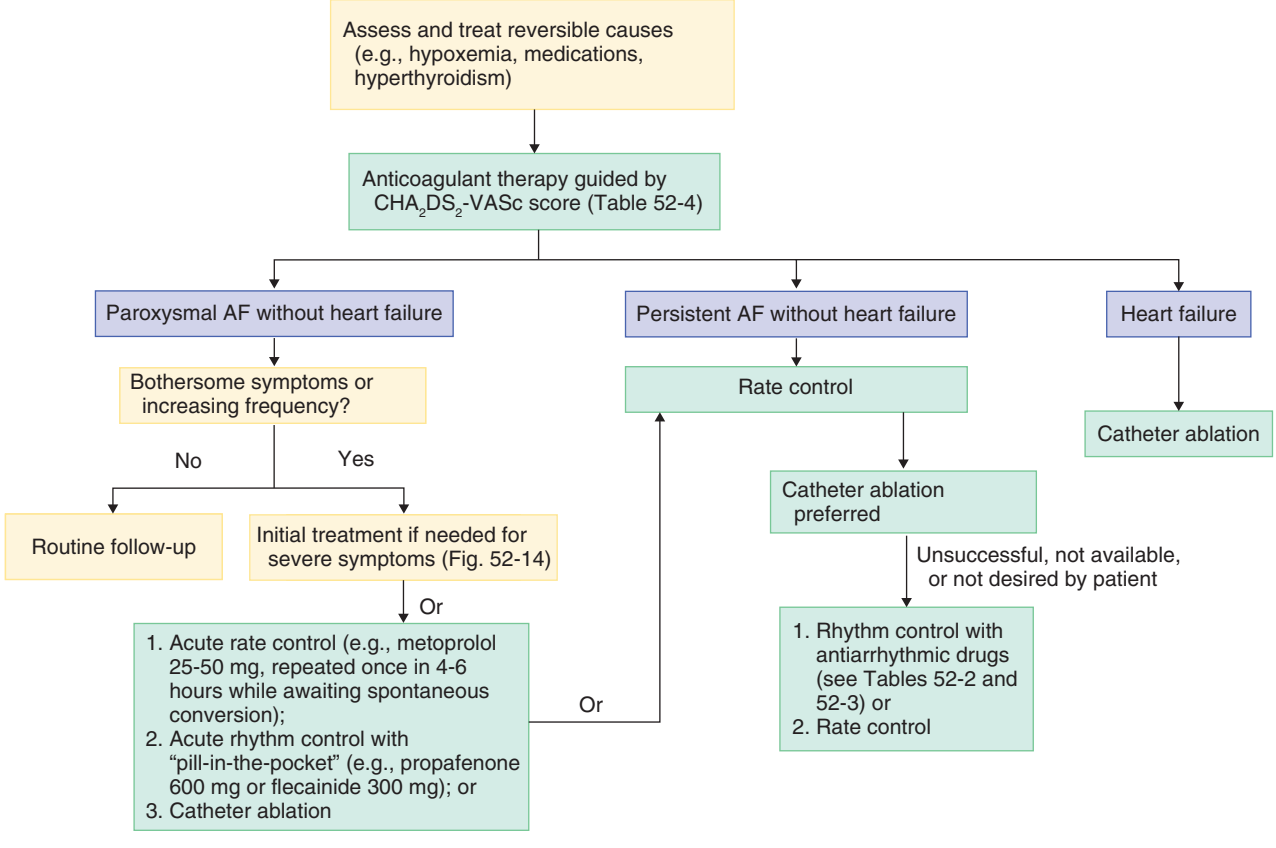

FIGURE 52-15. Treatment of recurrent paroxysmal or chronic persistent fibrillation (AF). Direct oral anticoagulants are strongly preferred over warfarin. If warfarin is used, the goal international normalized ratio is generally 2 to 3. (Adapted from Prystowsky EN, Padanilam BJ, Fogal RI. Treatment of atrial fibrillation. *JAMA.* 2015;314:278-288.)

years of age, weigh no more than 60 kg, or have a serum creatinine level of 1.5 mg/dL or higher) plus a $P2Y_{12}$ inhibitor such as clopidogrel (75 mg once daily) is safer and as efficacious as the two drugs plus aspirin.[A28] Another efficacious option for stented patients is dual therapy with dabigatran (110 or 150 mg twice daily) plus clopidogrel (75 mg once daily) or ticagrelor 180 mg once daily.[A29] The addition of dabigatran, rivaroxaban, or apixaban to aspirin under expert supervision is preferable to adding warfarin.[A30] At the time of an invasive procedure (Chapter 399), bridging anticoagulation is no better than interrupting anticoagulation[A31] except perhaps for the very highest risk patients.[21]

For patients with mechanical valves, warfarin must be used. However, rivaroxaban (20 mg daily) is safer and more effective for patients with AF and a bioprosthetic valve.[A32] Edoxaban is non-inferior to warfarin in patients who are in atrial fibrillation after transcatheter aortic valve replacement.[A33] Oral inhibition of factor XIa is a promising alternative to factor X inhibition.[A34]

For patients at very high risk of bleeding or with serious bleeding on anticoagulation, surgical removal of the left atrial appendage or exclusion of the left atrial appendage with an implanted device is a non-inferior alternative to anticoagulation.[A35,A36] Surgical exclusion of the left atrial appendage is increasingly performed when patients with AF undergo coronary artery bypass graft surgery, and in this situation it is associated with a reduction in the risk of subsequent stroke and bleeding.[A37] With this procedure, serious complications occur in about 2% of patients, and the net benefits from reduced bleeding may increase over time.[22]

PROGNOSIS

Paroxysmal AF can occur as a self-remitting arrhythmia for decades or can progress to permanent AF. Patients with persistent AF generally progress to permanent AF unless sinus rhythm is restored.

The major long-term risks of AF are stroke, which occurs at a rate of about 4% per year in the absence of anticoagulation but only about 0.5% per year with anticoagulation, with individual risks influenced by the presence of specific risk factors (see Table 52-4). The risk is about half as high with paroxysmal AF compared with persistent AF, but even a single paroxysmal AF event is clearly linked to an increased risk of stroke.[23] Persistent AF also increases the likelihood of new or worsening heart failure, especially in patients who have a poorly compliant left ventricle, because of the absence of atrial contraction. Poor rate control can result in tachyarrhythmia-induced left ventricular dysfunction. Prognosis is also linked to any underlying comorbid conditions that may precipitate AF or contribute to a rapid ventricular response.

53 VENTRICULAR ARRHYTHMIAS

HASAN GARAN

DEFINITIONS

Ventricular arrhythmias are cardiac rhythms that originate in the ventricular myocardium or in the His-Purkinje tissue. They include a wide spectrum of arrhythmias, including isolated premature ventricular contractions (PVCs) (Fig. 53-1A), nonsustained ventricular tachycardia (Fig. 53-1B), sustained ventricular tachycardia (Fig. 53-1C), and immediately life-threatening ventricular fibrillation (VF) (Fig. 53-2).

Ventricular tachycardia (VT) is arbitrarily defined as three or more ventricular contractions in a row at a rate faster than 100 beats per minute (see Fig. 53-1B). The definition of *sustained* VT—a continuous ventricular rhythm, at a rate faster than 100 beats per minute, with no interruption for 30 seconds

years of age, weigh no more than 60 kg, or have a serum creatinine level of 1.5 mg/dL or higher) plus a $P2Y_{12}$ inhibitor such as clopidogrel (75 mg once daily) is safer and as efficacious as the two drugs plus aspirin.[A28] Another efficacious option for stented patients is dual therapy with dabigatran (110 or 150 mg twice daily) plus clopidogrel (75 mg once daily) or ticagrelor 180 mg once daily.[A29] The addition of dabigatran, rivaroxaban, or apixaban to aspirin under expert supervision is preferable to adding warfarin.[A30] At the time of an invasive procedure (Chapter 399), bridging anticoagulation is no better than interrupting anticoagulation[A31] except perhaps for the very highest risk patients.[21]

For patients with mechanical valves, warfarin must be used. However, rivaroxaban (20 mg daily) is safer and more effective for patients with AF and a bioprosthetic valve.[A32] Edoxaban is non-inferior to warfarin in patients who are in atrial fibrillation after transcatheter aortic valve replacement.[A33] Oral inhibition of factor XIa is a promising alternative to factor X inhibition.[A34]

For patients at very high risk of bleeding or with serious bleeding on anticoagulation, surgical removal of the left atrial appendage or exclusion of the left atrial appendage with an implanted device is a non-inferior alternative to anticoagulation.[A35,A36] Surgical exclusion of the left atrial appendage is increasingly performed when patients with AF undergo coronary artery bypass graft surgery, and in this situation it is associated with a reduction in the risk of subsequent stroke and bleeding.[A37] With this procedure, serious complications occur in about 2% of patients, and the net benefits from reduced bleeding may increase over time.[22]

PROGNOSIS

Paroxysmal AF can occur as a self-remitting arrhythmia for decades or can progress to permanent AF. Patients with persistent AF generally progress to permanent AF unless sinus rhythm is restored.

The major long-term risks of AF are stroke, which occurs at a rate of about 4% per year in the absence of anticoagulation but only about 0.5% per year with anticoagulation, with individual risks influenced by the presence of specific risk factors (see Table 52-4). The risk is about half as high with paroxysmal AF compared with persistent AF, but even a single paroxysmal AF event is clearly linked to an increased risk of stroke.[23] Persistent AF also increases the likelihood of new or worsening heart failure, especially in patients who have a poorly compliant left ventricle, because of the absence of atrial contraction. Poor rate control can result in tachyarrhythmia-induced left ventricular dysfunction. Prognosis is also linked to any underlying comorbid conditions that may precipitate AF or contribute to a rapid ventricular response.

53 VENTRICULAR ARRHYTHMIAS

HASAN GARAN

DEFINITIONS

Ventricular arrhythmias are cardiac rhythms that originate in the ventricular myocardium or in the His-Purkinje tissue. They include a wide spectrum of arrhythmias, including isolated premature ventricular contractions (PVCs) (Fig. 53-1A), nonsustained ventricular tachycardia (Fig. 53-1B), sustained ventricular tachycardia (Fig. 53-1C), and immediately life-threatening ventricular fibrillation (VF) (Fig. 53-2).

Ventricular tachycardia (VT) is arbitrarily defined as three or more ventricular contractions in a row at a rate faster than 100 beats per minute (see Fig. 53-1B). The definition of *sustained* VT—a continuous ventricular rhythm, at a rate faster than 100 beats per minute, with no interruption for 30 seconds

ABSTRACT

Ventricular arrhythmias are cardiac rhythm disturbances that originate in the right or left ventricular myocardium or in the His-Purkinje (HP) tissue. The diagnosis of monomorphic ventricular tachycardia (VT) on 12-lead ECG may be challenging, and the differential diagnosis of regular-rate, wide-complex tachycardia includes any type of supraventricular tachycardia with aberrant conduction or with ventricular pre-excitation, as well as VT. The most reliable ECG observation in favor of VT is evidence of atrioventricular dissociation, but the clinical setting and the patient's background also play major roles in making an accurate diagnosis. A small proportion of the patients with documented, sustained VT have no identifiable structural heart disease. These idiopathic VTs may originate in the outflow tract of either ventricle or may arise in left fascicles of the HP system. Rare, genetically acquired ion-channel mutations may be the cause of specific types of VT, such as polymorphic torsade de pointes. Most commonly, however, VT occurs in patients with organic heart disease, such as acute or prior myocardial infarction or dilated or hypertrophic cardiomyopathy. VT may be immediately life-threatening. Heart failure from any cause significantly increases the risk of ventricular arrhythmias. Acute management of hemodynamically unstable VT and ventricular fibrillation (VF) should conform to the guidelines for advanced cardiac life support. Sustained VT or VF in patients with organic heart disease is a primary indication for implantable cardioverter-defibrillator (ICD) therapy. Catheter ablation therapy may be curative for idiopathic VTs and should be considered as a preferred alternative to long-term antiarrhythmic drug therapy. In contrast, the role of catheter ablation or antiarrhythmic drug therapy is palliative in patients with VT and advanced organic heart disease after they are protected with ICD implantation.

or longer—is equally arbitrary. However, most sustained VTs are much faster than 100 beats per minute (see Fig. 53-1C), persist for more than 30 seconds, and cause a substantial decrease in ventricular function and cardiac output, especially in patients with underlying organic heart disease, thereby resulting in acute heart failure, hypotension, syncope, or even circulatory collapse.

Monomorphic VT is electrocardiographically defined as a wide-complex tachycardia with no change in QRS configuration, frontal axis, or horizontal axis from one beat to the next (Fig. 53-3A). Polymorphic VT is characterized by beat-to-beat changes in the QRS morphology and axis, and very fast polymorphic VT may be difficult to distinguish from *ventricular fibrillation* (VF) (Fig. 53-3B). VF, which is a grossly irregular ventricular rhythm usually at a rate faster than 300 beats per minute, appears as low-amplitude continuous electrical activity on the surface electrocardiogram (ECG) and generates no cardiac output. Torsades de pointes and bidirectional polymorphic VT are two distinct subtypes of polymorphic VT. *Pleomorphic* VT describes the phenomenon of multiple clinical monomorphic VTs, each with distinct QRS configurations and axis observed at different times in the same patient.

EPIDEMIOLOGY

The prevalence of PVCs is a function of sampling method and duration, and PVCs may be seen in 50% of apparently healthy individuals if the monitoring time is 24 hours or longer. Asymptomatic PVCs may, however, be a marker of more serious underlying heart disease.

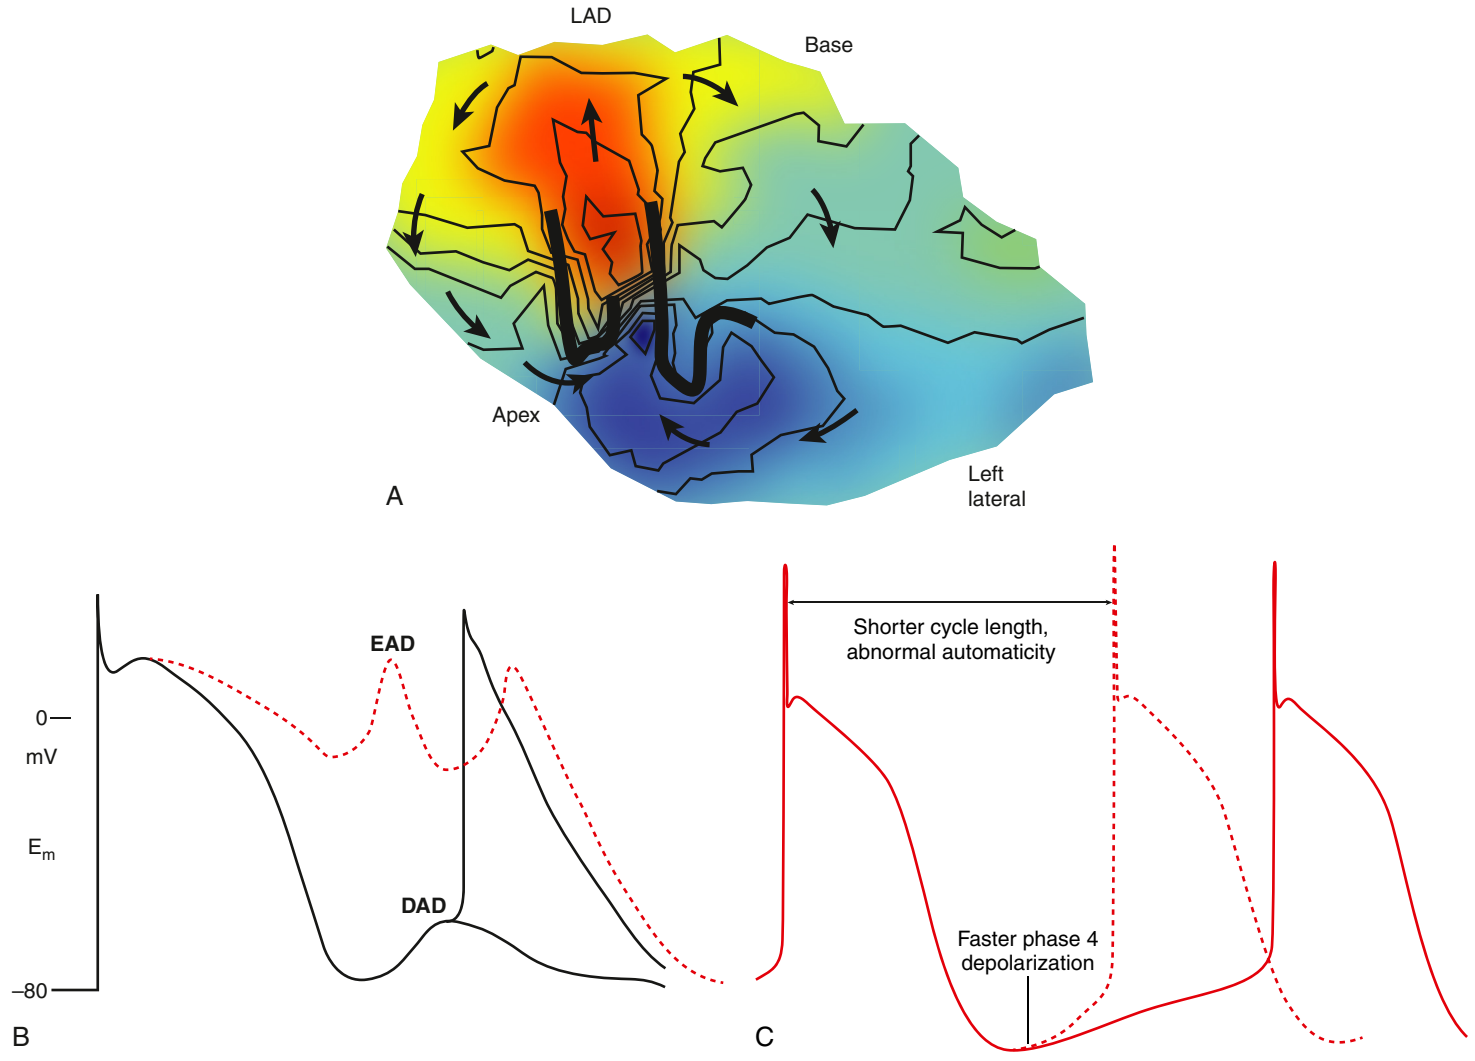
Nonsustained VT may be recorded in up to 3% of apparently healthy individuals with no identifiable heart disease. The prevalence of PVCs and nonsustained VT not only increases with age but also with the presence and severity of an underlying heart disease. Therefore, the finding of nonsustained VT often leads to a cardiac evaluation to exclude organic heart disease, even if it is incidentally discovered in an asymptomatic patient. The prevalence of nonsustained VT rises to 7 to 12% in the late phase of myocardial infarction (MI) and may be as high as 80% in patients with advanced heart failure owing to dilated cardiomyopathy (Chapter 47).

Approximately 10% of patients with documented sustained VT have no identifiable heart disease, in which case idiopathic VT is diagnosed. The prevalence of idiopathic VT is estimated to be only 15.5 in 100,000 in men and 12.3 in 100,000 in women.

VT or VF in patients with advanced organic heart disease accounts for an estimated 50% of all annual cardiovascular deaths in the United States. The nature of the underlying heart disease in patients dying of VT or VF is age dependent. Before 30 years of age, the heart diseases most commonly associated with VT and VF are genetically inherited cardiomyopathies or channelopathies (Chapter 47), whereas acute MI and cardiomyopathy (either ischemic or dilated nonischemic) are the most common underlying heart diseases in individuals older than 40 years. In about 15% of cases of sudden cardiac death without obvious underlying organic heart disease identifiable at autopsy, postmortem genetic analysis may identify a clinically actionable pathologic mutation in an ion channel that predisposes to VT and VF.

PATHOBIOLOGY

Based on their underlying mechanisms, ventricular arrhythmias are classified as re-entrant, triggered, or automatic (Chapter 48). Re-entry, commonly the result of activation in adjacent circuits sharing a common pathway referred to as the isthmus, is initiated by the simultaneous presence of conduction block in one pathway and abnormally slow conduction in an adjacent pathway, thereby allowing recovery of excitability in the former (E-Fig. 53-1A). One type of triggered activity results from early afterdepolarizations, which are rapidly repetitive depolarizations occurring during the late phase of the action potential in the setting of an abnormally delayed repolarization process (E-Fig. 53-1B). Another type of triggered activity results from delayed afterdepolarizations, which reach depolarization threshold and cause repetitive action potentials in the setting of elevated intracellular calcium concentrations (see E-Fig. 53-1B). Automatic arrhythmias arise from accelerated pacemaker activity (E-Fig. 53-1C).



E-FIGURE 53-1. **A**, Re-entry within the myocardial infarction zone in an experimental canine model of ventricular tachycardia (VT). The central region of slow abnormal conduction, commonly referred to as the isthmus, is characterized by narrow crowded isochrones flanked by arcs of bidirectional conduction block depicted by *dark lines*, isolating the isthmus and enabling the maintenance of re-entry. The *arrows* indicate the spread of the wave of depolarization outside the central isthmus, in the shape of a figure of eight, with the red zone as the early breakthrough of activation and the dark blue area as the late activation in the VT cycle, which is also the point of re-entry into the isthmus. LAD = left anterior descending. **B**, Schematic depiction of the cardiac action potential with early afterdepolarizations (EAD) during phase 3 of a prolonged action potential *(dotted lines)* and delayed afterdepolarizations (DAD) reaching threshold and resulting in a premature action potential at the end of phase 3 and the very start of phase 4. E_m = membrane potential. **C**, Schematic depiction of cardiac action potential with an increased slope of depolarization toward the threshold during phase 4, at a site of automatic tachycardia.

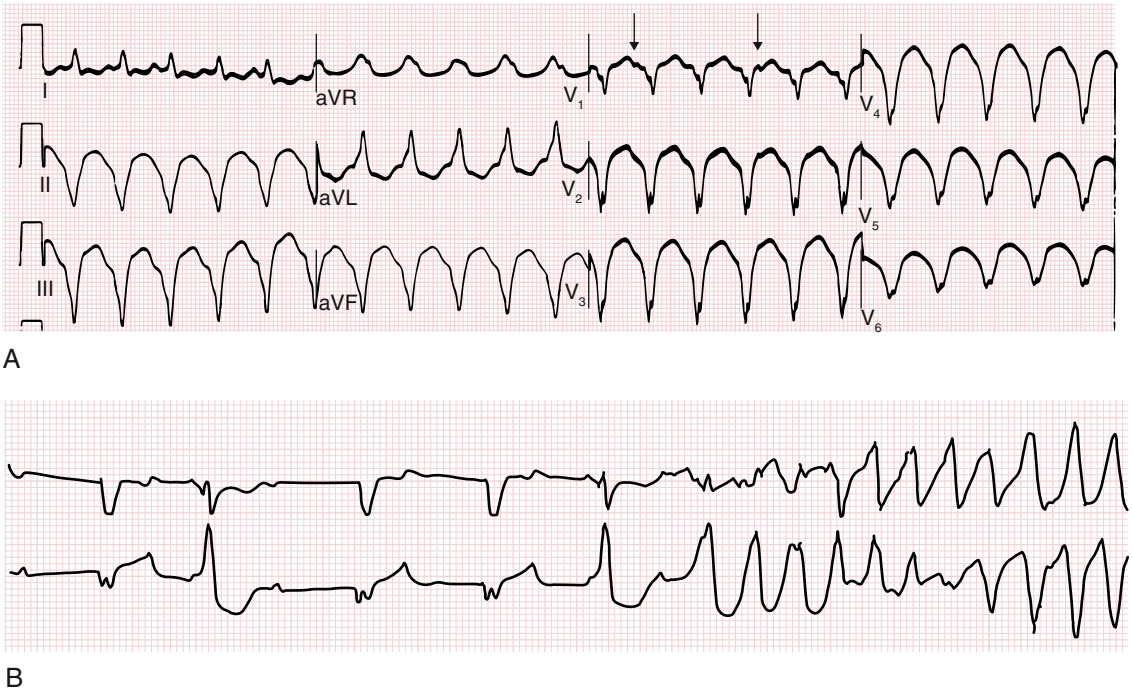


FIGURE 53-3. **A, Monomorphic ventricular tachycardia (VT) in a patient with a prior myocardial infarction. The *arrows* identify P waves in lead V_1, showing atrioventricular dissociation. No R wave is recorded in any of the precordial leads V_1 to V_6 during VT. B, Polymorphic VT in a patient with chronic ischemic cardiomyopathy and marked first-degree atrioventricular block. There is no QT prolongation before the onset of the polymorphic VT.**

Sustained re-entrant activation in the diseased myocardium is the most common cause of monomorphic VT and usually arises when scar (which may be subendocardial, transmural, or subepicardial), resulting from prior ischemic injury, creates an electrophysiologically abnormal substrate. Other pathologic conditions capable of creating a substrate for re-entry include inflammation (e.g., myocarditis), granuloma (e.g., cardiac sarcoidosis), fibrofatty infiltration (e.g., arrhythmogenic right ventricular cardiomyopathy), genetically caused sarcomeric disarray (e.g., hypertrophic cardiomyopathy), infiltration (e.g., amyloidosis, hemochromatosis), and iatrogenic scar (e.g., surgical repair of tetralogy of Fallot). These substrates may also result in polymorphic VT and VF by a similar re-entrant mechanism.

Triggered activity resulting from delayed afterdepolarizations is thought to be the underlying mechanism for most idiopathic monomorphic VT that has a focal site of origin in the right or left ventricular outflow tract, in one of the sinuses of Valsalva, the area of aortomitral continuity, or in the myocardial segment termed the left ventricular summit. Idiopathic VT from re-entry in the fascicles of the left bundle branch has a relatively narrow QRS complex that mimics right bundle branch block (RBBB) and anterior or posterior fascicular block. Idiopathic fascicular VTs may be electrocardiographically difficult to distinguish from idiopathic papillary muscle VTs. In Brugada syndrome, the primary cause is genetically acquired abnormal conduction in the epicardium of the right ventricular outflow tract.

Torsades de pointes, which is a specific type of polymorphic VT that derives its name from the rotating of the QRS axis, is caused by early afterdepolarizations that arise during a delayed repolarization process in the setting of genetic long QT syndromes or acquired long QT during therapy with QT-prolonging drugs. The cause may be either diminished outflowing repolarizing potassium currents, enhanced inflowing sodium currents due to incomplete inactivation of the sodium channel, or increased inflowing calcium currents. Although many episodes terminate spontaneously, the rates are usually very fast, and episodes of torsade can transform into sustained VF.

Bundle branch re-entry, which incorporates the right and the left bundle branches distally joined by the slowly conducting septal myocardium, may cause one or two nonsustained ventricular beats in a normal heart. However, sustained bundle branch re-entry occurs when myocardial disease causes chamber enlargement and bundle branch elongation and/or disease in the conduction system causes abnormally slow conduction, thereby creating the scenario for sustained bundle branch re-entry. The common type of bundle branch re-entry has anterograde activation over the right bundle and uses the left bundle retrogradely, thereby resulting in a left bunch branch block (LBBB) pattern on the surface ECG, but the reverse direction with RBBB pattern may also occur.

Accelerated pacemaker activity in an ectopic location, with rates exceeding the underlying sinus rhythm rate, may arise in settings such as transient inflammation, excess digoxin levels, intracellular calcium loading, electrolyte imbalance, and coronary reperfusion following occlusion. Bidirectional VT is thought to result from calcium overload of the myocytes owing to congenitally acquired, abnormal ryanodine receptor or calsequestrin function, or from digitalis toxicity, and it may transform to more malignant polymorphic VT and VF.

Finally, there is no consensus regarding the mechanisms underlying VF. Theoretically, VF may be initiated when a premature contraction falls in the vulnerable period of the action potential, thereby precipitating a re-entrant wave that breaks into sister wavelets and results in high-frequency electrical activity. In fact, VF may be regarded as an end stage for a variety of severe electrophysiologic abnormalities that result in chaotic activation.

CLINICAL MANIFESTATIONS

Ventricular arrhythmias can present in a variety of clinical settings (Table 53-1). They may be asymptomatic and detected only by an irregular pulse on a physical examination, on a routine ECG, or on an exercise test. Symptomatic ventricular arrhythmias can present as palpitations, dizziness, syncope (Chapters 39 and 49), shortness of breath, or sudden cardiac arrest (Chapter 50). The diagnosis may be confirmed by ambulatory ECG monitoring (Chapter 49), but more extended monitoring by a loop recorder may be needed to detect arrhythmias that may be rare and intermittent. Ambulatory monitoring can also help correlate arrhythmias with any symptoms they may cause. In some patients, exercise testing can be helpful for diagnosis.

Acute Myocardial Infarction

VT and VF may arise as early as minutes to hours after the onset of symptoms during coronary thrombosis, and prehospital VT and VF during acute MI are responsible for a large proportion of out-of-hospital sudden cardiac deaths (Chapter 50). The incidence of peri-infarction VF has declined over the past two decades, perhaps related to the widespread application of successful early coronary revascularization (Chapter 59) during acute MI. Among patients with ST elevation MI who now reach the hospital, about 3 to 4% develop VT, mostly during the acute phase. The incidence of VT in patients with non–ST elevation MI (Chapter 57) is lower, about 1%. Accelerated idioventricular rhythm (AIVR) is an automatic ventricular rhythm that is faster than the sinus rate but usually less than 120 beats per minute. It may occur

Brugada syndrome
Idiopathic ventricular fibrillation

TABLE 53-2 DISTINGUISHING VENTRICULAR TACHYCARDIA FROM SUPRAVENTRICULAR TACHYCARDIA WITH ABERRANT CONDUCTION

VENTRICULAR TACHYCARDIA	SUPRAVENTRICULAR TACHYCARDIA
AV dissociation	Same QRS morphology as preexisting bundle branch block in sinus rhythm
aVR: initial R > S or initial R or Q >40 msec	V_1: rsR′
Absence of any R waves in V_1 to V_6	
V_1 to V_6: onset of R to S >100 msec in any lead	
QRS duration >160 msec	
Initial R wave in aVR	

AV = atrioventricular.

immediately following coronary reperfusion after an acute MI, and it typically terminates spontaneously.

DIAGNOSIS

Not every wide-complex tachycardia is VT (Fig. 49-3). The diagnosis is straightforward when a His bundle electrogram is recorded during a wide-complex tachycardia in the cardiac electrophysiology laboratory, but diagnosis on a standard 12-lead ECG may be challenging (Table 53-2). The differential diagnosis of a sustained regular-rate wide-complex tachycardia includes any type of supraventricular tachycardia with aberrant conduction (Chapter 52), supraventricular tachycardia with ventricular preexcitation, bundle branch reentry, and myocardial VT. The clinical setting and the patient's background (e.g., history of previous MI or cardiomyopathy) play a major role in making an accurate diagnosis. A wide-complex tachycardia in a young and otherwise healthy individual with no structural heart disease is more likely to be a supraventricular tachycardia (SVT) conducted with aberration or with preexcitation, but it also may be idiopathic VT. Establishing a definitive diagnosis is critically important.

The most reliable electrocardiographic observation in favor of VT is evidence of atrioventricular (AV) dissociation, that is, the absence of any relationship between the atrial and ventricular rate, with the ventricular rate faster than the atrial rate (see Fig. 53-1C), or a regular wide-complex tachycardia with the atria fibrillating. Such findings immediately exclude SVT with aberration or preexcitation except for extremely rare cases of junctional tachycardia with aberrant conduction or nodo-fascicular/nodo-ventricular reentrant tachycardia. However, the absence of AV dissociation does not exclude VT because 1:1 ventriculoatrial conduction is present in about 50% of VTs and can be seen on the 12-lead ECG in 25% of cases. Fusion beats (which occur when an occasional sinus beat conducts through the AV node and reaches the His-Purkinje system at the same time as the VT source activates the myocardium, thereby resulting in a beat with a morphology that is the hybrid of a conducted QRS complex and the VT complex; Fig. 53-1C) also confirm AV dissociation but are observed only when VT rates are relatively slow.

Another approach is to rely on ECG lead aVR, where the presence of an initial R wave, notching on the initial downstroke of a predominantly negative QRS complex, and the width of an initial r-wave or q-wave > 40 ms strongly suggest VT. Other findings that favor VT include a QRS duration longer than 160 msec, or longer than 140 msec with an RBBB pattern. The absence of an RS complex in all precordial ECG leads or an interval of more than 100 msec from the onset of R to the nadir of S wave favors VT (Fig. 53-4; and see Fig. 53-3A). The absence of any R waves in the QRS complexes recorded from all six precordial leads (see Fig. 53-3A), described as *negative concordance*, strongly suggests VT, but is not a common finding. Prominent R waves observed in all six precordial ECG leads, termed *positive concordance*, may be seen in SVT with left ventricular preexcitation in patients without structural heart disease but otherwise also suggests VT with a basal site of origin. A wide-complex tachycardia with a QRS morphology identical to that of aberrantly conducted sinus rhythm manifesting bundle branch block (BBB) on a previously recorded ECG in the same patient should raise suspicion of bundle branch re-entry VT if the ECG shows AV dissociation, which excludes 1 : 1 aberrantly conducted supraventricular tachycardia.

If AV dissociation is not present, the differential diagnosis includes SVT with aberrant conduction, but the rare condition of preexcitation with an atriofascicular accessory pathway should also be considered in a patient with LBBB pattern and 1 : 1 AV ratio. A monomorphic wide-complex tachycardia with an irregular rate, manifested by more than 60-msec difference in cycle length from one beat to the next, is likely to be atrial fibrillation (AF) or atrial flutter, with variable AV block and aberrant conduction or with preexcitation. It is important to emphasize that severe electrolyte imbalances or the use of antiarrhythmic drugs diminishes the predictive accuracy of all of these diagnostic clues.

Sustained polymorphic wide-complex tachycardia with marked beat-to-beat changes in the QRS morphology is either atrial fibrillation with varying degrees of preexcitation from one beat to the next or ventricular tachycardia that either terminates spontaneously or transforms into VF. Torsades de pointes is frequently pause dependent—typically starting when a premature beat falls on the T wave of the beat following a long RR interval (Fig. 53-5). Finally, bidirectional VT manifesting a unique feature of beat-by-beat axis alternans may occur with digitalis toxicity or in congenital catecholaminergic polymorphic VT syndrome.

Several different algorithms based on the configurations of the QRS complexes have high sensitivity, high specificity, and acceptable predictive accuracy for distinguishing epicardial VT from endocardial VT (Table 53-3). If the site of origin is epicardial, the rapidly conducting His-Purkinje system is not available immediately, and the intramyocardial conduction delay produces a slurred initial component of the QRS complex, often called a *pseudo-delta wave*, which is manifested as a slow rate of rise of voltage before it reaches the intrinsicoid deflection (Fig. 53-6). Early recognition of ECG findings suggesting an epicardial origin of VT is important in planning and preparing a patient before a catheter ablation procedure (Chapter 54) because the epicardial approach requires a special technique in the cardiac electrophysiology laboratory.

Diagnostic cardiac electrophysiology testing (Chapter 49) may be indicated in patients who have organic heart disease and recurrent syncope but in whom the history, physical examination, ECG, echocardiogram, and ambulatory cardiac rhythm monitoring fail to clarify the cause, especially if the patient has a history of MI or cardiomyopathy, either of which increases the probability that VT may be the cause of syncope.

Identifying the Underlying Cause of Ventricular Arrhythmias

In patients with ventricular arrhythmia, the first step is to conduct a careful evaluation to exclude any underlying structural heart disease. This evaluation must include a comprehensive history and physical examination (Chapter 39),

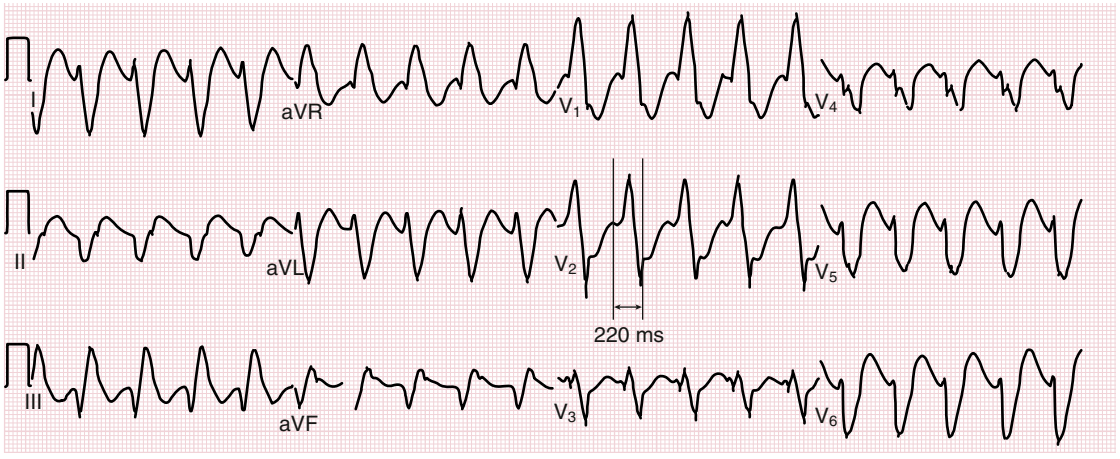

FIGURE 53-4. Monomorphic ventricular tachycardia in a patient with chronic ischemic cardiomyopathy. In lead V_2, the duration from the onset of the R wave to the nadir of the S wave is 220 msec. See text for further explanation.

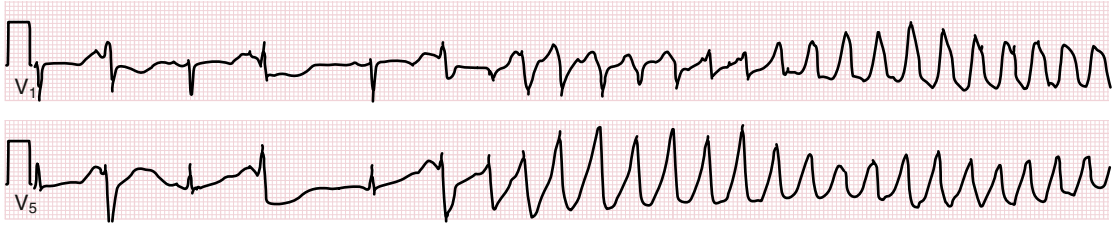

FIGURE 53-5. Torsades de pointes (TdP) in a patient with a markedly prolonged QT interval. A premature ventricular beat just after the peak of the T wave initiates TdP. As the tachycardia progresses, the rotation or the "twist" in the QRS axis is clearly observed in lead V_1, with the polarity of the signal changing gradually from negative to positive.

TABLE 53-3 ELECTROCARDIOGRAPHIC PARAMETERS TO HELP PREDICT AN EPICARDIAL ORIGIN OF VENTRICULAR TACHYCARDIA

PARAMETER	CRITERIA
Pseudo-delta wave	>75 msec favors epicardial site
Intrinsicoid deflection time	>85 msec favors epicardial site
Onset of R to nadir of S in precordial leads	>120 msec favors epicardial site
QRS duration	Epicardial longer
Q waves during VT in lead I	Favors epicardial site
Q waves during VT in II, III, aVF	Favors endocardial site
aVR/aVL amplitude ratio	Epicardial higher

VT = ventricular tachycardia.

electrocardiography, echocardiography (Chapter 43), extended cardiac rhythm monitoring (Chapter 49), and stress testing (Chapter 56). The family history may provide clues for the presence of an inherited cardiomyopathy (Chapter 47) or channelopathy. Cardiac magnetic resonance imaging (Chapter 44) is indicated in patients who are suspected of having sarcoidosis or arrhythmogenic right ventricular cardiomyopathy, and for risk stratification in patients with cardiomyopathy. Other tests to consider include 99 m technetium-pyrophosphate scan in patients suspected to have transthyretin cardiac amyloidosis (Chapters 47 and 174) and positron emission tomography to detect active myocardial inflammation (Chapter 44), conditions which predispose to ventricular tachyarrhythmias.

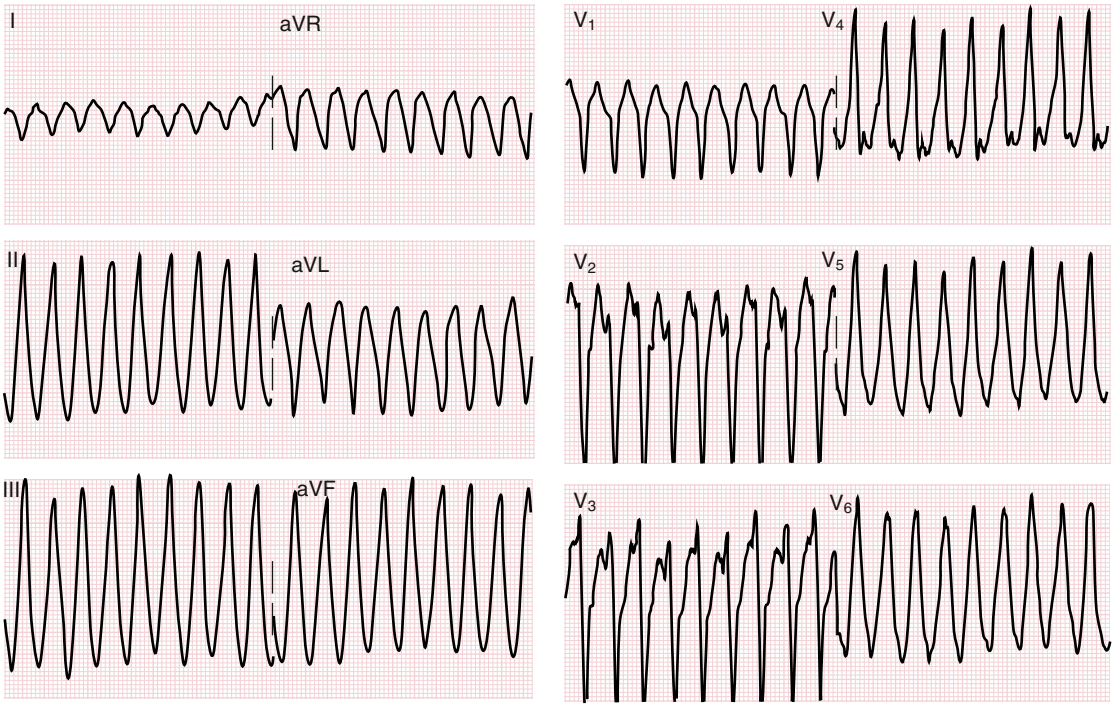
Despite a comprehensive evaluation, about 10 to 15% of patients will have VT with no identifiable structural or genetically identifiable cause. Most of the idiopathic monomorphic VTs are in one of two categories, distinguishable by ECG morphology. VTs that arise in the right or left ventricular outflow tract typically manifest an inferiorly directed frontal axis (E-Fig. 53-2); the QRS configurations and polarity observed in the right precordial leads (V_1 and V_2) may further discriminate the sites of origin as the right or the left ventricular outflow tract or one of the sinuses of Valsalva. VT originating in the right sinus of Valsalva closely resembles VT originating in the right ventricular outflow tract. In VT originating in the left sinus of Valsalva, the R wave duration and R/S wave amplitude ratio in leads V_1 and V_2 are significantly increased compared with VT from the right ventricular outflow tract. By comparison, idiopathic left ventricular tachycardia resulting from intrafascicular re-entry usually manifests RBBB and left axis deviation, but there may also be right axis deviation. The QRS complexes typically are not very wide because the involved region is His-Purkinje tissue adjacent to the interventricular septum. Idiopathic VT arising in one of the left ventricular papillary muscles has QRS complexes similar to those of intrafascicular re-entry (E-Fig. 53-3). Either of these typical patterns in a patient with no structural heart disease suggests idiopathic VT. Conversely, sustained VT that does not fall into either of these two broad categories should always raise a high index of suspicion that organic heart disease may be present.

Chronic Ischemic Heart Disease and Post–Myocardial Infarction Ventricular Tachycardia

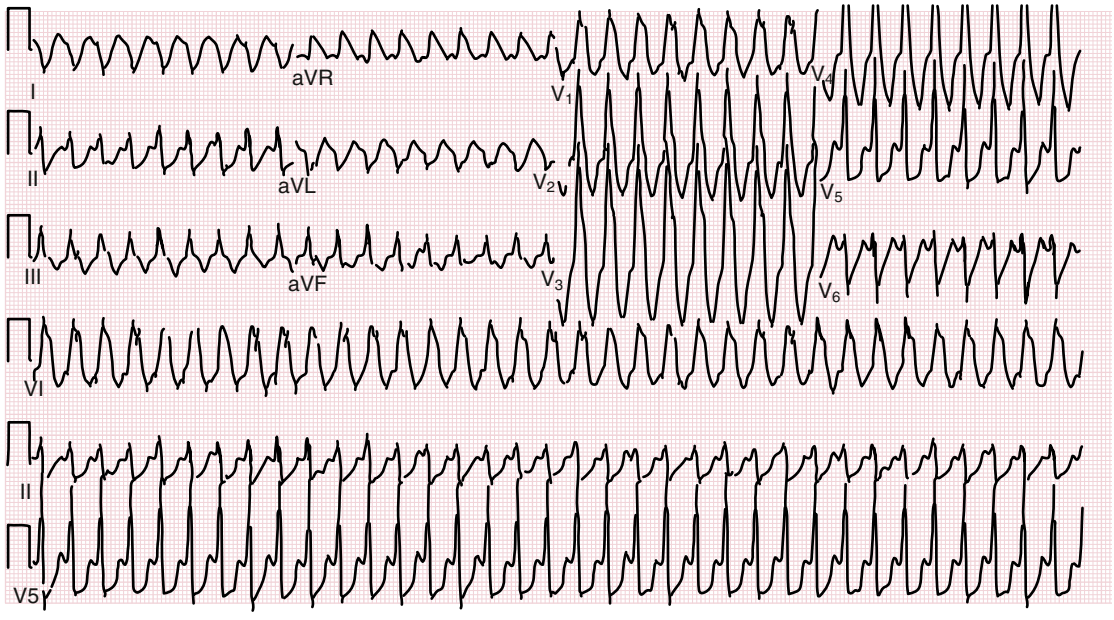
In survivors of ST elevation MI (Chapter 58), the risk of sudden cardiac death is 10 times higher during the first month than later during recovery. The prevalence of sustained VT by 6 weeks is about 1%, and VT may occur as late as 15 to 20 years after the acute MI without any intervening event. VT commonly, but not invariably, reflects poor left ventricular function. The electrophysiologic substrate is the surviving but electrophysiologically abnormal tissue embedded in the infarcted zone, which creates the conditions responsible for re-entry. The areas that harbor pathways underlying re-entry may be identified by low-amplitude fractionated endocardial electrograms recorded in late systole during sinus rhythm or in mid-diastole during VT in the cardiac electrophysiology laboratory. Up to 16% of the VTs in ischemic heart disease are of epicardial origin. The same pathologic substrate may cause polymorphic VT and VF that, unlike torsades de pointes, do not depend on a long QT interval.

Nonischemic Dilated Cardiomyopathy

The most common cause of sustained monomorphic VT in nonischemic cardiomyopathy (Chapter 47) is also re-entry within the myocardium, but it differs from the post-infarction VT of chronic ischemic heart disease. The pathologic substrates tend to be located in basal, lateral, and often perivalvular



E-FIGURE 53-2. **Electrocardiogram recorded during idiopathic ventricular tachycardia originating in the right ventricular outflow tract and manifesting a deeply inferior frontal axis and left bundle branch block mimicry in the precordial leads.**



E-FIGURE 53-3. **Ventricular tachycardia (VT) originating in the anterolateral papillary muscle.** Note the right bundle branch mimicry of the QRS and the right axis deviation, similar to the electrocardiographic configuration of an interfascicular re-entrant VT.

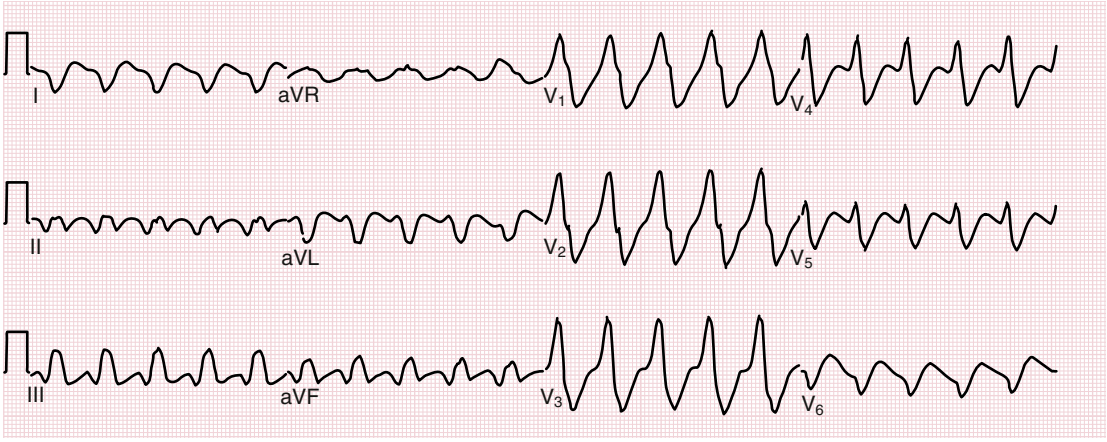


FIGURE 53-6. Monomorphic epicardial ventricular tachycardia in a patient with nonischemic dilated cardiomyopathy. The positive polarity pseudo-delta wave is prominent in the right precordial leads, and the negative polarity pseudo-delta wave is prominent in the inferior limb leads.

left ventricular areas, which may correlate with the location of intramyocardial or subepicardial scarring identified by imaging studies. The proportion of monomorphic VTs due to bundle branch re-entry is higher in nonischemic dilated cardiomyopathy compared with chronic ischemic heart disease.[1] Also, VT in nonischemic dilated cardiomyopathy is more likely to have an epicardial origin—as high as 35% overall and reaching 70% in Chagas disease.

Rapidly Reversing Cardiomyopathy

Patients with stress-induced cardiomyopathy (Chapter 47) will recover over several days to weeks, and patients with viral myocarditis may also recover relatively rapidly. Despite recovery of their ventricular systolic function, subgroups of patients with a history of myocarditis have a higher incidence of subsequent VT and mortality than the healthy controls over long-term follow-up.

Heart Failure

The failing heart from any underlying cause (Chapter 45) is highly vulnerable to ventricular arrhythmias. The proportion of sudden arrhythmic death depends on heart failure class and may be as high as 60% in class II to III heart failure. In patients with class IV heart failure, however, the fatal arrhythmia is more often an agonal bradyarrhythmia. Re-entrant VT is common, especially in patients whose heart failure is due to advanced ischemic heart disease, but triggered activity resulting from derangements of calcium homeostasis may also play a prominent role. In addition, hormonal factors, electrolyte abnormalities, and changes in autonomic nervous system activity also increase the vulnerability of the failing heart to ventricular arrhythmias.

Inflammatory and Infiltrative Disease

Among patients with sarcoidosis (Chapter 83), about 40 to 50% have cardiac involvement, which may first manifest as progressive AV block, VT, or both. Although the true prevalence of VT in sarcoidosis is not known, in the selected patients who have received implantable cardiac defibrillators (ICDs) for cardiac sarcoidosis diagnosed by endomyocardial biopsy, cardiac magnetic resonance imaging, or cardiac positron emission tomographic scans, about 15% per year have appropriate ICD discharges for sustained VT. Patients with other infiltrative heart diseases such as amyloidosis (Chapter 174), Fabry disease (Chapter 192), and hemochromatosis (Chapter 196) also have an elevated risk for VT and life-threatening ventricular arrhythmias.

Adult Congenital Heart Disease

VT may occur in the setting of any adult congenital heart disease with a ventricular surgical scar or patch, as is seen after repair of tetralogy of Fallot or a ventricular septal defect closure. It may also occur in a failing systemic right ventricle (Chapter 55). In patients with surgically repaired tetralogy of Fallot, the right ventricular outflow tract, with its scarring and artificial material, serves as an ideal milieu for re-entry and VT. In these patients, the prevalence of VT is about 5 to 10%, and about 2% have sudden cardiac death.

Genetically Inherited Cardiomyopathies

Hypertrophic cardiomyopathy (Chapter 47) is responsible for more than one third of sudden cardiac deaths in patients younger than age 25 years (Chapter 50), and mortality in young hypertrophic cardiomyopathy patients is almost exclusively due to VT and VF. Neither genetic testing nor a cardiac electrophysiology study can definitively identify patients at high risk for VT and VF, and the estimation of risk is based on findings such as a history of syncope, documented nonsustained VT especially in a young patient, a markedly thickened (>3 cm) interventricular septum, and a paradoxical decrease in blood pressure during exercise. Recent studies suggest that the extent of late gadolinium enhancement on cardiac magnetic resonance imaging may be a reliable predictor of serious ventricular arrhythmias in patients with hypertrophic cardiomyopathy.

Arrhythmogenic right ventricular cardiomyopathy[2] is a congenital cardiomyopathy (Chapter 47), usually with an autosomal dominant inheritance. The fibrofatty infiltration of the right ventricular myocardium, which may also involve the interventricular septum and the left ventricle, results in progressive electrophysiologic abnormalities, which may be manifest on the surface ECG as an epsilon wave (Fig. 53-7). The markedly altered conduction characteristics are conducive to re-entry. The incidence of VT in arrhythmic right ventricular cardiomyopathy is related to the severity of the pathologic myocardial changes and ranges from 25 to 100%, depending on the penetrance and the expressivity of the disease. VT typically is initiated by exercise and mimics LBBB in the precordial ECG leads. However, unlike idiopathic right ventricular outflow tract VT, the frontal axis may not be inferiorly directed, and multiple endocardial and epicardial sites of origin exist in about 60% of cases. Vigorous exercise may accelerate the progression of cardiomyopathy and increase the incidence of ventricular arrhythmia.

Genetically Inherited Ventricular Arrhythmias

Several genetically acquired syndromes, including the long QT syndromes, Brugada syndrome, and catecholaminergic polymorphic VT, increase the risk for sudden cardiac death due to ventricular tachyarrhythmias. Despite the remarkable genetic heterogeneity of long QT syndrome, most cases are LQT1, LQT2, and LQT3, which result from loss-of-function mutations in genes *KCNQ1* and *KCNH2* that code for two different potassium channels or gain-in-function mutations in the *SCN5A* gene that codes for the sodium channel.[3] The other genetic mutations are extremely rare. The VT of long QT syndrome is torsades de pointes, and both bradycardia and pauses increase its probability in patients who are predisposed. The incidence of torsades de pointes is influenced by multiple factors, including age, gender, the particular genetic mutation, and the magnitude of QT prolongation (Fig. 53-8A).

The electrocardiographic hallmark of Brugada syndrome, which also predisposes to ventricular tachyarrhythmias and sudden cardiac death, is coved ST segment elevations in the right precordial leads (Fig. 53-8B). In some cases, this pattern may not be present except when the patient is febrile. The inheritance is autosomal dominant, but the genetics are complex. A pathogenic variant of the *SCN5A* gene is present in less than 20% of the cases. Catecholaminergic polymorphic VT is a rare genetic condition resulting from abnormal calcium homeostasis. It is characterized by exercise-induced, wide-complex tachycardia manifesting alternating ECG axes from one beat to

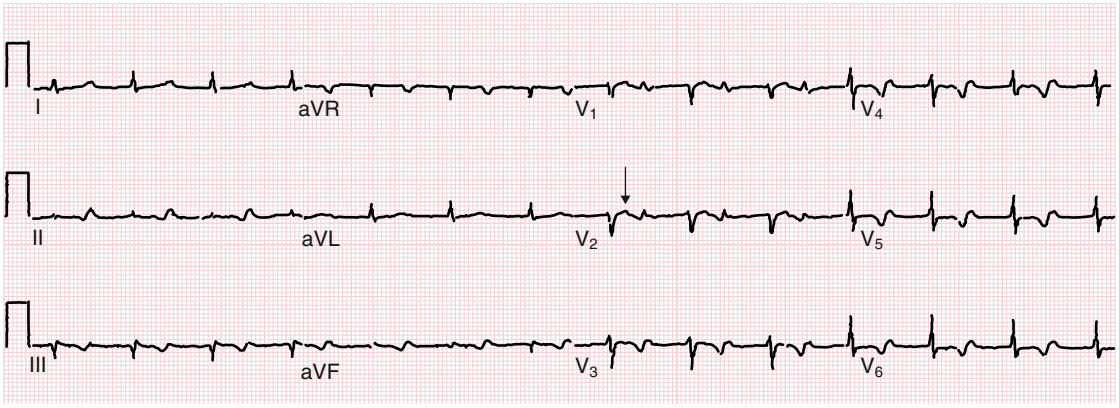

FIGURE 53-7. **This electrocardiogram was recorded in a patient with arrhythmogenic right ventricular cardiomyopathy, marked first-degree heart block, and recurrent ventricular tachycardia.** Epsilon waves, marked by the *arrow*, are visible in the right precordial leads.

the next. This condition also predisposes the patient to exercise-induced VF. In addition, a chromosomal haplotype causing overexpression of dipeptidyl peptidase-like protein-6 has been described in one type of familial idiopathic VF,[4] which is a rare but challenging subset of inheritable arrhythmia syndromes causing sudden cardiac death.

Iatrogenic Ventricular Tachycardia and Ventricular Fibrillation

QT-prolonging drugs, including class III antiarrhythmic drugs (see www.torsades.org), may precipitate torsades de pointes and VF in genetically predisposed individuals even if the baseline QTc is normal or borderline.[5] Class IC antiarrhythmic drugs may cause life-threatening VT in patients with ischemic or any other organic heart disease and in patients with Brugada syndrome. Ventricular scarring owing to aneurysmectomy, tetralogy of Fallot repair, ventricular septal defect repair, alcohol ablation of the interventricular septum to relieve dynamic outflow tract obstruction in hypertrophic cardiomyopathy, or implantation of a left ventricular assist device may create a substrate for re-entry and VT.

TREATMENT

Acute Management of Ventricular Tachycardia and Ventricular Fibrillation

The management of hemodynamically unstable VT and VF should conform to the guidelines for advanced cardiac life support (Chapter 50), with an emphasis on prompt defibrillation. For patients who have sustained VT with modest hypotension and normal mental status, intravenous drug therapy with lidocaine (given as a 50-mg bolus), procainamide (10 mg/kg or a total of 1000 mg over 20 minutes), or amiodarone (150 mg infused intravenously over 10 minutes) may be tried. In one randomized trial, procainamide was superior to amiodarone for promptly terminating wide-complex tachycardia with fewer adverse effects.[A1] Lidocaine, which is more efficacious at faster heart rates, is effective for terminating VT, but not for preventing recurrences, except in the setting of acute ischemia. By comparison, amiodarone is more effective at slower heart rates and therefore is better for preventing recurrent VT after sinus rhythm is restored. Intravenous calcium-channel blocker therapy should not be given unless the mechanism is known with certainty to be verapamil-sensitive idiopathic left ventricular tachycardia in a patient who does not have organic heart disease.

The most important factors in preventing early recurrence are the prompt identification and reversal of any precipitating causes. Examples include hypokalemia and other electrolyte imbalances, low oxygen saturation, intravenous β-agonist agents or milrinone, acute heart failure (Chapter 46), or myocardial ischemia (Chapters 57 and 58). Heart failure should be rigorously treated (Chapter 46) and the presence of residual myocardial ischemia suspected if VF is recurrent.

Treatment of Electrical Storm

Electrical storm describes frequently recurrent VT or VF requiring repeated shocks from an implanted cardioverter-defibrillator (ICD) or external defibrillations. Electrical storm rarely occurs in nonischemic cardiomyopathy or in genetically acquired ventricular arrhythmias. When this condition is encountered in the setting of ischemic heart disease, relief of ischemia is of paramount importance. If the electrical storm continues even after coronary reperfusion, insertion of an intra-aortic balloon pump and use of an intravenous β-blocker therapy, preferably with a short half-life drug (e.g., esmolol 500 μg/kg load over 1 minute, then 50 to 200 μg/kg per minute by intravenous infusion) should be considered. Intravenous lidocaine (2 to 4 mg per minute) or intravenous amiodarone (0.5 to 1.0 mg per minute) may also be used. Catheter ablation, if possible, may reduce the recurrence rate and potentially improve survival.[6] For recurrent ventricular arrhythmias refractory to traditional therapies, noninvasive radioablation (see later) or left-sided or bilateral cardiac sympathetic denervation may be effective. Another potential option is renal denervation.[7]

Treatment of PVCs and Idiopathic Ventricular Tachycardia

In the absence of structural heart disease, there is no convincing evidence that ventricular ectopic activity influences survival. Therefore PVCs do not need treatment in asymptomatic patients.[8] If ventricular ectopy results in symptoms that substantially decrease quality of life, a cardioselective β-blocker (e.g., metoprolol 50 mg twice daily or atenolol 50 mg once daily) is a safe but not a very effective first-choice therapy. If the frequency of PVCs and nonsustained VT reaches a critical level, however, the arrhythmia itself may result in decreased systolic ventricular function even in the absence of any other cause for cardiomyopathy. These patients should be treated aggressively, including catheter mapping and ablation (Chapter 54), to avoid progressive cardiomyopathy and heart failure without subjecting the patient to the potential adverse effects of antiarrhythmic drugs.

Although cardiac arrest resulting from transformation of idiopathic VT to VF is exceedingly rare, sustained VT at a rate faster than 200 beats per minute commonly causes cardiopulmonary symptoms and may cause syncope (Chapter 49), even in the absence of structural heart disease. Idiopathic VTs of outflow tract origin may respond to β-blocker therapy (e.g., metoprolol 50 mg every 12 hours or atenolol 50 mg daily), and a few may respond to an empirical trial of calcium-channel blockers (e.g., sustained-release diltiazem 120 to 240 mg daily or sustained-release verapamil 120 to 240 mg daily). However success rates are low, ranging from 25 to 50%. The so-called idiopathic left ventricular tachycardia resulting from left fascicular re-entry frequently responds to verapamil (e.g., sustained-release 180 to 360 mg daily), but papillary muscle VT may not.

Catheter ablation therapy (Chapter 54) can cure 80 to 90% of cases of idiopathic ventricular arrhythmia with a low risk (<1%) and should be considered as a preferred alternative to long-term antiarrhythmic drug therapy.[9] If careful catheter mapping in the right ventricular outflow tract does not yield a suitable target, the left ventricular outflow tract, right or left sinus of Valsalva, or the aortomitral continuity may be the site of origin. Failures are usually due to an inability to induce the arrhythmia reliably with electrophysiologic testing or VT that originates in epicardial sites beyond safe access for an ablation catheter (e.g., close proximity to a coronary artery).

By comparison to the relatively benign prognosis of idiopathic sustained VT, idiopathic VF accounts for 5 to 10% of all cases of sudden cardiac death (Chapter 50) in patients without organic heart disease. The appropriate treatment for survivors of idiopathic VF is no different than for any other survivor of VF (i.e., ICD therapy), but some patients may have findings on electrophysiologic testing that are amenable to catheter ablation—which may decrease the risk for recurrence but still does not obviate the need for ICD protection.

Therapy for Ventricular Tachycardia and Ventricular Fibrillation in Structural Heart Disease

Implantable Cardiac Defibrillator Therapy and Antiarrhythmic Drugs

Sustained VT or VF in patients with organic heart disease is a primary indication for ICD therapy.[10,11,A2] A subcutaneous ICD is as safe and effective as a transvenous ICD for patients who do not have an indication for pacing.[A3]

After an acute MI, an ICD implanted as primary prevention therapy reduces mortality in patients who have survived more than 40 days and have a left ventricular ejection fraction of 30% or less.[A4] For patients who have class II or III heart failure regardless of the etiology of their organic heart disease and who have a left ventricular ejection fraction of less than 35%, an ICD also significantly reduces sudden cardiac death, although it may not prolong life in patients with nonischemic heart failure because of the high burden of death from other causes.[A5] By comparison, ICDs do not reduce mortality when routinely implanted soon after MI or in patients after recent coronary artery revascularization.

In patients with ischemic heart disease and a chronically depressed ejection fraction of less than 30%, insertion of an ICD reduces the mortality rate by 20%, from 36 to 29%, over the next 5 years. By comparison, amiodarone (Table 52-3) reduces the risk of sudden arrhythmic death but does not improve survival. In patients with advanced organic heart disease, the presence of frequent PVCs and nonsustained VT portend a poor prognosis, but suppression of ventricular ectopic activity with antiarrhythmic drugs does not improve prognosis; in fact, suppression of PVCs with class IC antiarrhythmic drugs in patients with prior MI increases mortality. Therefore, antiarrhythmic drugs currently serve as palliative treatment to modify the course of VT in patients with an ICD, rather than as definitive therapy. Amiodarone (100 to 400 mg daily) is more successful than β-blockers or sotalol for this palliative therapy of VT.[A6]

In patients who are clinically unstable because of incessant VT, reversible precipitating factors should be sought and, if present, corrected promptly. Intravenous β-blockers (e.g., esmolol 50 to 200 μg/kg per minute) and amiodarone (0.5 to 1.0 mg per minute) constitute first-line therapy. Intravenous lidocaine (e.g., 2 to 4 mg per minute) can be added, especially if myocardial ischemia is present, and emergent catheter ablation may be considered.

Catheter Ablation

Catheter ablation is usually also palliative rather than definitive treatment for VT in patients with structural heart disease, but it can significantly reduce the frequency of recurrent VT, ICD discharge, and adverse cardiac events.[A7,A8] Catheter ablation is most successful when clinical VT can be reproduced in the cardiac electrophysiology laboratory and tolerated for a long enough period to allow detailed catheter mapping and to validate the underlying mechanism and site of origin. Catheter ablation can be performed safely in patients with advanced heart failure. However, preventive catheter ablation before ICD implantation is not clearly better than reserving ablation for patients who need it as supplemental therapy.[A9]

Radioablation

Application of stereotactic body radiation is an investigational noninvasive method of treatment for recurrent VT,[12] especially VT storm.[13] The precise location of the target requires a synthesis of anatomic and electrophysiologic data using cardiac magnetic resonance imaging (MRI), cardiac single photon emission computed tomography (SPECT), a 12-lead ECG recorded during VT, and electrophysiologic imaging information. A single fraction of 25 Gy is delivered to the VT substrate while avoiding healthy tissue. Late postprocedure complications include exacerbation of heart failure and pericarditis.

Torsades de Pointes and Catecholinergic Polymorphic VT

In an acute setting with frequently recurrent torsades de pointes, magnesium sulfate (1 to 2 g intravenous infusion over 10 to 30 minutes) may be effective. Temporary pacing should be considered if the patient exhibits excessive bradycardia or prolonged pauses.

An ICD is recommended for patients who present with aborted cardiac arrest. Otherwise, the first line of preventive therapy for torsades de pointes in patients with long QT syndrome is β-blocker therapy (e.g., metoprolol 50 to 100 mg daily, atenolol 50 mg daily, or nadolol 40 mg daily and titrated as tolerated), but its success is influenced by gender and the magnitude of QT prolongation, as well as by the specific genotype. However, about 25% of patients continue to experience ventricular arrhythmias on full doses of β-blocker therapy and require an ICD. Left cardiac sympathetic denervation can substantially reduce the incidence of torsades de pointes and syncope in high-risk patients, as well as decrease the frequency of shocks in patients with an ICD.

β-Blockers (Table 52-3) are also the drugs of choice for catecholaminergic polymorphic VT, with ICD therapy recommended for patients with recurrent syncope or documented VT while on β-blocker therapy. Oral flecainide (Table 52-3) may be an effective adjunct in such patients.

Treatment of Genetically Acquired Ventricular Tachycardia and Ventricular Fibrillation

Most of the VTs observed in patients with arrhythmogenic right ventricular cardiomyopathy may be reproducibly induced by programmed cardiac stimulation and are amenable to catheter ablation. Nearly half of these VTs have an epicardial site of origin, and simultaneous endocardial and epicardial catheter mapping and ablation may be the most effective method of treatment. However, catheter ablation cannot substitute for concomitant ICD therapy. In patients with hypertrophic cardiomyopathy, ICD therapy is routinely recommended, especially in young high-risk patients (Chapter 47), and amiodarone may sometimes be useful.

For Brugada syndrome, catheter ablation of the electrophysiologically abnormal substrate in the right ventricular outflow tract epicardium can lead

to eventual disappearance of the pathognomonic ST elevation on the ECG. Quinidine (600 to 900 mg daily in three or four divided doses) is the only antiarrhythmic drug that appears to be useful to treat this syndrome. However, follow-up periods are not long enough to know whether catheter ablation or quinidine can obviate the need for an ICD in high-risk patients who have unprovoked Brugada pattern in their resting ECG and have a history of syncope.

Iatrogenic Ventricular Tachycardia

For sustained monomorphic VT in patients with surgically repaired congenital heart disease, catheter mapping and ablation are recommended. The techniques are similar to those used for catheter ablation of ischemic VT. Although sustained VT or VF during the course of left ventricular assist device therapy is usually well tolerated acutely, recurrent intractable VT or VF can result in right heart failure and in frequent ICD shocks, both of which may carry significant morbidity. Amiodarone (200 to 400 mg daily) and β-blocker therapy (e.g., metoprolol 100 to 200 mg daily) may be effective in at least rendering VT no longer incessant, and catheter ablation therapy has occasionally been tried in refractory VT with modest success.

PROGNOSIS

VT or VF in the early minutes or hours of acute MI has not been shown to affect the long-term prognosis in patients who survive to hospital discharge. Sustained monomorphic VT occurring after the hyperacute phase but within the next few days of an anterior wall MI portends poor prognosis, with about a seven-fold increase in subsequent mortality, because it usually occurs after the necrosis of a large amount of myocardium.

The modern natural course of untreated VT and VF perhaps can best be assessed from prospective studies of patients receiving ICD therapy. Among patients who have had documented sustained VT, appropriate ICD therapy for VT or VF occurs in about 70% of patients within 2 years and 85% of patients within 3 years. For patients who have survived cardiac arrest, the rate is about 70% at 3 years. These figures underscore the high rate of recurrence of VT and VF in patients with organic heart disease presenting with sustained ventricular arrhythmias.

The prognosis of patients with PVCs or nonsustained VT is less well known but is critically dependent on the underlying heart disease. No study to date has shown any survival benefit of treating PVCs or nonsustained VT in patients who do not have underlying organic heart disease and who do not develop a cardiomyopathy as a result of their ventricular ectopic activity. In high-risk patients who have ischemic heart disease, a left ventricular ejection fraction of less than 40%, and electrically induced sustained VT, the 2-year rate of cardiac arrest or death from ventricular arrhythmia is more than 30%.

54 ELECTROPHYSIOLOGIC PROCEDURES AND SURGERY

PETER A. SANTUCCI AND DAVID J. WILBER

TRANSTHORACIC CARDIOVERSION AND DEFIBRILLATION

Transthoracic defibrillation, which rapidly delivers a stored charge to the heart across two surface pads or paddle electrodes, is used emergently for life-threatening tachycardias (Chapter 50). Cardioversion, which refers to shock delivery synchronized with the QRS complex, is advised in patients with either supraventricular arrhythmias (Chapter 52) or ventricular tachycardia (VT; Chapter 53) because a nonsynchronized shock coincident with the vulnerable period of the T wave may precipitate ventricular fibrillation (VF). The shock extinguishes tachyarrhythmias by simultaneously depolarizing large portions of the atria and/or ventricles. Defibrillation is used for disorganized rhythms in which synchronization to the QRS complex is not appropriate, such as VF or rapid polymorphic VT. In these emergent situations, attempts to synchronize may delay delivery of the shock.

The success of cardioversion or defibrillation is affected by the shock waveform and shock strength. Biphasic shock waveforms are recommended because they are significantly more effective than monophasic waveforms at equivalent energies. Shock energies vary by indication and between defibrillator units but are generally from 50 to 360 J. Other technique-dependent variables that maximize the energy delivered to the heart include increasing paddle pressure, delivery of the shock during expiration, and repetitive shocks. Patient-related factors that may decrease the probability of successful cardioversion and defibrillation include metabolic disturbances, a longer duration of arrhythmia, cardiac enlargement, chronic obstructive pulmonary disease, barrel-chested habitus, and higher body weight. Elective cardioversion is performed with the patient in the fasting state, usually with a short-acting anesthetic agent.

PRECAUTIONS AND COMPLICATIONS

Cardioversion of atrial fibrillation (AF) and atrial flutter (Chapter 52) may be complicated by thromboembolism, but this risk can be minimized by excluding the presence of an atrial thrombus on a transesophageal echocardiogram or by therapeutic anticoagulation with a direct-acting anticoagulant for at least 3 weeks before elective cardioversion (see Fig. 52-14, and Chapters 52 and 70). All patients should be anticoagulated for 1 month after cardioversion if AF or atrial flutter has been present for longer than 48 hours.

VF may rarely occur even when shocks are synchronized to the QRS complex. The risk is increased with electrolyte disturbances and digitalis toxicity, so elective cardioversion should be delayed in such patients. Although patients may develop mild elevations of serum troponin levels after cardioversion, sometimes with transient ST segment elevation, clinical myocardial dysfunction is rare. Post-shock bradycardia or asystole sometimes can require atropine (0.5 to 3.0 mg intravenously) or emergency transcutaneous pacing. If a patient has a pacemaker or an implantable cardioverter-defibrillator (ICD), the shocking electrodes should be placed as far away from the generator as possible and at a right angle from the pacemaker leads if feasible. Both the generator and pacing threshold should be checked after the procedure.

CARDIAC IMPLANTABLE ELECTRONIC DEVICES

Pacemakers are implanted to eliminate bradycardia, and ICDs offer highly effective protection for life-threatening ventricular tachyarrhythmias (Chapter 53). Cardiac resynchronization pacing is an essential tool for managing heart failure (Chapter 46) and is available in devices with or without the capacity for defibrillation. Implantable loop recorders, which are the preferred approach for detecting occult, infrequent, and short-lived paroxysmal arrhythmias (Chapter 49), are especially useful for patients who have syncope or may have occult AF as the cause of a stroke.

Modern devices are highly programmable and provide a wealth of diagnostic information that the clinician can use to diagnose abnormalities and to tailor therapy. The diagnostic data regarding the device's performance and

If a patient has a pacemaker or an implantable cardioverter-defibrillator (ICD), the shocking electrodes should be placed as far away from the generator as possible and at a right angle from the pacemaker leads if feasible. Both the generator and pacing threshold should be checked after the procedure.

CARDIAC IMPLANTABLE ELECTRONIC DEVICES

Pacemakers are implanted to eliminate bradycardia, and ICDs offer highly effective protection for life-threatening ventricular tachyarrhythmias (Chapter 53). Cardiac resynchronization pacing is an essential tool for managing heart failure (Chapter 46) and is available in devices with or without the capacity for defibrillation. Implantable loop recorders, which are the preferred approach for detecting occult, infrequent, and short-lived paroxysmal arrhythmias (Chapter 49), are especially useful for patients who have syncope or may have occult AF as the cause of a stroke.

Modern devices are highly programmable and provide a wealth of diagnostic information that the clinician can use to diagnose abnormalities and to tailor therapy. The diagnostic data regarding the device's performance and

ABSTRACT

Interventional procedures and surgery have become commonplace and crucial in managing a variety of heart rhythm disorders. These approaches include cardioversion/defibrillation, implantable electronic devices, catheter and surgical ablation, and closure of the left atrial appendage. Cardiac resynchronization therapy is a critical tool in the management of patients who have heart failure with reduced ejection fraction and a widened QRS.

Catheter ablation has become a mainstay of treatment for patients suffering from many forms of tachyarrhythmias and symptomatic ectopy, including AV nodal reentry, reciprocating tachycardias due to accessory pathways, focal atrial tachycardias, typical and complex atrial flutters, paroxysmal and persistent atrial fibrillation, and ventricular tachycardia. Arrhythmia surgery is an option for atrial fibrillation, both for rhythm control and for the reduction of embolic risk, particularly in patients undergoing cardiac surgery for other reasons. Catheter-based left atrial appendage occlusion can reduce the risk of stroke in patients who have persistent atrial fibrillation and who are poor candidates for long-term anticoagulation.

the presence of arrhythmias can be routinely transmitted directly from home to the appropriate health care provider.

An important issue is the use of magnetic resonance imaging (MRI) in patients with an implanted cardiac device. Historically, such devices were considered a contraindication to MRI, but most newer devices and leads are now engineered to be classified as "MRI conditional." These patients can safely undergo MRI with appropriate management. Even patients with more modern MRI nonconditional devices often can safely undergo MRI for both thoracic and nonthoracic indications,[1] provided that the patients are appropriately screened and that their devices are reprogrammed according to standard protocols.[A1]

TEMPORARY PACING

Temporary pacing is used in patients who may not require long-term pacing as well as in emergencies, such as asystolic cardiac arrest (Chapter 50). Transcutaneous pacing with electrode pads applied to the chest wall may be the quickest option and can be life-saving, but it is uncomfortable and should be used sparingly. Usually, however, time allows for temporary pacemaker leads to be inserted percutaneously, typically through an internal jugular or subclavian vein, and to be positioned gently in the right ventricular apex, ideally under fluoroscopic guidance. Another indication for temporary pacing is to maintain a higher heart rate (typically 85 to 100 beats per minute) in order to suppress torsades de pointes (Chapter 53) until the causative factor, such as an offending drug, has been eliminated. Prophylactic temporary pacing is used in patients who have high-degree atrioventricular (AV) block in the setting of an acute myocardial infarction (Chapter 58) and for patients who are at a high risk for developing symptomatic bradycardia during an interventional or surgical cardiac procedure (e.g., during transcatheter aortic valve replacement; Chapter 60).

The most common complication of temporary pacing is infection. The risk can be minimized by proper sterile technique, limiting temporary pacing to 48 hours, or replacing the lead at that time under optimal sterile conditions.

PERMANENT PACING

Indications for Permanent Pacemaking for Bradycardias

Pacemakers are implanted either to alleviate symptoms caused by bradycardia or to prevent severe symptoms in patients in whom symptomatic bradycardia is likely to develop (Tables 54-1 and 54-2).[2] The most common bradycardia-induced symptoms are dizziness or lightheadedness, syncope or near-syncope (Chapters 39 and 49), fatigue, and heart failure. Exercise intolerance caused by a poor heart rate response to exertion (chronotropic incompetence) is another common indication. Because these symptoms can be nonspecific, documentation of an association between symptoms and bradycardia should be obtained whenever possible before a pacemaker is recommended.[3] In some patients, a simple electrocardiogram (ECG) may be sufficient to document the need for a pacemaker. If the bradycardia is intermittent, other diagnostic testing, such as 24-hour ambulatory monitoring, a continuous external or implantable loop recorder, an implantable event monitor, or an electrophysiology test (Chapter 49), may be needed to document a relationship between symptoms and bradycardia.

Correctable causes of bradycardia (Chapter 51) should be excluded. Examples include hypothyroidism (Chapter 207), electrolyte disturbances, and medications such as β-adrenergic blocking agents, calcium-channel blocking agents, digitalis, and antiarrhythmic medications (Chapters 51 and 52). Other temporary causes of bradycardia that may not require a permanent pacemaker include acute ischemia or infarction, perioperative bradycardia following cardiac surgery, and neurocardiogenic causes. Patients with sleep-related bradycardia or transient pauses do not generally warrant permanent pacing. At times, a pacemaker is necessary to allow continued treatment with a medication that is responsible for the bradycardia, such as an antiarrhythmic medication or an AV nodal blocking agent needed for AF with a rapid ventricular response.

Pacing Systems

Permanent pacing systems most commonly consist of a pulse generator connected with one to three leads implanted into the heart to sense intrinsic activity and to deliver pacing pulses as needed. Pacemaker leads are inserted percutaneously via the axillary or subclavian vein, or by cephalic vein cutdown. Less often, leads are placed epicardially during cardiac surgery. Atrial leads are often placed in the right atrial appendage, but they may be placed in a variety of locations, in part based on local electrical threshold measurements. Ventricular leads are typically positioned in the right ventricular apex, right ventricular septum, or outflow tract, and they are commonly secured in place with a helical screw, known as "active fixation," for biventricular pacing (Fig. 54-1).

TABLE 54-1 CLASS I INDICATIONS* FOR IMPLANTATION OF A PERMANENT PACEMAKER

SINUS NODE DYSFUNCTION
Symptomatic sinus bradycardia
Symptomatic chronotropic incompetence
Symptomatic sinus bradycardia resulting from required drug therapy
ATRIOVENTRICULAR BLOCK
Third-degree and advanced second-degree AV block associated with symptomatic bradycardia
Third-degree and advanced second-degree AV block in an awake patient with asystole of >3 seconds or an escape rate of <40 beats per minute or with an infranodal escape rhythm
Atrial fibrillation with a pause of ≥5 sec
Third-degree and advanced second-degree AV block due to postoperative AV block that is not expected to resolve
Third-degree and advanced second-degree AV block with neuromuscular diseases such as myotonic muscular dystrophy, Kearns-Sayre syndrome, and Erb dystrophy
Asymptomatic third-degree AV block if cardiomegaly or left ventricular dysfunction is present, or if the block is below the AV node
CHRONIC BIFASCICULAR BLOCK
Advanced second-degree or intermittent third-degree AV block
Type II second-degree AV block
Alternating bundle branch block
AFTER ACUTE PHASE OF MYOCARDIAL INFARCTION
Second-degree infranodal AV block with alternating bundle branch block
Third-degree infranodal AV block
Transient advanced second-degree or third-degree infranodal AV block and associated bundle branch block
Persistent symptomatic second-degree or third-degree AV block
CAROTID SINUS SYNDROME
Recurrent syncope caused by spontaneous carotid sinus stimulation or carotid sinus pressure that induces asystole of >3 sec in duration

*Class I indications are conditions for which a pacemaker is indicated.
AV = atrioventricular.
Adapted from Gillis AM, Russo AM, Ellenbogen KA, et al. HRS/ACCF expert consensus statement on pacemaker device and mode selection. *J Am Coll Cardiol*. 2012;60:682-703.

TABLE 54-2 CLASS IIA INDICATIONS* FOR IMPLANTATION OF A PERMANENT PACEMAKER

SINUS NODE DYSFUNCTION
Heart rate of <40 beats per minute when a clear association between symptoms consistent with bradycardia and the actual presence of bradycardia has not been demonstrated
Syncope of unclear etiology when sinus node dysfunction is demonstrated by electrophysiologic testing
ATRIOVENTRICULAR BLOCK
Persistent third-degree AV block with an escape rate of >40 beats per minute in an asymptomatic adult without cardiomegaly
Asymptomatic second-degree infranodal AV block
First-degree or second-degree AV block associated with symptoms similar to pacemaker syndrome
Asymptomatic type II second-degree AV block with a narrow QRS
CHRONIC BIFASCICULAR BLOCK
Syncope, when other potential causes of syncope have been excluded
An HV interval of ≥100 msec
Pathologic pacing-induced infranodal AV block during electrophysiologic testing
CAROTID SINUS SYNDROME
Syncope without clear provocative events and with asystole of >3 sec during carotid sinus pressure

*Class IIA indications are conditions for which a pacemaker is reasonable.
AV = atrioventricular; HV = His-ventricle.
Adapted from Tracy CM, Epstein AE, Darbar D, et al. 2012 ACCF/AHA/HRS focused update of the 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2012;60:1297-1313.

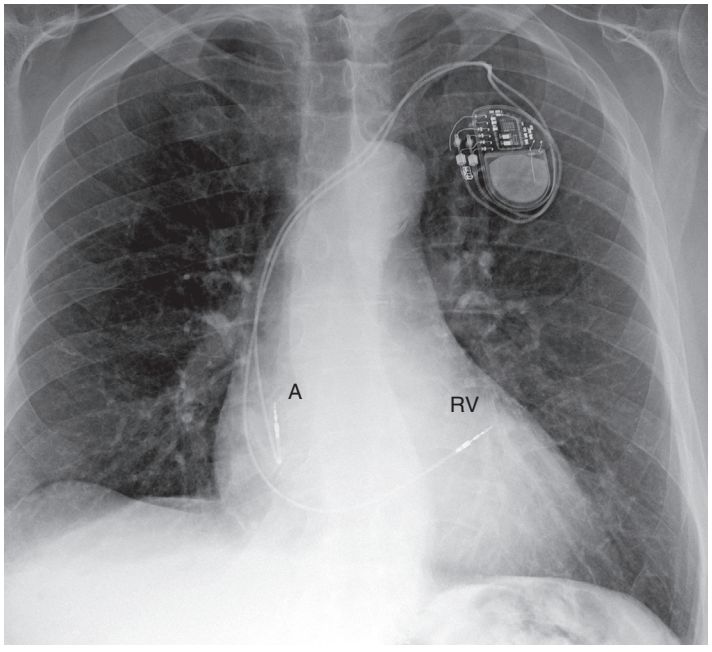

FIGURE 54-1. Chest radiograph of a patient with a dual-chamber (atrial and right ventricular) pacemaker.

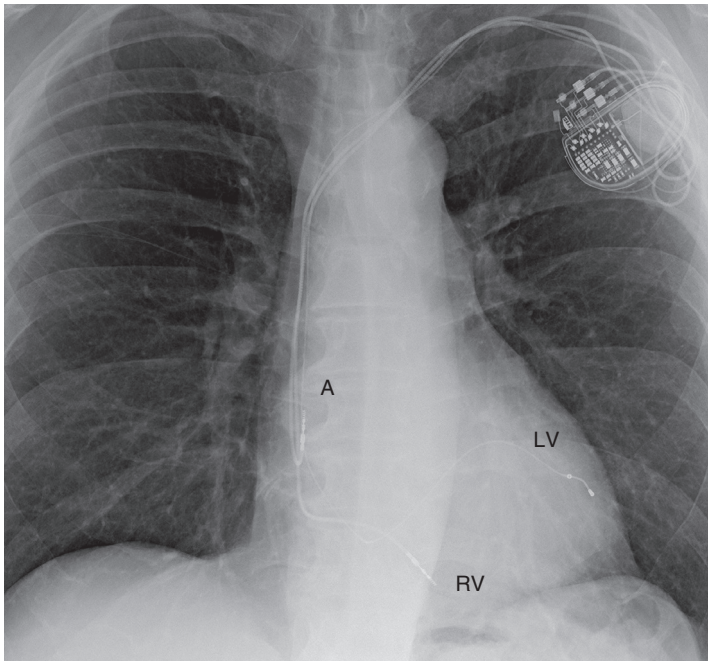

FIGURE 54-3. Chest radiograph of a patient with an atrial and biventricular pacemaker.

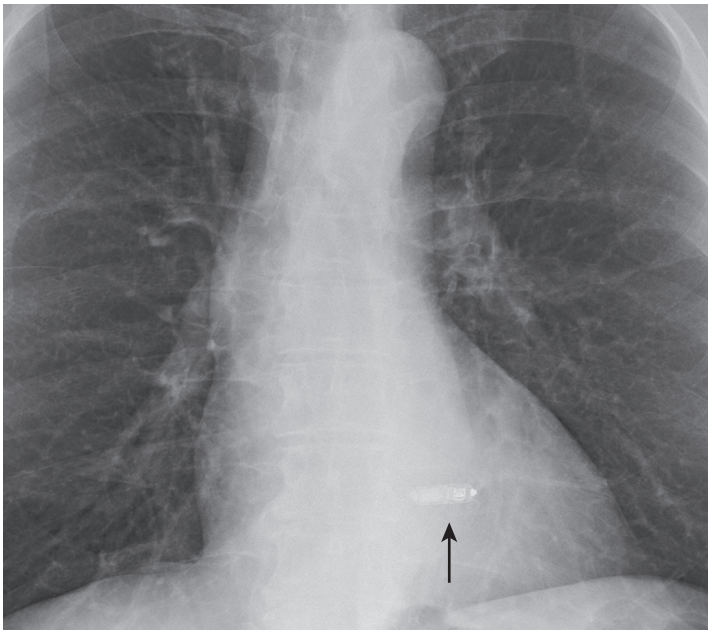

FIGURE 54-2. Chest radiograph of a leadless pacemaker (arrow) positioned in the right ventricle.

A leadless pacing system,[4] with a miniaturized generator and delivery system combined into a single unit, can be implanted, typically in the right ventricle (Fig. 54-2). These leadless pacemakers are commonly used in patients who have permanent AF and AV block. However, they also can frequently sense and track atrial mechanical activity to pace the ventricle while maintaining AV synchrony in patients with AV block and sometimes are used in patients who are in sinus rhythm with AV block.

With traditional systems, pulse generators are powered by lithium-based pacemaker batteries, which have an 8- to 12-year (or more) lifespan and can weigh less than 30 g. These generators typically are implanted subcutaneously in the infraclavicular region. The programmability of many different parameters has become standard, as has the ability of the pacemaker to provide diagnostic and telemetric data.

Synchronous biventricular pacing can preserve the ventricular synchrony that is lost when only one ventricle is paced and the other's activation is delayed. The usual option is biventricular pacing with one lead in the right ventricle and one in the coronary venous system to pace the lateral left ventricle (Fig. 54-3), typically with an atrial lead in patients who are not in permanent atrial fibrillation. Permanent His-bundle pacing is also increasingly being used to maintain the patient's intrinsic conduction system, thereby avoiding ventricular dyssynchrony.[5] Yet another emerging option for physiologic pacing is left bundle branch area pacing, which may produce lower and more stable pacing thresholds in some patients.[A2] Each paced beat will have a configuration that depends on the site of the pacing lead (Fig. 54-3).

Pacing Modes and Programming

Pacing modes are described by a simple code. The first letter represents the chamber being paced (A for atrium, V for ventricle, D for dual chamber). The second letter identifies the chamber whose depolarizations are being sensed by the pacemaker (A, V, D, or O for no sensing). The third letter indicates whether the pacemaker is functioning in an inhibited (I) mode, a tracking (T) mode, in both modes (D), or asynchronously (O). The fourth letter designates whether the pacemaker can modulate the pacing rate, usually by increasing pacing rates with physical activity (R).

The most appropriate pacing mode must be determined for each individual and may change with the patient's status. By far the most common permanent pacing modes now used in the United States are DDD and DDDR. VVI and VVIR modes are used mainly in patients who have chronic AF with symptomatic pauses or bradycardia. Mode-switching pacemakers can pace in the DDD mode during sinus rhythm and automatically switch to rate-responsive (VVIR) ventricular pacing during paroxysmal AF or other supraventricular arrhythmias. Automatic mode switching from AAI(R) to DDD(R) is also available for patients with sinus node dysfunction and intermittent AV block.

Many patients' devices are programmed at settings chosen to minimize the right ventricular pacing burden, not only to conserve the battery, but also to reduce pacing-induced ventricular dyssynchrony, which sometimes can lead to impaired ventricular function. This potential side effect is particularly a concern in patients who have a normal intrinsic QRS duration and then undergo single-chamber right ventricular pacing. However, in patients who require resynchronization therapy, a very high percentage of ventricular pacing is the goal.

In patients with sinus node dysfunction, atrial or dual-chamber pacing significantly reduces the risk for AF and improves quality of life compared with ventricular pacing. Because such patients are at substantial risk of symptomatic AV block, initial dual-chamber pacing is commonly used, although atrial pacing alone is an option for selected patients with normal AV conduction. Because chronotropic incompetence is frequent in this patient population, a rate-responsive mode (AAIR or DDDR) is usually recommended. In patients with AV block, dual-chamber pacing improves quality of life, reduces the risk for developing AF, and avoids the 7 to 25% risk for developing the pacemaker syndrome, which consists of symptoms of weakness, lightheadedness, exercise intolerance,

or palpitations owing to the absence of AV synchrony during single-chamber ventricular pacing. For these reasons, current consensus guidelines recommend dual-chamber pacing for most patients with sinus node dysfunction or AV block.

Synchronous biventricular pacing or His-bundle pacing is preferred in bradycardic patients who have a left ventricular ejection fraction of 50% or below and who are expected to need pacing for more than 40% of their heartbeats. With atrial pacing, this synchrony can simulate normal cardiac function. In patients who require permanent pacing, the risk of future ventricular arrhythmias guides the need for simultaneous insertion of an implantable cardioverter defibrillator.

The electrocardiogram of paced patients depends on the site and frequency of pacing (Fig. 54-4)

COMPLICATIONS OF PACEMAKERS

Complications can be either acute or late. About 1 to 2% of patients develop acute complications from the implantation procedure itself, including infection,[6] pneumothorax, cardiac tamponade owing to pericarditis or perforation of the atrium or ventricle, lead dislodgement, subclavian vein thrombosis, and pocket complications. The subcutaneous pocket may develop a hematoma, seroma, dehiscence, or local infection. Pocket hematomas can be painful and increase the risk of infection. Their occurrence can be minimized by meticulous operative technique and postoperative care, as well as by interrupting anticoagulation when feasible. In patients who require uninterrupted anticoagulation, a strategy of continued oral anticoagulant treatment at the time of implantation of a pacemaker or an ICD markedly reduces the incidence of clinically significant device-pocket hematoma compared with bridging therapy with heparin.

Late complications include venous thrombosis or obstruction (including the superior vena cava syndrome; Fig. 86-8), the pacemaker syndrome, pacing-induced ventricular dyssynchrony that can cause heart failure, infection, and various forms of pacemaker malfunction. The latter include failure to pace, failure to capture, and sensing abnormalities, most often resulting

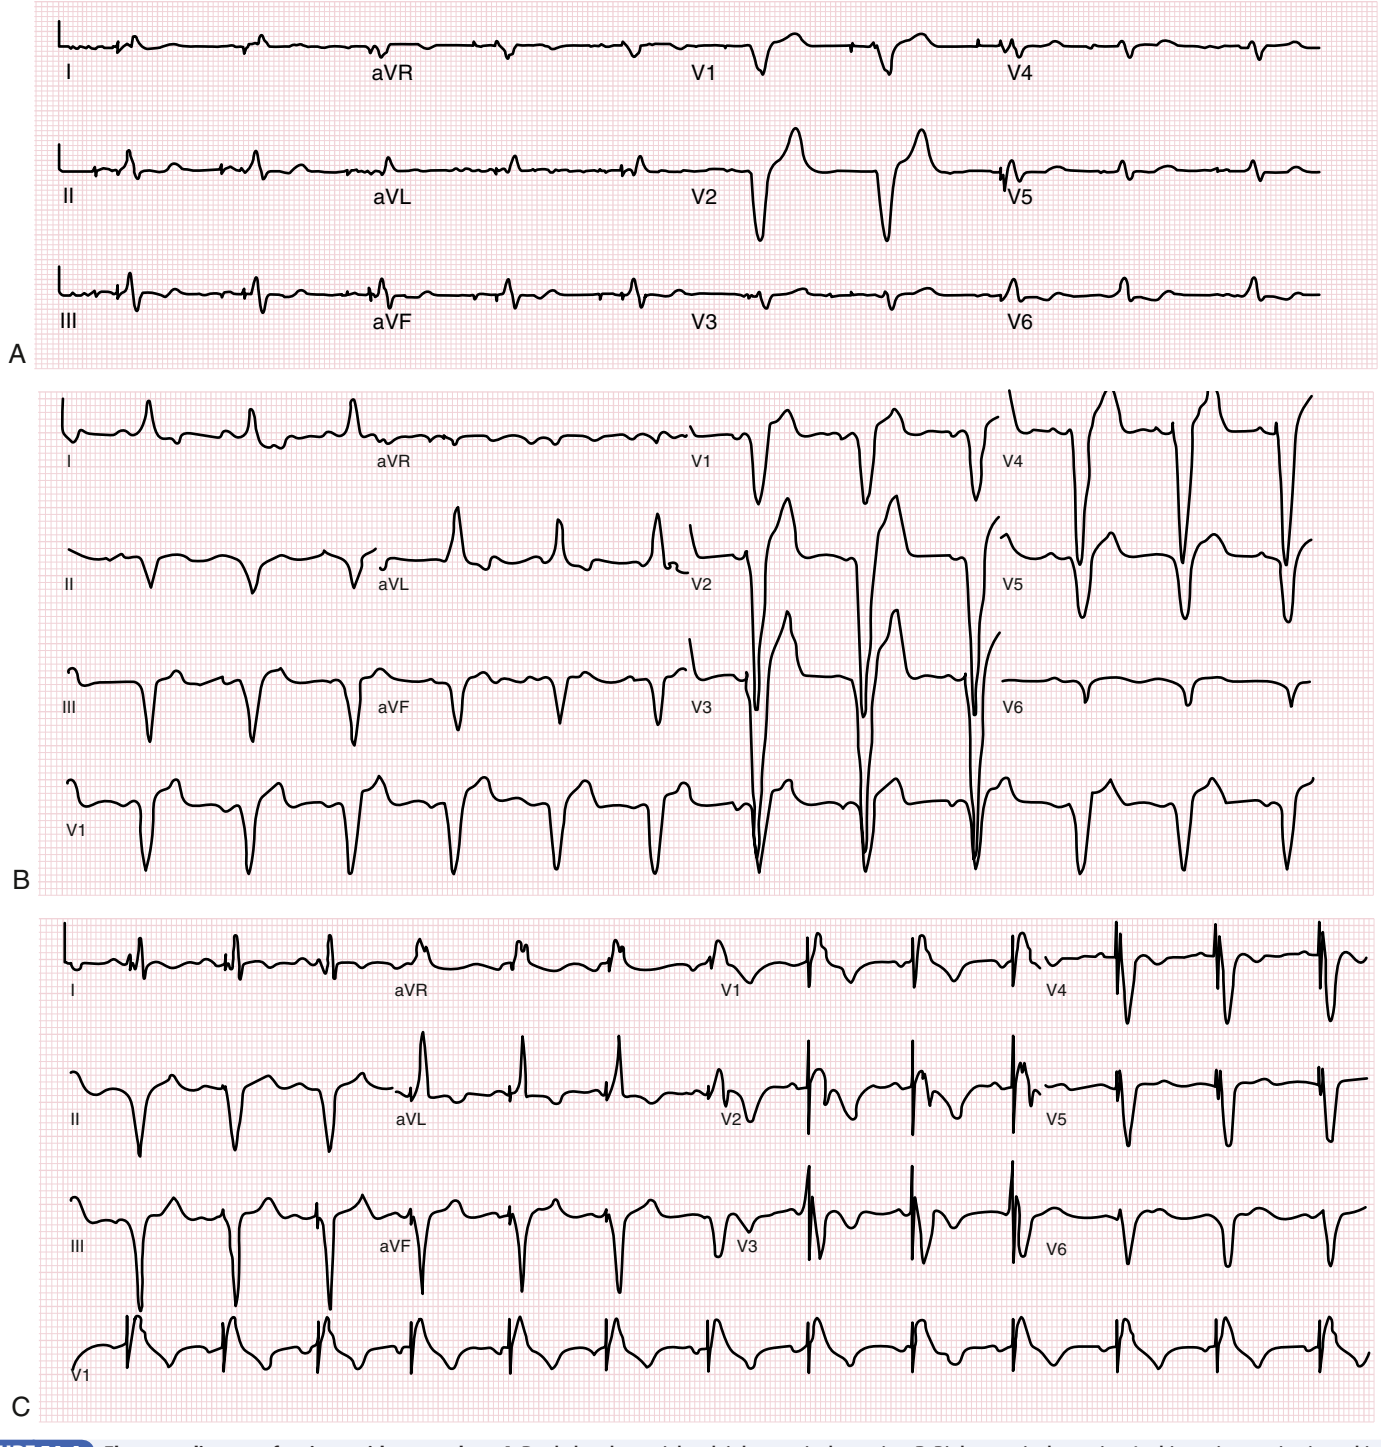

FIGURE 54-4. Electrocardiogram of patients with pacemakers. A, Dual-chamber atrial and right ventricular pacing. **B,** Right ventricular pacing. In this tracing, pacing is tracking the sinus P waves that are sensed with an atrial lead (with a single-chamber ventricular pacemaker, the P waves would be dissociated). **C,** Same patient after being upgraded to a biventricular pacemaker. Note the changes in lead V_1 and V_2 and the partial narrowing of the QRS that are often seen by adding simultaneous pacing of the left ventricle.

from lead abnormalities (conductor fractures, insulation breaks or changes at the lead-tissue interface). Pacemaker infections typically involve primarily the subcutaneous pacemaker pocket, but long-term resolution of infection generally requires removal of both the pulse generator and leads as well as extended antibiotic therapy (Chapter 61). Nearly 40% of patients have coexisting valve involvement, predominantly tricuspid valve infection (Chapter 61), with mortality rates as high as 15% in the hospital and 20 to 25% at 1 year. Less commonly, pulse generator malfunctions, including premature battery depletion, may occur. Long-term problems may also result from inappropriate programming. The emerging use of leadless pacing eliminates many of the risks of conventional pacing systems and is becoming increasingly common as experience grows and the technology advances.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS AND CARDIAC RESYNCHRONIZATION THERAPY

Abnormal and prolonged ventricular activation, indicated by a QRS duration greater than 120 msec, may cause dyssynchronous activation of the left ventricle and, as a result, diminished systolic function. Right ventricular pacing, particularly from the apex, also is associated with a delayed activation sequence and, as a result, interventricular and intraventricular mechanical dyssynchrony. Cardiac resynchronization therapy requires synchronized pacing of both ventricles or physiologic pacing by means of His-bundle pacing or left bundle branch pacing.[7]

Implantable Cardioverter-Defibrillators

Indications

ICDs are a highly effective method for detecting and terminating life-threatening ventricular arrhythmias (Chapter 53). They are used both for secondary prevention following an episode of sustained VT or VF and for primary prevention in individuals at high risk for sudden cardiac death (Table 54-3). Examples include patients with ischemic or nonischemic dilated cardiomyopathy with a left ventricle ejection fraction of 35% or less and class II or III heart failure,[A3] as well as selected patients with conditions such as hypertrophic cardiomyopathy, Brugada syndrome, and long QT syndrome (Chapters 47, 53, and 58).[8]

ICD Pulse Generators and Leads

Procedures for implanting transvenous ICDs are analogous to those used for permanent pacemakers. The pulse generators, although still somewhat larger than pacemakers (with some models now <1 cm in thickness, <28 mL in volume, and around 60 g), deliver biphasic shocks at programmable energies while recording the electrogram during the arrhythmia and its treatment (E-Fig. 54-1). They also can provide anti-tachycardia pacing, as well as dual-chamber bradycardia pacing or cardiac resynchronization pacing therapy.

ICD implantation and lead configuration (Figure 54-5) are designed to deliver sufficient energy to the ventricular myocardium to ensure reliable defibrillation. The most common pathway for this energy is from the implanted pectoral pulse generator to a coil electrode on the distal portion of the transvenous lead that is positioned in the right ventricle (E-Fig. 54-2). The majority of transvenous ICD pulse generators can deliver up to 30 to 40 J, which exceeds the typical defibrillation energy threshold of 10 to 15 J, thereby allowing a substantial margin of safety for defibrillation.

An alternative to a transvenous ICD is the subcutaneous ICD.[9] However, subcutaneous systems currently have a larger pulse generator, somewhat shorter battery longevity, and do not provide usual bradycardic, anti-tachycardic, or resynchronization pacing therapy. The pulse generator must deliver higher stored energy (80 J) compared with transvenous defibrillation to ensure an adequate margin of safety for defibrillation, but data show that the device's effectiveness for sensing and terminating VF is comparable to that of transvenous systems.[A4] It is an attractive option for patients who have had prior complications from transvenous systems (e.g., vein thrombosis, infection) or issues with intravenous access, as well as for primary prevention in patients in whom frequent shocks or the need for pacing are not anticipated. However, the choice of an ICD system must be individualized to a patient's overall needs.

Programming of ICDs

The goals of ICD programming are to provide the appropriate detection of all arrhythmias, the discrimination of ventricular from supraventricular rhythms, and appropriate anti-tachycardia pacing and shocks only when needed for sustained arrhythmias. The shocks are programmed to provide an adequate margin of safety for reliable cardioversion and defibrillation. In addition, bradycardic pacing therapy should be optimized to provide an appropriate heart rate response to exertion while minimizing right ventricular pacing. Conversely, the ventricles are ideally paced for all beats in patients in whom cardiac resynchronization (see later) is needed.

ICD recipients may have sustained monomorphic VT that can be painlessly terminated by appropriately timed, overdrive anti-tachycardia pacing. ICD shocks

TABLE 54-3 INDICATIONS FOR IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR IMPLANTATION

CLASS I*: SECONDARY PREVENTION
Cardiac arrest survivor (VF or unstable sustained VT not associated with a completely reversible cause)
Spontaneous sustained VT (irrespective of stability) and structural heart disease
Syncope of unknown origin associated with clinically relevant and hemodynamically significant sustained VT or VT induced at electrophysiologic testing
CLASS I*: PRIMARY PREVENTION
Prior myocardial infarction (≥40 days), LVEF <35%, NYHA class II or III
Prior myocardial infarction (≥40 days), LVEF <30%, NYHA class I
Nonischemic dilated cardiomyopathy, LVEF ≤35%, NYHA class II or III
Prior myocardial infarction, LVEF <40%, spontaneous NSVT, inducible sustained VT or VF at electrophysiologic testing
CLASS IIA†
Nonischemic dilated cardiomyopathy, significant LV dysfunction, and syncope
Sustained VT and normal or near-normal ventricular function
Hypertrophic cardiomyopathy and one or more risk factors for sudden death
Arrhythmogenic right ventricular cardiomyopathy and one or more risk factors for sudden death
Long QT syndrome with syncope or VT despite β-blocker therapy
Nonhospitalized patients awaiting cardiac transplantation
Brugada syndrome and syncope or VT
Catecholaminergic polymorphic VT and syncope or VT on β-blocker therapy
Cardiac sarcoidosis, giant cell myocarditis, or Chagas disease

*Class I indications are conditions for which an implantable cardioverter-defibrillator is indicated.
†Class IIA indications are conditions for which an implantable cardioverter-defibrillator is reasonable.
LVEF = left ventricular ejection fraction; NSVT = nonsustained ventricular tachycardia; NYHA = New York Heart Association; VF = ventricular fibrillation; VT = ventricular tachycardia.

are uncomfortable and are not intended for routine conversion of more benign tachycardias. Optimal anti-tachycardia pacing can successfully terminate VT without a shock while also minimizing the risk that it will accelerate into VF.

ICDs incorporate a variety of programmable discrimination algorithms designed to withhold unnecessary therapies for brief episodes of rapid supraventricular arrhythmias, especially sinus tachycardia or AF. In addition, many ventricular arrhythmias will self-terminate within seconds, so algorithms designed to delay therapy for a short time can reduce unnecessary shocks. Optimal programming reduces the patient's discomfort, maximizes the life of the pulse generator battery, and reduces the potential adverse effects of unneeded shocks. Incorporating higher rate cutoffs, detection delay, rhythm discriminators, and anti-tachycardia pacing can reduce inappropriate device shocks by 50% and mortality by 30% compared with standard ICD programming, without significantly increasing the risk for syncope. Many athletes with ICDs can engage in vigorous and competitive sports without physical injury or failure to terminate the arrhythmia.

Indications for Cardiac Resynchronization Therapy

Resynchronization therapy promotes more synchronous ventricular contraction and results in "reverse remodeling" with a reduction in ventricular volumes, improved systolic function, and clinical improvement in heart failure (Chapter 46). In clinical trials of patients with reduced systolic function, QRS duration longer than 120 msec, and class III or ambulatory class IV heart failure, the addition of cardiac resynchronization therapy to guideline-directed medical therapy is associated with an approximately 30% reduction in hospitalizations and a 24 to 36% reduction in total mortality. Functional improvement in heart failure symptoms and quality of life is seen in a majority of patients, but 30 to 40% of patients may not improve symptomatically. Superior outcomes are associated with longer QRS durations (>150 msec) and a left bundle branch block QRS configuration, whereas patients with imaging-identified mechanical dyssynchrony alone, in the absence of QRS prolongation, do not improve.

Clinical trials have also established that the benefit of cardiac resynchronization therapy extends to patients with less severe heart failure symptoms (class I or II), in whom it appears to delay the onset of symptomatic heart failure and significantly reduce heart failure events over the next 1 to 7 years if the ejection fraction is 30% or less and the QRS duration is more than 130 msec, especially in patients with left bundle branch block. As noted previously, cardiac resynchronization therapy is also recommended for the treatment of bradycardia in patients who have a left ventricular ejection fraction of 50% or less and who likely will have more than 40% paced beats. The role of physiologic His-bundle and left bundle branch pacing continues to evolve. Evidence suggests the clinical results match or exceed those of biventricular pacing.[10] Current accepted usage largely follows indications for cardiac resynchronization therapy (Table 54-4).

TABLE 54-4 INDICATIONS FOR IMPLANTATION OF A CARDIAC RESYNCHRONIZATION THERAPY (CRT) DEVICE

CLASS I INDICATIONS*
LVEF ≤35%, sinus rhythm, LBBB (≥150 msec), NYHA class II, III, or ambulatory class IV on guideline-directed medical therapy
CLASS IIA INDICATIONS†
LVEF ≤35%, sinus rhythm, LBBB (120-149 msec), NYHA class II, III, or ambulatory class IV on guideline-directed medical therapy
LVEF <35%, sinus rhythm, non-LBBB (≥150 msec), NYHA class III or ambulatory class IV on guideline-directed medical therapy
LVEF ≤35%, atrial fibrillation, on guideline-directed medical therapy, and both: • Requires ventricular pacing or otherwise meets CRT criteria • Near 100% pacing with CRT can be achieved by either atrioventricular node ablation or pharmacologic rate control
LVEF ≤35% on guideline-directed medical therapy and are undergoing new or replacement device implantation with anticipated requirement for significant (>40%) ventricular pacing
In patients who have atrioventricular block, an indication for permanent pacing, a left ventricular ejection fraction between 36 and 50%, and are expected to require ventricular pacing more than 40% of the time, it is reasonable to choose pacing methods that maintain physiologic ventricular activation (e.g., cardiac resynchronization therapy or His bundle pacing) rather than right ventricular pacing.

*Class I indications are conditions for which CRT is indicated.

†Class IIA indications are conditions for which CRT is reasonable.

LBBB = left bundle branch block; LVEF = left ventricular ejection fraction; NYHA = New York Heart Association (functional class).

Combined Resynchronization and Cardioverter Defibrillator Therapy

In patients who meet criteria for both cardiac resynchronization therapy and an ICD, implantation of a device with both functions (CRT-D) may provide additional mortality benefit. The burden of comorbidity does not appear to compromise the clinical benefits of cardiac resynchronization therapy plus an ICD compared with an ICD alone.[A5] However, cardiac resynchronization therapy alone may be appropriate for some patients with more advanced heart failure, extensive comorbidity, and limited life expectancy when the primary objective is symptomatic improvement, and the added value of defibrillation is not desired or less clear.[A6]

Complications

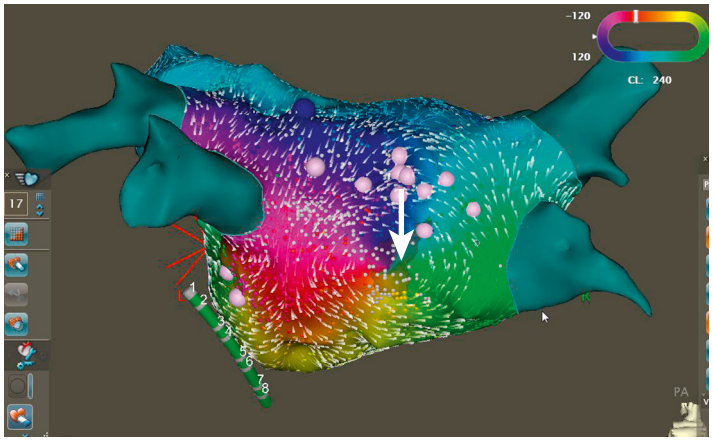
Many of the complications related to ICDs and cardiac resynchronization therapy are similar to those associated with pacemakers. Overall, major complications occur in 2 to 3% of new ICD implants and are more common during pulse generator replacement (5 to 6%). Use of an absorbable antibiotic-eluting envelope can significantly reduce the risk of major infection and should be considered in patients at high risk.[A7]

Long-term complications are primarily related to late infection and lead failure. Given their larger size and complexity, ICD leads are more likely to fail (1 to 4% annually) than are pacemaker leads (<0.5% annually). Lead failure is most often due to insulation failure or fracture of the conductor wires. Cardiac resynchronization therapy devices have the highest likelihood of procedure-related complications or lead dislodgement, predominantly owing to dislodgement of the coronary sinus lead. Phrenic nerve stimulation, which may occur with left ventricular pacing, manifests as a left-sided thumping sensation that is generally palpable; it can often be corrected with programming adjustments. In underserved countries, a resterilized pacemaker or defibrillator can be implanted with infection and failure rates similar to new devices.[11]

Although an occasional therapeutic ICD discharge is common, flurries of discharges require urgent evaluation to determine the cause. Such causes can range from flurries of VT or VF, which may have a correctable precipitant (e.g., an electrolyte imbalance, drug toxicity), to AF or another supraventricular tachycardia (SVT) with a rapid ventricular response, lead fracture, or insulation failure. An important consideration is the potential psychological impact of ICD shocks, and some patients may require psychiatric help in managing anxiety after receiving one or more shocks. In some cases, antiarrhythmic drug therapy (see Tables 52-2 and 52-3), catheter ablation, or both may reduce or eliminate the arrhythmias associated with frequent shocks (Chapter 53).

CATHETER ABLATION

Catheter ablation is a common and often preferred method for treating various forms of tachycardia. For appropriate arrhythmias, ablation often has higher success rates and is more definitive when compared with medical therapy. In addition, the treatment can be curative for some arrhythmias and avoid the need for chronic medication or future urgent intervention. Ablation is used for arrhythmias that depend upon a critical anatomic site, region, or regions of myocardial tissue that can be selectively necrosed to eliminate the arrhythmia. Depending on the arrhythmia, the target sites for ablation may be selected based on location, by substrate, by a local electrogram during a diagnostic electrophysiologic study (Chapter 49), by various mapping techniques, or by the response to maneuvers during an episode of sustained tachycardia. For some arrhythmias, reproduction of the clinical arrhythmia during diagnostic electrophysiologic testing (Chapter 49) is critical and can be facilitated by judicious use of sedation and intravenous infusion of catecholamines or other agents. Electroanatomic mapping has facilitated the ablation of many forms of tachyarrhythmias, allowed for substantial reductions in the need for fluoroscopy, and enabled ablation of complex arrhythmias with good success rates (E-Fig. 54-3).



E-FIGURE 54-3. Electroanatomic map of an atypical atrial flutter around a scar *(arrow)* on the posterior left atrium. Catheter ablation restored sinus rhythm.

TISSUE EFFECTS OF APPLIED ENERGY

Catheter ablation is performed by several means, including radio frequency energy, cryoablation, and laser ablation. The most common form uses radio frequency energy, typically in the range of 300 to 750 kHz, applied in a unipolar fashion between a small catheter-tip electrode in contact with the targeted myocardium and a large dispersive cutaneous patch electrode. Irreversible myocyte injury occurs with a tissue temperature higher than 50° C, with visually apparent tissue destruction at higher than 60° C. Saline irrigation of the electrode reduces heating at the tissue-electrode interface, allows for higher energy delivery when needed, moves the zone of maximal heating deeper into the tissue, and thus can allow for larger and deeper lesions with less risk of surface char and coagulum. Among other energy sources, cryoablation is the most widely used, whereas laser, microwave, and ultrasound have limited applications at present. Pulsed field ablation, which is still investigational, utilizes non-thermal electrical fields that are rapid and tissue-selective, thereby potentially reducing the risk of collateral injury.[12]

The most common serious complication of ablation is cardiac tamponade, owing to mechanical perforation of the heart by an electrode catheter. Rarely, high-degree AV block can occur when the target is near the AV node. Pulmonary vein stenosis is a rare complication of AF ablation. Also, depending on the type of ablation, collateral injury may occur to a phrenic nerve, the esophagus, or other nearby tissues. When epicardial ablation is performed, usually via percutaneous subxiphoid pericardial access, the coronary arteries could potentially be injured if ablation is delivered too nearby.

CATHETER ABLATION OF SUPRAVENTRICULAR TACHYCARDIAS

Catheter ablation is the recommended first-line treatment for paroxysmal SVT, Wolff-Parkinson-White (WPW) syndrome, or typical atrial flutter that is symptomatic enough to warrant therapy (Chapter 52). For atypical atrial flutters, ablation is becoming more common as success rates now approach those for typical atrial flutter. Ablation is rarely recommended for inappropriate sinus tachycardia because outcomes are less predictable, often partial, and may result in undesired sinus node dysfunction.

AV nodal re-entrant tachycardia (Chapter 52), which is the most common type of paroxysmal SVT, is successfully eliminated in 98% of cases (with a <1% risk for high-degree AV block), usually by radio frequency ablation of the "slow" limb of the re-entry circuit, most often at the posteroseptal aspect of the right atrium.

Accessory pathways are the next most common cause of paroxysmal SVT and can be due to manifest accessory pathways showing preexcitation (WPW syndrome) or concealed pathways that conduct only in retrograde fashion (no preexcitation on an ECG). Left-sided accessory pathways are ablated by using either a retrograde aortic or a transseptal approach, whereas right-sided and septal lesions are ablated with a venous approach. Detailed mapping is essential to identify the optimal site to ablate the accessory pathway, usually on either the atrial or the ventricular aspect of the mitral or tricuspid annulus. For the ablation of an accessory pathway, the success rate is 90 to 98%, with an overall complication rate of 2 to 3% and a less than 0.1% risk for a fatal complication.

Atrial tachycardias often arise in the right atrium and are mapped using a venous approach, but left atrial tachycardias require a transseptal approach. Approximately 10 to 20% of patients with atrial tachycardia have more than one focus and may be associated with other forms of SVT, particularly AV nodal re-entrant tachycardia. If the atrial tachycardia originates from a single site, ablation has about a 90% success rate, and complications are rare. For patients with multiple sources of atrial tachycardia, long-term success rates are lower.

Typical atrial flutter (Chapter 52), which arises in the right atrium, can be eliminated by ablation directed at a critical isthmus located in the low right atrium, between the tricuspid annulus and the inferior vena cava. The long-term success rate is more than 90%, with a less than 1% risk for serious complications.

ABLATION FOR ATRIAL FIBRILLATION

The primary aim of ablation for AF currently is to reduce the burden of recurrent episodes of AF in patients with symptoms and thereby to improve quality of life. Catheter ablation of AF has been effective in treating paroxysmal, persistent, and long-standing persistent (>1 year) AF. The optimal approach for the ablation of AF (Chapter 52) is an area of active investigation, but pulmonary vein isolation remains the cornerstone of most AF ablation procedures. For patients with recurrent paroxysmal AF, a primary driver of the arrhythmia is from focal sources in the regions surrounding the proximal portions of the pulmonary vein and sometimes other thoracic veins as they insert into atrial myocardium. Focally triggered arrhythmias may arise from other right and left atrial sites in 10 to 20% of patients.

For patients with recurrent symptomatic paroxysmal AF despite at least one antiarrhythmic drug trial, catheter ablation significantly reduces the risk for recurrent atrial arrhythmias by 50 to 70% and significantly improves quality of life compared with continued attempts to control the arrhythmia with alternative drug therapy.[13,14] The strategy of early intervention to maintain sinus rhythm (including ablation and/or antiarrhythmic drugs) may reduce mortality and stroke compared with standard medical care[A8] (see Chapter 52). First-line ablation therapy, without the requirement for prior antiarrhythmic drug failure, results in similar improvements and may lead to lower rates of recurrences.[A9–A11] For patients with symptomatic heart failure, and especially for patients who require an ICD or cardiac resynchronization therapy, catheter ablation is clearly the preferred initial therapy because it reduces all-cause mortality.[A12–A14]

Because AF is a progressive disease, however, the window of opportunity for intervention to prevent progression from paroxysmal to permanent AF or to prevent stroke, heart failure, or death may be limited. In patients with persistent AF, pulmonary vein isolation is also commonly performed early after diagnosis because it is less successful in patients with persistent AF of longer than 1 year's duration.[15]

Due to limited responses with pulmonary vein isolation alone, a variety of additional ablation targets have been tried, with mixed and often disappointing results. However, low-voltage myocardium-guided ablation can be helpful in selected patients.[A15]

Overall, the 1-year success rate of catheter ablation is 75 to 85% for paroxysmal AF and 60 to 75% for persistent AF. The most serious complications of AF ablation are atrial perforation, thromboembolism, and atrioesophageal fistula, with an overall risk of about 2%. Other complications are phrenic nerve injury, pulmonary vein stenosis, or vascular access issues. Left atrial macro-re-entrant arrhythmias, which can be a sequela of AF ablation, may require additional ablation.

In patients with refractory AF associated with an uncontrolled ventricular rate despite pharmacologic AV node blockade, ablation of the AV node can improve symptoms, functional capacity, and left ventricular function. In AV node ablation, third-degree AV block is intentionally induced with a success rate that approaches 100%. When the ablation lesions are placed sufficiently proximal in the AV junction, a junctional escape rhythm usually can be preserved. All patients require a permanent pacemaker to provide adequate rate response to physical activity.

ABLATION OF VENTRICULAR ARRHYTHMIAS

Ablation to manage ventricular arrhythmias is most commonly used for sustained VT, idiopathic monomorphic VT, and VT associated with structural heart disease, including ischemic cardiomyopathy, nonischemic dilated cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, sarcoidosis, congenital heart disease, and the Brugada syndrome.[16] However, it also may be used in selected patients with ventricular fibrillation or frequent premature ventricular contractions.

Ablation for the treatment of idiopathic VT carries a high (85% to 100%) success rate (Chapter 53), whether it arises in the outflow tract of the right ventricle or arises from other sites, including the AV valve annuli, the sinuses of Valsalva, the left ventricular septum, or the papillary muscles. Given these outcomes, ablation is recommended in symptomatic patients, either after failure of initial drug therapy or as first-line therapy, depending in part on the patient's preference. Complications are rare, and patients can usually avoid medications or an ICD.

By comparison, VT in patients with coronary artery disease and other forms of structural heart disease usually arises in diseased tissue in either ventricle. In patients with a prior myocardial infarction, ablation is often performed endocardially adjacent to or within an area of previous infarction in the left ventricle (E-Fig. 54-3). In patients with recurrent VT despite antiarrhythmic medications, VT ablation is more effective than an escalation of drug therapy.[A16]

In other forms of structural disease, percutaneous epicardial ablation may be needed. Ablation may not always be curative, but it may markedly diminish the frequency of VT episodes and reduce discharges of an ICD. Success rates range from 65 to 95%, with serious complications in about 5% of patients.

Although radio frequency catheter ablation is the most common method, other forms of ablation are sometimes used. An emerging noninvasive option is ablation via electrophysiology-guided stereotactic body radiotherapy.[17]

ARRHYTHMIA SURGERY

ATRIAL FIBRILLATION

Surgical ablation of AF can involve isolation of the pulmonary vein or a full biatrial Maze procedure, in which a series of incisions or linear lesions created by cryoablation or radio frequency ablation subdivides the atria into smaller segments unlikely to sustain AF. The most common current indication for the Maze procedure is the treatment of symptomatic AF in patients undergoing other cardiac surgical procedures, such as coronary revascularization or valve replacement or repair. AF surgery added to mitral valve surgery significantly reduces the recurrence of AF in patients with persistent or long-standing persistent AF. A variety of simpler and even minimally invasive operative procedures have been developed for AF, but their long-term efficacy and role in the treatment of AF are still being defined.

VENTRICULAR TACHYCARDIA

Surgical treatment by subendocardial resection or cryoablation of scar tissue (Chapter 53) in patients with a prior myocardial infarction can eliminate VT in selected patients (E-Fig. 54-4), with a success rate of 85 to 90%, but it carries an operative mortality rate of 5 to 15% even in experienced centers. Because of this high mortality and the development of catheter-based techniques, this procedure is generally limited to patients who have refractory VT or who have recurrent VT and other indications for cardiac surgery, such as large aneurysms associated with heart failure or the need to implant a left ventricular assist device.

CLOSURE OF THE LEFT ATRIAL APPENDAGE

The left atrial appendage, where blood tends to stagnate, is by far the most common site of origin for thromboembolism in patients with AF. Occlusion, removal, or isolation of the left atrial appendage can protect patients from stroke and thromboembolic events. In patients who are not suitable candidates for long-term anticoagulation (typically due to a propensity for bleeding or to poor adherence), occlusion of the left atrial appendage is at least as efficacious and safe as persisting with anticoagulation.[A17] The most widely used technique deploys an endocardial occlusion device, inserted percutaneously via transeptal puncture to the ostium of the left atrial appendage. After endothelialization of the luminal surface, these devices generally do not require long-term anticoagulation. Risks include dislodgement, residual leaks, and device-related thrombus. In patients who have AF and are undergoing cardiac surgery for another indication, epicardial closure of the left atrial appendage (amputation, stapling, or clip) can significantly reduce the risk of ischemic stroke or systemic embolism compared with anticoagulation alone during a mean follow-up of nearly 4 years.[A18]

55 CONGENITAL HEART DISEASE IN ADULTS

JUDITH THERRIEN AND ARIANE J. MARELLI

The convergence of major progress in medicine, pediatrics, and cardiovascular surgery has resulted in the survival of an increasingly large number of adult patients with congenital heart disease. An estimated 2.4 million people are currently living with congenital heart disease in the United States, two thirds of whom are adults. Adult care providers are becoming increasingly responsible for these patients, commonly in concert with a cardiologist and a tertiary care facility.

EPIDEMIOLOGY

Congenital heart defects are diagnosed in approximately 1% of births in the United States. An overall prevalence of 3 to 4 per 1000 adults has been documented. The median age of patients with *severe* lesions has increased from childhood to late adolescence. Advances in medical and surgical therapy have increased the survival of patients with congenital heart defects. Nearly 300,000 people in the United States are estimated to have severe congenital heart disease, defined as a combination of at least two or more abnormalities, typically associated with cyanosis at birth.

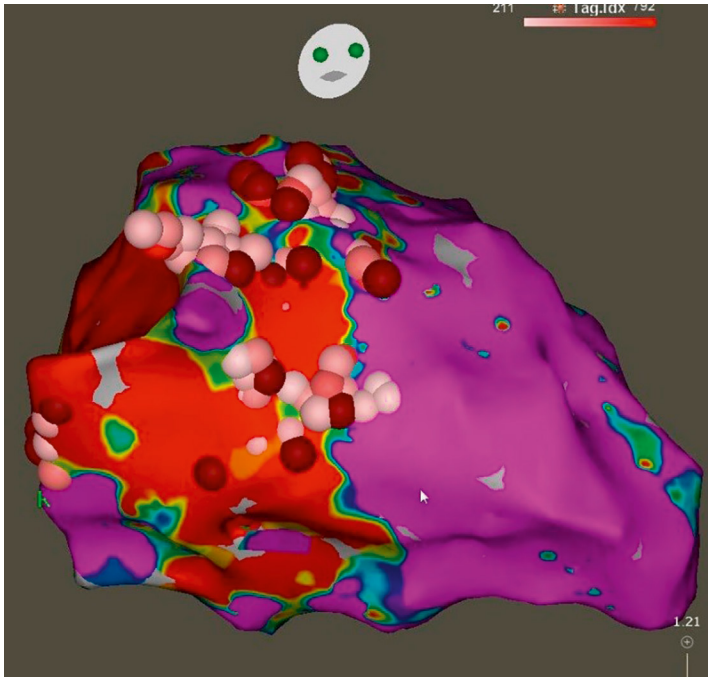
Bicuspid aortic valve occurs in about 2% of the general population, is the most common congenital cardiac anomaly encountered in adult populations, and accounts for up to half of surgical cases of aortic stenosis in adults (Chapter 60). Atrial septal defects (ASDs) constitute 30 to 40% of cases of congenital heart disease in adults, with ostium secundum ASD accounting for 7% of all congenital lesions. A solitary ventricular septal defect (VSD) represents 15 to 20% of all congenital lesions and is the most common lesion observed in children; its high spontaneous closure rates explain the lesser prevalence in adults. Patent ductus arteriosus (PDA) accounts for 5 to 10% of all congenital cardiac lesions in infants with a normal birthweight. Pulmonary stenosis and coarctation of the aorta represent 3 to 10% of all congenital lesions.

Tetralogy of Fallot is the most common cyanotic congenital anomaly observed in adults. Together with complete transposition of the great arteries, these lesions account for 5 to 12% of congenital heart disease in infants. More complex lesions, such as tricuspid atresia, univentricular heart, congenitally corrected transposition of the great arteries, Ebstein anomaly, and double-outlet right ventricle, account for 2.5% or less of all congenital heart disease.

PATHOBIOLOGY

Genetic Determinants

About 20% of congenital heart defects are associated with a syndrome or chromosomal anomaly, and the most common such chromosomal anomaly is Down syndrome (trisomy 21), in which about 50% of patients have defects of the endocardial cushions and the ventricular septum. VSDs also occur in 90% of patients with trisomy 13 and trisomy 18. The most frequently observed defects in patients with Turner syndrome (45,X) are aortic coarctation, aortic stenosis, and atrial septal defect. About 15% of patients with tetralogy of Fallot have a deletion on chromosome 22q11; prevalence is higher in those with a right aortic arch. Abnormalities involving the chromosomal band 22q11 can also result in a group of syndromes, the most common of which is DiGeorge syndrome. The shared phenotypic features are designated CATCH-22 syndromes, that is, a combination of *c*ardiac defects, *a*bnormal facies, *t*hymic



E-FIGURE 54-4. Voltage map of the left ventricle in a patient with ischemic cardiomyopathy and multiple ventricular tachycardias. Ablation of channels *(round tags)* within the anterior portion of a large anteroseptal scar (*red areas* of low voltage) was required to eliminate multiple ventricular tachycardias.

ARRHYTHMIA SURGERY

ATRIAL FIBRILLATION

Surgical ablation of AF can involve isolation of the pulmonary vein or a full biatrial Maze procedure, in which a series of incisions or linear lesions created by cryoablation or radio frequency ablation subdivides the atria into smaller segments unlikely to sustain AF. The most common current indication for the Maze procedure is the treatment of symptomatic AF in patients undergoing other cardiac surgical procedures, such as coronary revascularization or valve replacement or repair. AF surgery added to mitral valve surgery significantly reduces the recurrence of AF in patients with persistent or long-standing persistent AF. A variety of simpler and even minimally invasive operative procedures have been developed for AF, but their long-term efficacy and role in the treatment of AF are still being defined.

VENTRICULAR TACHYCARDIA

Surgical treatment by subendocardial resection or cryoablation of scar tissue (Chapter 53) in patients with a prior myocardial infarction can eliminate VT in selected patients (E-Fig. 54-4), with a success rate of 85 to 90%, but it carries an operative mortality rate of 5 to 15% even in experienced centers. Because of this high mortality and the development of catheter-based techniques, this procedure is generally limited to patients who have refractory VT or who have recurrent VT and other indications for cardiac surgery, such as large aneurysms associated with heart failure or the need to implant a left ventricular assist device.

CLOSURE OF THE LEFT ATRIAL APPENDAGE

The left atrial appendage, where blood tends to stagnate, is by far the most common site of origin for thromboembolism in patients with AF. Occlusion, removal, or isolation of the left atrial appendage can protect patients from stroke and thromboembolic events. In patients who are not suitable candidates for long-term anticoagulation (typically due to a propensity for bleeding or to poor adherence), occlusion of the left atrial appendage is at least as efficacious and safe as persisting with anticoagulation.[A17] The most widely used technique deploys an endocardial occlusion device, inserted percutaneously via transeptal puncture to the ostium of the left atrial appendage. After endothelialization of the luminal surface, these devices generally do not require long-term anticoagulation. Risks include dislodgement, residual leaks, and device-related thrombus. In patients who have AF and are undergoing cardiac surgery for another indication, epicardial closure of the left atrial appendage (amputation, stapling, or clip) can significantly reduce the risk of ischemic stroke or systemic embolism compared with anticoagulation alone during a mean follow-up of nearly 4 years.[A18]

About 15% of patients with tetralogy of Fallot have a deletion on chromosome 22q11; prevalence is higher in those with a right aortic arch. Abnormalities involving the chromosomal band 22q11 can also result in a group of syndromes, the most common of which is DiGeorge syndrome. The shared phenotypic features are designated CATCH-22 syndromes, that is, a combination of *c*ardiac defects, *a*bnormal facies, *t*hymic

ABSTRACT

As a result of major advances in diagnosis and interventional therapy, there are now more adults than children living with congenital heart disease in the United States and other industrialized countries worldwide. More than 20 phenotypes range from defects between the atria, the ventricles, and the great arteries to well-recognized associations of defects such as tetralogy of Fallot and atrioventricular canal defects. Follow-up is often shared between internists and specialized adult congenital heart disease centers to ensure adequate surveillance for potential complications and timely interventions to prevent long-term morbidity and mortality. Common cardiovascular complications include arrhythmias, residual valvular dysfunction, heart failure, and infective endocarditis. Superimposed cardiovascular disease as a result of atherosclerosis increases the cumulative burden of heart disease. This chapter is a concise starting point for understanding the lifelong management of cardiovascular and systemic issues facing this growing group of patients and their caregivers.

hypoplasia, cleft palate, and *h*ypocalcemia. For families with a child who carries a congenital cardiac malformation due to a chromosomal anomaly, the risk of the cardiac malformation in future children is related to the risk of recurrence of the chromosomal anomaly itself.

Typically, single mutant genes are also associated with syndromes of cardiovascular malformations, although not every patient with the syndrome has the characteristic cardiac anomaly. Examples include osteogenesis imperfecta (autosomal recessive; Chapter 239), associated with aortic valve disease; Jervell and Lange-Nielsen syndrome (autosomal recessive) and Romano-Ward syndrome (autosomal dominant), associated with a prolonged QT interval and sudden death; and Holt-Oram syndrome (autosomal dominant), in which an ASD occurs with a range of other skeletal anomalies. Osler-Weber-Rendu telangiectasias (Chapter 159) are associated with pulmonary arteriovenous fistulas. Williams syndrome (Chapters 31 and 32) occurs with supravalvular aortic stenosis in most cases. Noonan syndrome is associated with pulmonary stenosis, ASD, and hypertrophic cardiomyopathy. Although autosomal dominant inheritance has been implicated for both, most cases are sporadic. Deletion at chromosome 7q11.23 has been identified in patients with Williams syndrome, and a gene defect has been mapped to 12q22-qter in patients with Noonan syndrome (Chapter 47).

The risk for recurrence when the mother carries a sporadically occurring congenital lesion varies from 2.5 to 18%, depending on the lesion. Obstructive lesions of the left ventricular outflow tract have the highest recurrence rates in offspring. When the father carries the lesion, 1.5 to 3% of the offspring are affected. When a sibling has a congenital cardiac anomaly, the risk for recurrence in another sibling varies from 1 to 3%.

Genetic screening for the 22q11.2 microdeletion should be considered if patients with tetralogy of Fallot plan to have children. Without the 22q11 deletion, the risk of congenital heart disease in the fetus is 4 to 6%.

CLINICAL MANIFESTATIONS

History

Congenital heart disease is a lifelong condition during which the patient and the lesion evolve concurrently. The differential diagnosis of native and surgical anatomy in the adult with an unknown diagnosis depends on whether the patient is cyanotic or acyanotic. On completion of the evaluation, the following questions should be answered (Fig. 55-1): What is the native anatomy? Has this patient undergone surgery for the condition? What, if any, are the residual hemodynamic sequela?

Physical Examination

Physical examination of the heart and circulation includes the general physical appearance, the arterial pulse, the jugular venous pulse, the chest inspection, precordial percussion and palpation, and auscultation (Chapter 39).

Laboratory Investigations

A 12-lead electrocardiogram (ECG), chest radiograph, and baseline oxygen saturation should be part of every initial assessment. Two-dimensional transthoracic echocardiography (Chapter 43) and Doppler and color flow imaging are used to establish the diagnosis and to monitor the evolution of documented hemodynamic complications. Transesophageal echocardiographic examination is particularly useful in adults and is increasingly important during interventional catheter-guided therapy and surgery. Magnetic resonance imaging (Chapter 44) and computed tomography (Chapter 44) are useful adjuncts. Cardiac catheterization for congenital heart disease has shifted from pure diagnosis to include intervention. Coronary arteriography is recommended for adults older than 40 years in whom surgical intervention is contemplated.

SIMPLE LESIONS

ISOLATED SHUNT LESIONS

Hemodynamic complications of significant shunts relate to volume overload and chamber dilation of the primary chamber receiving the excess left-to-right shunt and to damage to the pulmonary vascular bed. The size and duration of the shunt determine the clinical course and therefore the indications for closure. The degree of shunting is a function of both the size of the communication and, depending on its location, biventricular compliance or pulmonary and systemic vascular resistance. Clinically apparent hemodynamic sequelae of shunts are typically apparent or can be expected to occur when pulmonary to systemic flow ratios, as inferred by Doppler echocardiography or measured by cardiac catheterization, exceed 1.5 : 1. Secondary enlargement of the cardiac chambers receiving excess shunt flow in diastole occurs if the shunt size is hemodynamically significant; in addition, the pulmonary artery becomes enlarged as pulmonary pressure rises.

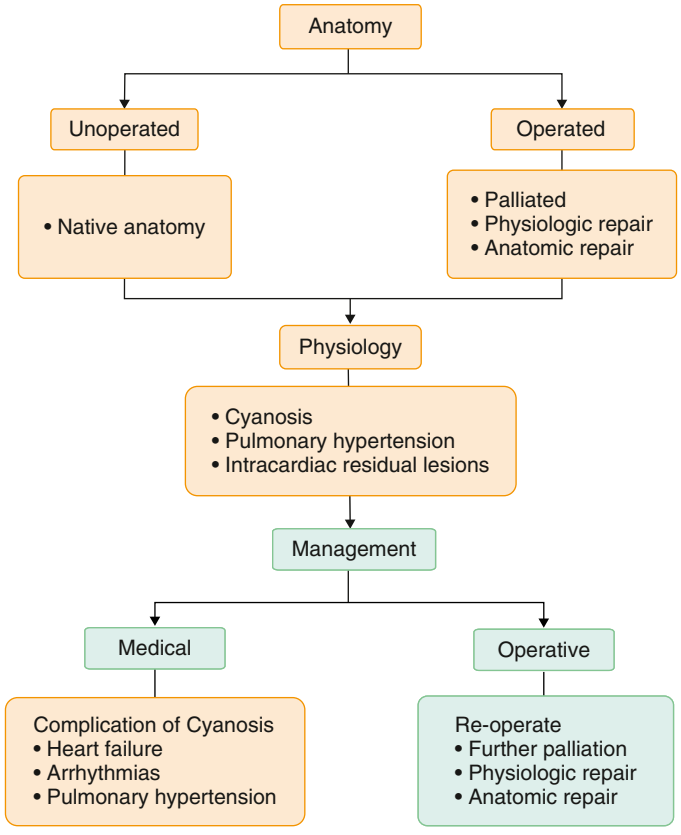

FIGURE 55-1. **The goals of complete clinical assessment in congenital heart disease are to define the anatomy and residual sequela to determine appropriate management and follow-up.**

PATENT FORAMEN OVALE AND ATRIAL SEPTAL DEFECT

Classification of ASDs is based on anatomic location. Most commonly, an ostium secundum ASD occurs in the central portion of the interatrial septum as a result of an enlarged foramen ovale or excessive resorption of the septum primum (Video 55-1). The combination of a secundum ASD and acquired mitral stenosis is known as *Lutembacher syndrome*, the pathophysiology of which is determined by the relative severity of each. Abnormal development of the embryologic endocardial cushions results in a variety of atrioventricular canal defects, the most common of which consists of a defect in the lower part of the atrial septum in the ostium primum location, typically accompanied by a cleft mitral valve and mitral regurgitation. The sinus venosus defect, which accounts for 2 to 3% of all interatrial communications, is located superiorly at the junction of the superior vena cava and right atrium and is generally associated with anomalous drainage of the right-sided pulmonary veins into the superior vena cava or right atrium. Less commonly, interatrial communications can be seen at the site of the coronary sinus, typically associated with an anomalous left superior vena cava.

The pathophysiology is determined by the effects of the shunt on the heart and pulmonary circulation. Right atrial and right ventricular dilation occurs as shunt size increases with pulmonary to systemic flow ratios greater than 1.5 : 1. Superimposed systemic hypertension and coronary artery disease modify left ventricular compliance and favor left-to-right shunting. Mitral valve disease can occur in up to 15% of patients older than 50 years. Right-sided heart failure, atrial fibrillation, or atrial flutter can occur as a result of chronic right-sided volume overload and progressive ventricular and atrial dilation. Stroke can result from paradoxical emboli, atrial arrhythmias, or both. A rise in pulmonary pressure occurs because of the increased pulmonary blood flow. Pulmonary hypertension is unusual before 20 years of age but is seen in 50% of patients older than 40 years. The overall incidence of pulmonary vascular obstructive disease is 15 to 20% in patients with ASD. Eisenmenger complex (see later) with reverse shunting, a late and rare complication of isolated secundum ASD, is reported in 5 to 10% of patients.

Up to 30% of adults have evidence of a pink-patent foramen ovale without hemodynamic evidence of shunt at rest. Clinical studies have demonstrated that the prevalence of patent foramen ovale is three times higher in patients with cryptogenic stroke (Chapter 376), particularly before the age of 55 years, because of right-to-left shunting and paradoxical embolization of material from the venous circulation.

DIAGNOSIS

Atrial Septal Defect

Although most ASDs are minimally symptomatic in the first three decades, more than 70% become impaired by the fifth decade.[1] Initial symptoms include exercise intolerance, dyspnea on exertion, and fatigue caused most commonly by right-sided heart failure and pulmonary hypertension. Palpitations, syncope, and stroke can occur with the development of atrial arrhythmias.

Precordial palpation typically discloses a normal left ventricular impulse unless the patient also has mitral valve disease. If the patient has a significant left-to-right shunt, the right ventricular impulse usually can be felt in the left parasternal area in end expiration or in the subxiphoid area in end inspiration. A dilated pulmonary artery can sometimes be felt in the second left intercostal space. On auscultation, the hallmark of an ASD is the wide and fixed splitting of the second heart sound, because the increase in venous return elevates the right atrial pressure during inspiration, thereby decreasing the degree of left-to-right shunting and offsetting the usual phasic respiratory changes. Pulmonary valve closure, as reflected by P_2, is delayed because of right ventricular overload and the increased capacitance of the pulmonary vascular bed. A soft midsystolic murmur generated by the increased flow across the pulmonary valve is usually heard in the second left interspace. In the presence of a high left-to-right shunt volume, increased flow across the tricuspid valve is heard as a mid-diastolic murmur at the lower left sternal border. With advanced right-sided heart failure, evidence of systemic venous congestion is present.

The ECG characteristically shows an incomplete right bundle branch block pattern (Fig. 55-2). Right axis deviation and atrial abnormalities, including a prolonged PR interval, atrial fibrillation, and flutter, are also seen. Typically, the chest radiograph shows pulmonary vascular plethora with increased markings in both lung fields consistent with increased pulmonary blood flow (see Fig. 44-6). The main pulmonary artery and both its branches are dilated. Right atrial and right ventricular dilation can be seen. Echocardiography is diagnostic and provides important prognostic information (E-Fig. 55-1). Ostium primum and secundum ASDs are easily identifiable with transthoracic imaging, but a sinus venosus ASD can be missed unless it is specifically sought. With Doppler study, pulmonary artery pressures can be quantified, and the interatrial shunt ratio can be estimated.

Patent Foramen Ovale

A patent foramen ovale without a resting shunt is not detectable on physical examination and is not associated with ECG abnormalities. The diagnosis is established by transesophageal Doppler echocardiography accompanied by injections of agitated saline to detect a right-to-left shunt during the Valsalva maneuver (Chapter 39).

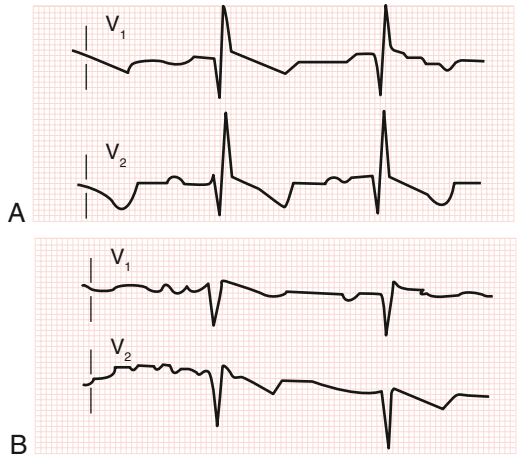

FIGURE 55-2. Electrocardiographic hallmark in atrial septal defect. Right precordial leads V_1 and V_2 illustrate two variants of an incomplete right bundle branch block pattern, the rSrT pattern (**A**) and the rsR′ pattern (**B**).

TREATMENT AND PROGNOSIS

Closure of an ASD, either percutaneously or surgically, is indicated in the presence of right-sided heart enlargement, with or without symptoms. In patients older than 40 years with symptoms and significant shunts, closure improves functional status and survival. A centrally located ASD or patent foramen ovale measuring up to 3.5 cm can be occluded by transcatheter techniques in a cardiac catheterization laboratory.[1,2] Advantages of this approach include the avoidance of sternotomy and cardiopulmonary bypass.[A1] Surgical closure is usually reserved for patients in whom concomitant repair of associated valvular anomalies is required, anomalous pulmonary veins are present, or device closure is not technically feasible.

In the presence of a significant shunt, closure of an ASD before 25 years of age without evidence of pulmonary hypertension results in a long-term outcome that is similar to that of age- and sex-matched controls. Advanced age (60 years) is not a contraindication to ASD closure in the presence of a significant shunt because a significant number of patients will show evidence of symptomatic improvement, although such late closure may not improve longevity.[3] Preoperative pulmonary artery pressure and the presence or absence of pulmonary vascular disease are important predictors of successful interventional outcome.

In patients who have had a cryptogenic stroke,[4] the presence of an atrial septal aneurysm may be more predictive of recurrent stroke than the size of the shunt.[5] Percutaneous closure of a patent foramen reduces the risk of recurrent stroke and chronic anticoagulations at the expense of a higher rate of periprocedure complications,[A2-A5] and closure is commonly recommended if the infarct appears to be embolic and no other cause can be identified.[6] A residual shunt after closure portends a higher risk of future stroke, with the risk generally proportional to the magnitude of the residual shunt.[7] By comparison, closure of a patent foramen ovale is not recommended as a treatment for migraine headache (Chapter 367).[8]

VENTRICULAR SEPTAL DEFECT

For anatomic classification of VSDs, the interventricular septum can be divided into four regions. Defects of the membranous septum, or infracristal VSDs, are located in a small translucent area beneath the aortic valve and account for up to 80% of VSDs. These VSDs typically show a variable degree of extension into the inlet or outlet septum, hence their designation as perimembranous (Video 55-2). Infundibular defects or supracristal outlet VSDs occur in the conal septum above the crista supraventricularis and below the pulmonary valve. Inlet defects are identified at the crux of the heart between the tricuspid and mitral valves and are usually associated with other anomalies of the atrioventricular canal. Defects of the trabecular or muscular septum can be multiple and occur distal to the septal attachment of the tricuspid valve and toward the apex.

Approximately half of all native VSDs are small, and more than half of them close spontaneously; moderate or even large VSDs may also close in 10% or less of cases. The highest closure rates are observed in the first decade of life; spontaneous closure in adult life is unusual.

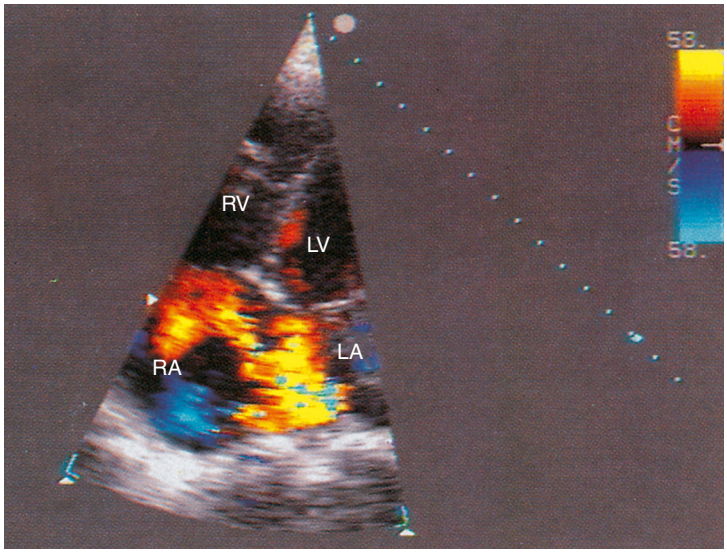
Patients who have a small defect with trivial or mild shunts are defined as those with a shunt of less than 1.5 and normal pulmonary artery pressure and vascular resistance. Minimal or mild defects usually cause no significant hemodynamic or physiologic abnormality.

Patients with moderate defects have a shunt ratio of greater than 1.2, with elevated pulmonary artery pressure but not elevated pulmonary vascular resistance. Patients with a large and severe defect have an elevated left-to-right shunt (1.5 : 1 or higher) with high pulmonary pressure and elevated pulmonary vascular resistance. A moderate or severe defect causes left atrial and ventricular dilation consistent with the degree of left-to-right shunting. Shunting across the ventricular septum occurs predominantly during systole when left ventricular pressure exceeds that on the right; diastolic filling abnormalities occur in the left atrium. With moderate or severe defects, the right side of the heart becomes affected as a function of the rise in pulmonary artery pressure and pulmonary blood flow.

Eisenmenger complex develops in about 10% of patients with VSDs, usually when there is no resistance to flow at the level of the defect, which can be as large as the aorta. When a systolic pressure gradient is present between the ventricles, the physiologic severity may be trivial or mild but can also be moderate or severe.

DIAGNOSIS

An adult with a VSD most commonly has a small restrictive lesion that either was small at birth or has undergone some degree of spontaneous closure. Patients with a trivial or mild shunt across a small, restrictive VSD are usually asymptomatic. Physical examination discloses no evidence of systemic or



E-FIGURE 55-1. Color flow Doppler apical four-chamber view showing blood flow from the left atrium (LA) to the right atrium (RA) through a moderately sized atrial septal defect. LV = left ventricle; RV = right ventricle. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)

pulmonary venous congestion, and jugular venous pressure is normal. A thrill may be palpable at the left sternal border. Auscultation reveals normal S_1 and S_2 without gallops. A grade 4 or louder, widely radiating, high-frequency, pansystolic murmur is heard maximally in the third or fourth intercostal space and reflects the high-pressure gradient between the left and right ventricles throughout systole. The striking contrast between a loud murmur and otherwise normal findings on cardiac examination is an important diagnostic clue. The ECG and chest radiograph are also normal in patients with small VSDs.

Patients with moderately sized VSDs typically are symptomatic as children and are therefore more likely to have repair at a young age. Adults with large, nonrestrictive VSDs that have not been operated on typically have had Eisenmenger complex for most of their lives. If not, they usually have a combination of pulmonary hypertension and left-sided volume overload resulting from a significant left-to-right shunt. Such patients are rarely seen today in developed countries but may still be encountered in the developing world.

In adults, shortness of breath on exertion can be the result of both pulmonary venous congestion and elevated pulmonary pressure. On physical examination, a diffuse palpable left ventricular impulse occurs with a variable degree of right ventricular hypertrophy and an accentuated second heart sound. A systolic murmur persists as long as pulmonary vascular resistance is below systemic resistance. The ECG commonly shows left atrial enlargement and left ventricular hypertrophy. The chest radiograph shows shunt vascularity with an enlarged left atrium and ventricle. The degree of pulmonary hypertension determines the size of the pulmonary artery trunk.

Echocardiography can identify the defect and determine the significance of the shunt by assessing left atrial and ventricular size, pulmonary artery pressure, and presence or absence of right ventricular hypertrophy. Cardiac catheterization is reserved for those in whom surgery is considered. Adults with a small defect of no physiologic significance need not be studied invasively. Those with Eisenmenger complex have severe pulmonary vascular disease and are not surgical candidates. Patients who have a moderately sized shunt that appears hemodynamically significant and in whom pulmonary pressures are elevated are most likely to benefit from direct measurements of pulmonary vascular resistance and reactivity.

TREATMENT AND PROGNOSIS

Patients with Eisenmenger complex have pulmonary vascular resistance that is prohibitive to surgery. For this group of patients, management centers on the medical complications of cyanosis (see later). In a few patients with small defects, complications can relate to progressive tricuspid insufficiency caused by septal aneurysm formation or to acquired aortic insufficiency when an aortic cusp becomes engaged in the high-velocity jet flow generated by the defect. The intermediate group of patients with a defect of moderate physiologic significance should have their VSDs closed unless closure is contraindicated by high pulmonary vascular resistance. For a perimembranous VSD, transcatheter closure is as effective as open surgical closure and has a lower rate of minor adverse events.[9]

Cumulative survival, which is about 85% at 40 years, is slightly lower than in the general population. Cumulative event-free survival after surgery is about 70% at 40 years, and a concomitant cardiac lesion (e.g., patent ductus arteriosus) and aortic cross-clamp time are determinants of late events. Late results after operative closure of isolated VSDs include residual patency in up to 20% of patients, only about 5% of whom need a reoperation. Rhythm disturbances after surgical closure of VSDs include tachyarrhythmias and conduction disturbances. Right bundle branch block occurs in one third to two thirds of patients, whereas first-degree atrioventricular block and complete heart block occur in less than 10%. Sudden cardiac death after surgical repair of VSD occurs in 2% of patients.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus connects the descending aorta to the main pulmonary trunk near the origin of the left subclavian artery (E-Fig. 55-2). Normal postnatal closure results in fibrosis and degenerative changes in the ductal lumen, leaving in its place the residual ligamentum arteriosum, which rarely can become part of an abnormal vascular ring.

The physiologic consequences of a PDA are determined by its size and length as well as by the ratio of pressure and resistance of the pulmonary and aortic circulations on either end of the duct. If systolic and diastolic pressure in the aorta exceeds that in the pulmonary artery, aortic blood flows continuously down a pressure gradient into the pulmonary artery and then returns to the left atrium. The left atrium and subsequently the left ventricle dilate, whereas the right side of the heart becomes progressively affected as pulmonary hypertension develops.

A small PDA has continuous flow throughout the entire cardiac cycle without left-sided heart dilation, pulmonary hypertension, or symptoms. However, patients with a small PDA develop infectious endarteritis at a rate of about 0.45% per year after the second decade, and closure should be considered.

A PDA is of moderate or large size but still restrictive when a left-to-right shunt occurs throughout systole and diastole is of variable duration. Left atrial or ventricular dilation and pulmonary hypertension will vary with the quantity of left-to-right shunting, as well as with the secondary effects on the pulmonary vascular bed. Symptoms generally increase by the second and third decades and include dyspnea, palpitations, and exercise intolerance. As heart failure, pulmonary hypertension, or endarteritis develops, mortality rises to 3 to 4% per year by the fourth decade, and two thirds of patients die by 60 years of age. Eisenmenger complex with systemic or suprasystemic pulmonary pressure and a right-to-left shunt develops in 5% of patients with an isolated PDA.

DIAGNOSIS

In patients with Eisenmenger physiology, a right-to-left shunt from the pulmonary artery to the descending aorta results in decreased oxygen saturation in the lower extremities compared with the upper extremities. This difference in cyanosis and clubbing is most prominent in the toes. With a large left-to-right shunt, the pulse pressure widens as diastolic flow into the pulmonary artery lowers systemic diastolic pressure. The arterial pulse becomes bounding as a result of increased stroke volume. Precordial palpation discloses variable left and right ventricular impulses as determined by the relative degree of left-sided volume overload and pulmonary hypertension. In the presence of a continuous aortopulmonary gradient, the classic "machinery" murmur of a PDA can be heard at the first or second left intercostal space below the left clavicle. As the pulmonary pressure rises, the diastolic component of the murmur becomes progressively shorter. With the development of Eisenmenger physiology and equalization of aortic and pulmonary pressure, the entire murmur may disappear, and the clinical findings are dominated by pulmonary hypertension.

In older patients, the chest radiograph shows calcification at the location of the PDA. Characteristically, the ascending aorta and pulmonary artery are dilated, and the left-sided chambers are enlarged. Echocardiography may not directly visualize the PDA but can accurately identify it by a Doppler signal that often parallels the length of the murmur. Cardiac catheterization to assess pulmonary vascular resistance is commonly indicated before closure.

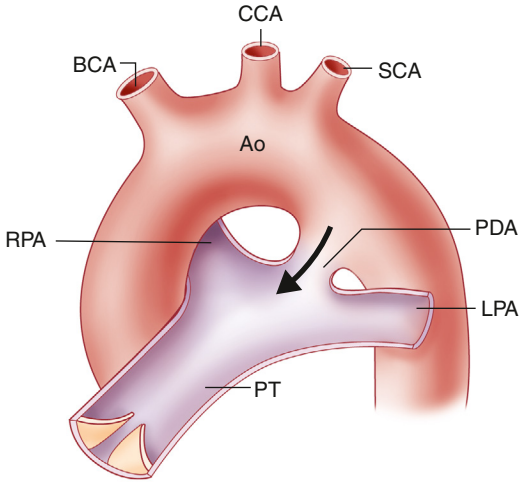
TREATMENT AND PROGNOSIS

Ibuprofen can accelerate the closure of PDA in premature infants but may not reduce the need for an interventional procedure to eliminate the shunt.[A6] After ligation of a PDA in infancy or early childhood, cardiac function is commonly normal, and no special follow-up is required. If pulmonary artery pressure and pulmonary vascular resistance are substantially elevated, preoperative evaluation should assess the degree of reversibility. With Eisenmenger complex, closure is contraindicated. Closure of a PDA either percutaneously or surgically is indicated in the presence of left-sided heart enlargement or if prior endarteritis has occurred. Reported operative mortality rates vary from less than 1 to 8%, depending on the presence of calcification and the degree of pulmonary hypertension. Transcatheter or coil occlusion is an accepted procedure in adults. Residual shunt rates vary from 0.5 to 8%, depending on the device used.

PULMONARY ARTERIOVENOUS FISTULAS

Pulmonary arteriovenous fistulas can occur as isolated congenital disorders or as part of generalized hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome; Chapter 159). These fistulas typically occur in the lower lobes or the right middle lobe and can be small or large, single or multiple. The arterial supply usually comes from a dilated, tortuous branch of the pulmonary artery.

The most common finding is that of abnormal opacity on a chest radiograph in a patient with buccal ruby patches or in an otherwise healthy adult who has mild cyanosis. Shunting between deoxygenated pulmonary arterial blood and the oxygenated pulmonary venous blood results in a physiologic right-to-left shunt. The degree of shunting is typically small and not significant enough to result in dilation of the left atrium and ventricle. Heart failure is unusual. Hemoptysis can result if a fistula ruptures into a bronchus. In patients with hereditary hemorrhagic telangiectasia, angiomas occur on the lips and mouth as well as in the gastrointestinal tract and on pleural, liver, and vaginal surfaces. Epistaxis is most common, but cerebrovascular accidents can also occur. Patients with hereditary hemorrhagic telangiectasia can have symptoms that resemble those of a transient ischemic attack even in the absence of right-to-left shunting. On physical examination, cyanosis and clubbing can be notable or barely detectable. Auscultation



E-FIGURE 55-2. Anatomy of a patent ductus arteriosus. Note the relationships of the position of the ductus, left subclavian artery, and pulmonary artery bifurcation. Ao = aorta; BCA = brachiocephalic; CCA = common carotid artery; LPA = left pulmonary artery; PDA = patent ductus arteriosus; PT = pulmonary trunk; RPA = right pulmonary artery; SCA = subclavian artery. (From Perloff JK, ed. *Clinical Recognition of Congenital Heart Disease*. 4th ed. Philadelphia: WB Saunders; 1994:510.)

can disclose soft systolic or continuous noncardiac murmurs on the chest wall adjacent to the fistula. The murmur typically increases with inspiration. The ECG is usually normal. The chest radiograph shows one or more densities, typically in the lower lobes or in the right middle lobe. An echocardiogram can confirm the presence of the fistula by showing early opacification of the left atrium in the absence of any other intracardiac communication when saline is injected into a peripheral vein. The absence of a hemodynamically significant shunt can be confirmed by documenting normal cardiac chamber size.

If the hypoxemia is progressive or if a neurologic complication is documented to have occurred because of paradoxical emboli, fistula closure should be considered.[10] Options include percutaneous catheter techniques (e.g., embolization) if the fistula is small and accessible or a pulmonary wedge resection or lobectomy if the fistula is large. Multiple or recurrent fistulas create a major therapeutic challenge.

ISOLATED OBSTRUCTIVE LESIONS OF THE RIGHT AND LEFT VENTRICULAR OUTFLOW TRACT

Complications of obstructive lesions of the outflow tract relate to the secondary effects of exposure to pressure overload in the chamber proximal to the obstruction. The inability to increase systemic or pulmonary blood flow in the face of a fixed obstruction can cause exercise intolerance, inadequate myocardial perfusion, ventricular arrhythmias, and sudden death.

RIGHT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

Obstruction of the right ventricular outflow tract can occur at the level of the pulmonary valve (see later), above it in the main pulmonary artery or its branches, or below it in the right ventricle itself. Supravalvular and branch pulmonary artery stenoses are important and common complications in patients with tetralogy of Fallot (see later). Residual supravalvular pulmonary stenosis is sometimes seen after palliative pulmonary artery banding to decrease pulmonary blood flow in patients with large left-to-right shunts. Congenital branch pulmonary artery stenosis can occur in isolation or with valvular pulmonary stenosis, shunt lesions, or a variety of syndromes.

VALVULAR PULMONARY STENOSIS

Isolated congenital valvular pulmonary stenosis (Chapter 60) is a common lesion due to a bicuspid valve in 20% of cases, a dysplastic valve caused by myxomatous changes and severe thickening in 10% of cases, and an abnormal trileaflet valve in most of the remaining cases. Fusion of the leaflets results in a variable degree of thickening and calcification in older patients.

DIAGNOSIS

A patient with moderate or even severe pulmonary stenosis may be asymptomatic. With severe stenosis, exercise intolerance can be associated with presyncope and ventricular arrhythmias. Progressive right-sided heart failure is the most common cause of death. On physical examination of patients with significant pulmonary stenosis, jugular venous pressure has a dominant *a* wave, reflecting a noncompliant right ventricle. Palpation discloses a sustained parasternal lift of right ventricular hypertrophy. An expiratory systolic ejection click is characteristic if the leaflets are still mobile. In moderate or severe stenosis, a grade 3 or louder systolic murmur can be heard and felt in the second left interspace. The length of the murmur increases as it peaks progressively later in systole with an increasing degree of obstruction. If right-sided heart failure occurs, tricuspid insufficiency and systemic venous congestion develop. The ECG can show right axis deviation and tall, peaked right atrial P waves in lead II. With more than mild stenosis, the R wave exceeds the S wave in lead V_1. On chest radiography, the main pulmonary artery can be dilated even if the stenosis is mild. Characteristically, the left pulmonary artery is more dilated than the right because of the leftward direction of the high-velocity jet. A variable degree of right ventricular hypertrophy is manifested as right-sided chamber enlargement. Echocardiography can establish the diagnosis and determine the severity by Doppler ultrasound examination, so cardiac catheterization is not required.

TREATMENT AND PROGNOSIS

The 25-year survival of patients with valvular pulmonary stenosis is greater than 95%. For patients with mild (<50 mm Hg gradients) and moderate (50 to 80 mm Hg gradients) pulmonary stenosis, bacterial endocarditis, complex ventricular arrhythmias, and progression of the stenosis are uncommon.

Depending on symptoms, percutaneous balloon valvotomy should be considered for patients with isolated valvular pulmonary stenosis and mean Doppler gradients of 30 mm Hg or greater unless there is moderate or severe pulmonary regurgitation. In the presence of a doming valve, pulmonary valvuloplasty is the procedure of choice for adults,[11] who achieve persistently good results at 10-year follow-up. When valvuloplasty cannot be performed or is unsuccessful, transcatheter pulmonary valve replacement provides good hemodynamic and clinical outcomes for at least 7 years after implantation. For patients with hypoplastic pulmonary arteries or subvalvular stenosis (double-chambered right ventricle), surgical resection of right ventricular muscle bands can be performed.

LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

Stenosis of the left ventricular outflow tract can occur at, below, or above the aortic valve. Discrete subaortic stenosis, most commonly caused by a fibromuscular ring just below the valve, accounts for 15 to 20% of all cases of congenital obstruction of the left ventricular outflow tract. Concomitant aortic insufficiency occurs in 50% of cases. Supravalvular aortic stenosis results from thickened media and intima above the aortic sinuses; early coronary atherosclerosis or even ostial coronary obstruction can occur.

CONGENITAL VALVULAR AORTIC STENOSIS

The normal aortic valve has three cusps and commissures. A unicuspid aortic valve accounts for most cases of severe aortic stenosis in infants (Chapter 60). A bicuspid aortic valve, which occurs in about 0.8% of infants[12] and is the most common congenital cardiac malformation, functions normally at birth but often becomes gradually obstructed as calcific and fibrous changes occur.

DIAGNOSIS

Symptoms include angina, exertional dyspnea, presyncope, and syncope and may progress to heart failure. The auscultatory hallmark of a bicuspid aortic valve in an adolescent or young adult is an audible systolic ejection click that is typically of a higher pitch than the first heart sound and is best heard not at the cardiac base but at the apex. The sound is caused by sudden movement of the stenotic valve as it moves superiorly in systole and is followed by the typical aortic stenosis murmur (Chapter 60). When significant calcification of the valve results in reduced mobility, the ejection sound is no longer heard. The diagnosis is easily confirmed by two-dimensional echocardiography, with which the number and orientation of aortic cusps can readily be identified.

TREATMENT AND PROGNOSIS

Conservative management is generally indicated for mild stenosis with a peak gradient of less than 25 mm Hg, but close supervision is required because 20% of these patients require an intervention during long-term follow-up. Unlimited athletic participation is allowed only for asymptomatic patients with peak gradients of less than 20 to 25 mm Hg, a normal ECG, and a normal exercise test result. Aortic valvuloplasty can be considered in young adults, but calcification limits its success, and valve replacement is usually required (Chapter 60). For adults, treatment decisions are similar to those for aortic stenosis from other causes. For patients with subvalvular aortic stenosis, surgical intervention is indicated in the presence of peak gradients above 50 mm Hg, symptoms, or progressive significant aortic insufficiency.

The estimated overall 25-year survival rate for patients with congenital valvular aortic stenosis diagnosed in childhood is 85%. Children with initial peak cardiac catheterization gradients of less than 50 mm Hg have long-term survival rates of higher than 90%, as opposed to survival rates of 80% in those with gradients of 50 mm Hg or greater.

COARCTATION OF THE AORTA

Aortic coarctation typically occurs just distal to the left subclavian artery at the site of the aortic ductal attachment or its residual ligamentum arteriosum. Less commonly, the coarctation ridge lies proximal to the left subclavian. A bicuspid aortic valve is the most common coexisting anomaly, but VSDs and PDAs are also seen.

The most common complications of aortic coarctation are systemic hypertension (Chapter 64) and secondary left ventricular hypertrophy with heart failure. Heart failure occurs most commonly in infants and then after 40 years of age. The high pressure proximal to the obstruction stimulates the growth of collateral vessels from the internal mammary, scapular, and superior intercostal arteries to the intercostals of the descending aorta. Collateral circulation increases with age and contributes to perfusion of the lower extremities and

the spinal cord. Aneurysms occur most notably in the ascending aorta and in the circle of Willis. Premature coronary disease is thought to be related to the resulting hypertension. Complications, including bacterial endarteritis at the coarctation site or, more commonly, endocarditis at the site of a bicuspid aortic valve, cerebrovascular complications, myocardial infarction, heart failure, and aortic dissection, occur in 2 to 6% of patients, more frequently in those with advancing age who have not undergone surgery.

DIAGNOSIS

Young adults may be asymptomatic with incidental systemic hypertension and decreased lower extremity pulses. Coarctation should always be considered in adolescents and young adult men with unexplained upper extremity hypertension. The pressure differential can cause epistaxis, headaches, leg fatigue, or claudication. Older patients have angina, symptoms of heart failure, and vascular complications.

On physical examination, the lower half of the body is typically slightly less developed than the upper half. Blood pressure measurements should be obtained in each arm and one leg; an abnormal measurement is an increase of less than 10 mm Hg in popliteal systolic blood pressure compared with arm systolic blood pressure. The diastolic pressure should be the same in the upper and lower extremities. A pressure differential of more than 30 mm Hg between the right and the left arms is consistent with compromised flow in the left subclavian artery. Right brachial palpation characteristically reveals a strong or even bounding pulse compared with a slowly rising or absent femoral, popliteal, or pedal pulse. Examination of the eyegrounds can reveal tortuous or corkscrew retinal arteries. Precordial palpation is consistent with left ventricular pressure overload. On auscultation, a systolic ejection sound reflecting the presence of a bicuspid aortic valve should be sought. The coarctation itself generates a systolic murmur heard posteriorly, in the midthoracic region, the length of which correlates with the severity of the coarctation. Over the anterior of the chest, systolic murmurs reflecting increased collateral flow can be heard in the infraclavicular areas and the sternal edge or in the axillae.

In adult coarctation, the most common finding on the ECG is left ventricular hypertrophy. On the chest radiograph, the location of the coarctation segment between the dilated left subclavian artery above and the leftward convexity of the descending aorta below results in the "3 sign" (Fig. 55-3). Bilateral rib notching as a result of dilation of the posterior intercostal arteries is seen on the posterior of the third to eighth ribs when the coarctation is below the left subclavian artery. Unilateral rib notching sparing the left ribs is observed when the coarctation occurs proximal to the left subclavian artery. Transthoracic echocardiography documents the gradient in the descending aorta and determines the presence of left ventricular hypertrophy. Magnetic resonance imaging (Chapter 44) is the best modality for visualizing the anatomy of the descending aorta. Cardiac catheterization should measure pressures and assess collaterals when surgery is contemplated.

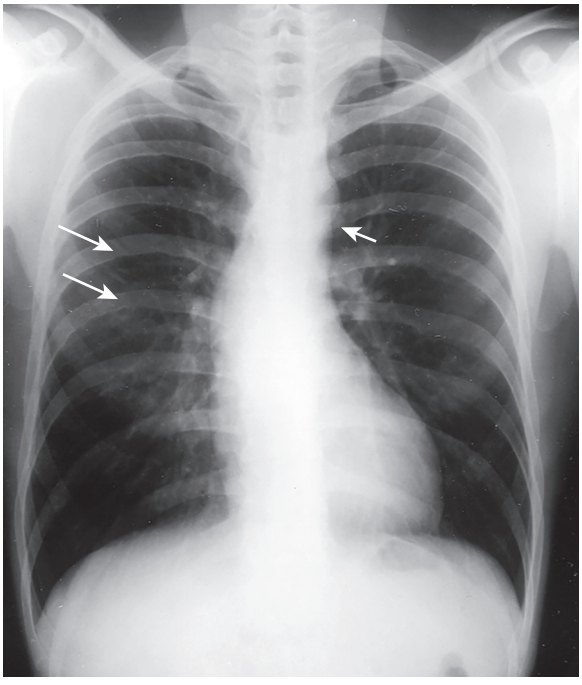


FIGURE 55-3. Chest radiograph of a patient with coarctation of the aorta. The radiographic "3 sign" formed by the dilated subclavian artery above and the dilated aorta below (*short arrow*) is shown. Note the notching, best seen at the level of the seventh and eighth ribs (*long arrows*). The dilated ascending aortic segment can also be seen.

TREATMENT AND PROGNOSIS

Intervention, typically catheter-based in adults,[13] is recommended in patients who have systemic hypertension with a peak gradient of 20 mm Hg or more on cardiac catheterization or who have evidence of significant collateral flow on imaging studies. Fifty percent of patients repaired when they are older than 40 years have residual hypertension, whereas those who have undergone surgery between the ages of 1 and 5 years have a less than 10% prevalence of hypertension on long-term follow-up.

ANOMALIES OF THE SINUSES OF VALSALVA AND CORONARY ARTERIES

SINUS OF VALSALVA ANEURYSMS

At the base of the aortic root, the aortic valve cusps are attached to the aortic wall, above which three small pouches, or sinuses, are seated. The right coronary artery originates from one sinus and the left main coronary artery from a second; the third is called the *noncoronary sinus*. A weakness in the wall of the sinus can result in aneurysm formation with or without rupture. In more than 90% of cases, the aneurysm involves the right or noncoronary cusp. Rupture typically occurs into the right side of the heart at the right atrial or ventricular level with a resulting large left-to-right shunt driven by the high aortic pressure.

A previously asymptomatic young man typically has chest pain and rapidly progressing shortness of breath sometimes after physical strain. The physical examination is consistent with significant heart failure. Even if the communication is between the aorta and the right side of the heart, biventricular failure is not unusual. The classic murmur is loud and continuous, often with a thrill. A murmur of aortic insufficiency secondary to damage to the adjacent aortic valve may be superimposed. The chest radiograph shows volume overload of both ventricles with evidence of shunt vascularity and pulmonary venous congestion. The echocardiogram is diagnostic. Cardiac catheterization can verify the integrity of the coronary artery adjacent to the ruptured aneurysm.

Even though symptoms may abate as the heart dilates, progressive cardiac decompensation typically results in death within 1 year of the rupture. A ruptured sinus of Valsalva aneurysm therefore requires urgent surgical repair.

CORONARY ARTERY FISTULAS

Fistulas arise from the right or left coronary arteries and in 90% of cases drain into the right ventricle, the right atrium, or the pulmonary artery in order of decreasing frequency. Typically, young patients are asymptomatic, but supraventricular arrhythmias are seen with progressive dilation of the intracardiac chambers. Angina can occur as the fistula creates a coronary steal by diverting blood away from the myocardium. Heart failure is seen with large fistulas. A continuous murmur heard in a young, otherwise normal acyanotic, asymptomatic patient should suggest the diagnosis. Most fistulas are associated with a small shunt, and hence the murmur is often less than grade 3 and is heard in the precordial area. Unless the shunt is large, the ECG is normal, as is the chest radiograph. The echocardiogram, especially the transesophageal echocardiogram, is diagnostic. Percutaneous transcatheter closure with coil embolization is preferred, but surgical ligation is also an alternative.

ANOMALOUS ORIGIN OF THE CORONARY ARTERIES

The left main coronary artery normally arises from the left sinus of Valsalva and courses leftward, posterior to the right ventricular outflow tract. The right coronary artery arises from the right sinus of Valsalva and courses rightward to the right ventricle. Isolated ectopic or anomalous origins of the coronary arteries (see Fig. 55-4) are seen in 0.6 to 1.5% of patients undergoing coronary angiography.[14]

The most common anomaly is ectopic origin of the left circumflex artery from the right sinus of Valsalva, followed by anomalous origin of the right coronary artery from the left sinus and anomalous origin of the left main coronary artery from the right sinus. If the anomalous coronary artery does not course between the pulmonary artery and aorta, the prognosis is favorable.

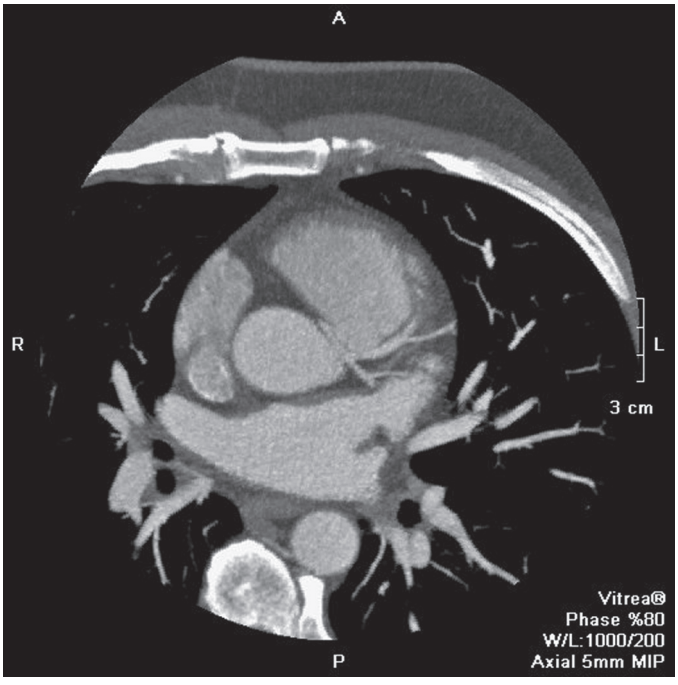

FIGURE 55-4. **Frame from a computed tomographic angiographic study showing the origin of the left main coronary artery arising from the right sinus of Valsalva and coursing anteriorly between the aorta and pulmonary artery.** (From Kern MJ, Kirtane AJ. Catheterization and angiography. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.)

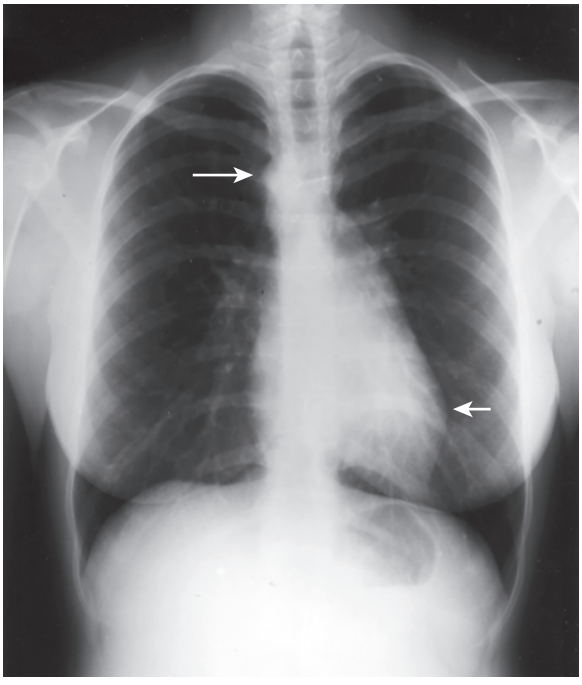

FIGURE 55-5. **Chest radiograph of an adult after tetralogy of Fallot repair.** A right aortic arch with rightward indentation of the trachea (*long arrow*) can be seen. The right ventricular apex remains upturned (*short arrow*). Note the sternal wires consistent with intracardiac repair, clarifying the fullness of the pulmonary artery segment often seen after extensive enlargement of the right ventricular outflow tract.

Risks of ischemia, myocardial infarction, and death are greatest when the left main coronary artery courses between both great vessels.

Coronary arteries can also originate from the pulmonary trunk. If both the right and left arteries originate from the pulmonary trunk, death usually occurs in the neonatal period. If only the left anterior descending coronary artery originates from the pulmonary trunk, the rate of survival to adulthood is approximately 10%, depending on the development of collateral retrograde flow to the anomalous artery from a normal coronary artery. This collateral flow may cause a continuous murmur along the left sternal border, congestive heart failure from the large shunt, and a coronary steal syndrome as blood is diverted away from the normal artery.

A single coronary ostium can provide a single coronary artery that branches into right and left coronary arteries, the left then giving rise to the circumflex and the anterior descending arteries. The ostium can originate from the right or left aortic sinus. The coronary circulation is functionally normal unless one of the branches passes between the aorta and the pulmonary artery.

Diagnostic procedures include angiography, magnetic resonance imaging, and transesophageal echocardiography. For an anomalous coronary artery that originates from the pulmonary artery, surgical reimplantation into the aorta is preferred. For an anomalous artery that courses between the pulmonary artery and aorta, a bypass graft to the distal vessel is preferred.

SPECIFIC COMPLEX LESIONS

TETRALOGY OF FALLOT

Tetralogy of Fallot, the most common cyanotic malformation, is characterized by superior and anterior displacement of the subpulmonary infundibular septum, which causes the tetrad of pulmonary stenosis, VSD, aortic override, and right ventricular hypertrophy. The VSD is perimembranous in 80% of cases. Additional cardiac anomalies include a right-sided aortic arch in up to 25% of patients. An anomalous left anterior descending artery originating from the right coronary cusp and crossing over the right ventricular outflow tract is seen in 10% of cases. Other associated anomalies include ASD, left superior vena cava, defects of the atrioventricular canal, and aortic insufficiency. With pulmonary atresia, pulmonary blood flow occurs through aortic to pulmonary collaterals.

Complete surgical repair in childhood consists of patch closure of the VSD and relief of the right ventricular outflow tract obstruction. Adequate pulmonary blood flow is ensured by reconstruction of the distal pulmonary artery bed. Previous palliative shunts are usually taken down. Complete repair in childhood yields a 90 to 95% 10-year survival rate with good functional results, and 30-year survival rates may be as high as 85%.

After repair, residual pulmonary stenosis, proximal or distal, can be seen. Some degree of pulmonary insufficiency is common, particularly if a patch has been inserted at the level of the pulmonary valve or if a pulmonary valvotomy has been performed. Residual VSDs can be found in up to 20% of patients. Patients may be asymptomatic or may have symptoms related to long-term complications after surgical repair. Symptoms can reflect residual right ventricular pressure or volume overload or arrhythmias at rest or with exercise. Angina can occur in a young patient if surgical repair has damaged an anomalous left anterior descending artery as it courses across the right ventricular outflow tract. In acyanotic adults, clubbing commonly regresses.

On physical examination, a right ventricular impulse is often felt as a result of residual pulmonary insufficiency or stenosis. A systolic murmur can represent residual pulmonary stenosis, residual VSD, or tricuspid insufficiency. A diastolic murmur can reflect aortic or pulmonary insufficiency. Ventricular arrhythmias are common after repair, with an incidence of sudden death as high as 5%.

The ECG in unrepaired tetralogy of Fallot shows right axis deviation, right atrial enlargement, and dominant right ventricular forces over the precordial leads. The most common finding after repair is complete right bundle branch block, which is seen in 80 to 90% of patients. The chest radiograph typically shows an upturned apex with a concave pulmonary artery segment giving the classic appearance of a boot-shaped heart. Figure 55-5 demonstrates the findings in an adult after repair. The apex is persistently upturned, although the pulmonary artery segment is no longer concave. Echocardiography can confirm the diagnosis and document intracardiac complications in repaired and unrepaired patients. Shunt patency can be determined by Doppler examination. Magnetic resonance imaging can accurately document stenosis in the distal pulmonary artery bed. Cardiac catheterization is reserved for patients in whom operative or reoperative treatment is contemplated or in whom the integrity of the coronary circulation needs to be verified.

Patients with a change in exercise tolerance, angina, or evidence of right-sided heart failure and those with symptomatic arrhythmias or syncope should be referred for complete evaluation. Surgical reintervention is generally considered when right ventricular pressure is more than two thirds the systemic pressure because of residual right ventricular outflow tract obstruction, free pulmonary regurgitation with right ventricular dysfunction, sustained arrhythmias, or a residual VSD causes a significant shunt.

Patients should be seen yearly by an adult congenital heart specialist for assessment of right ventricular function, pulmonary valve dysfunction, and arrhythmia. Surveillance should include a history, physical examination, and

12-lead ECG. Sudden cardiac death can occur in 3 to 6% of patients observed between 20 and 30 years, sometimes despite favorable hemodynamics.[15]

COMPLETE TRANSPOSITION OF THE GREAT ARTERIES

Complete transposition of the great arteries is the second most common cyanotic lesion, and surgically corrected adults are increasingly common. In simple transposition of the great arteries, the atria and ventricles are in their normal positions, but the aorta arises from the right ventricle, and the pulmonary artery arises from the left ventricle. When the aorta is anterior and rightward with respect to the pulmonary artery, as is most common, D-transposition is present. The native anatomy has the pulmonary and systemic circulations in parallel, with deoxygenated blood recirculating between the right side of the heart and the systemic circulation, whereas oxygenated blood recirculates from the left side of the heart to the lungs. The condition is incompatible with life unless a VSD, PDA, or ASD is present or an ASD is created; a hemodynamically significant VSD is present in 15% of cases. Subpulmonary obstruction of the left ventricular outflow tract occurs in 10 to 25% of cases.

The arterial switch operation transects the aorta and pulmonary artery above their respective valves and switches them to become realigned with their physiologic outflow tracts and appropriate ventricles. The proximal coronary arteries are translocated from the sinuses of the native aorta to the neoaorta (native pulmonary artery). The 22-year survival rate of patients with transposition of the great arteries who underwent operation between 1990 and 2009 is 93%. Long-term complications include neoaortic regurgitation, supravalvular stenosis, and coronary artery complications.

CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES

In congenitally corrected transposition of the great arteries, the great arteries are transposed, the ventricles are inverted, but the atria remain in their normal position. The systemic circulation (left atrium, morphologic right ventricle, and aorta) and pulmonary circulation (right atrium, morphologic left ventricle, and pulmonary artery) are in series. The patient is therefore acyanotic unless an intracardiac shunt is also present. The right ventricle is aligned with the aorta and performs lifelong systemic work, which accounts in part for its eventual failure. Patients with congenitally corrected transposition of the great arteries and no other associated defects can remain free of symptoms until the sixth decade, at which time significant atrioventricular valve regurgitation, failure of the right (systemic) ventricle, supraventricular arrhythmias, and heart block occur.

EBSTEIN ANOMALY

In Ebstein anomaly of the tricuspid valve, the right side of the heart consists of three anatomic components: the right atrium proper, the true right ventricle, and the atrialized portion of the right ventricle between the two. The displaced septal and posterior tricuspid leaflets lie between the atrialized right ventricle and the true right ventricle. Functionally, the valve is regurgitant because it is unable to appose its three leaflets during ventricular contraction. Valvular regurgitation and asynchronous, abnormal right ventricular function cause the dilation and right-sided heart failure observed in the more severe forms of the lesion. The wide spectrum of severity of the anomaly is based on the degree of tricuspid leaflet tethering and the relative proportion of atrialized and true right ventricle. The most common associated cardiac defect, a secundum ASD or patent foramen ovale, is reported in more than 50% of patients. On physical examination, a clicking "sail sound" is heard as the second component of S_1 when tricuspid valve closure becomes loud and delayed.

The 12-lead ECG typically shows highly peaked P waves with a wide, often bizarre-looking QRS complex. Preexcitation (Chapter 52) occurs in 20% of patients, whereas supraventricular tachyarrhythmias, atrial fibrillation, and atrial flutter occur in 30 to 40% of patients.

When patients of all ages are taken together, the predicted mortality is approximately 50% by the fourth or fifth decade. Complications include atrial arrhythmias, cyanosis, and, if there is an intra-atrial communication, stroke.

Intervention is considered when functional status or cyanosis worsens, significant atrial arrhythmias are documented, or a cerebrovascular accident occurs. Surgical options include replacement or repair of the tricuspid valve and closure of the ASD.

ATRIOVENTRICULAR CANAL DEFECT

A partial atrioventricular canal defect refers to an ostium primum ASD with a cleft mitral valve. The anomaly is manifested as a hemodynamic combination of an ASD with a variable degree of mitral regurgitation. The 12-lead ECG shows the typical findings of left axis deviation with a Q wave in leads I and aVL and a prolonged PR interval. The echocardiogram shows a defect in the inferior portion of the interatrial septum and a cleft mitral valve.

A complete atrioventricular canal defect is an uncommon defect consisting of a primum ASD, an inlet VSD that usually extends to the membranous interventricular septum, and a common atrioventricular valve. Adults who have not been operated on usually have Eisenmenger syndrome.

Surgical repair consists of closing the interatrial or interventricular communication with reconstruction of the common atrioventricular valve or closure of the cleft in the mitral valve. An adult who has undergone repair may have significant residual regurgitation of the mitral or tricuspid valve. Even after surgery, acquired subaortic obstruction can occur.

UNIVENTRICULAR HEART AND TRICUSPID ATRESIA

The terms *single ventricle, common ventricle*, and *univentricular heart* have been used interchangeably to describe the double-inlet ventricle, in which one ventricular chamber receives flow from both the tricuspid and mitral valves. In 75 to 90% of cases, the single ventricle is a morphologic left ventricle. Obstruction of one of the great arteries is common.

In tricuspid atresia, no orifice is found between the right atrium and right ventricle, and an underdeveloped or hypoplastic right ventricle is present. The morphologic left ventricle is consistently normally developed and therefore becomes the single functional ventricle. Typically, blood flows into the right atrium, then through an obligatory ASD and to the left atrium, where it then proceeds to the left ventricle. Variable features include a VSD, the abnormal position of the great arteries, and the relative degree of pulmonary stenosis, all of which are used to classify tricuspid atresia.

Adult patients rarely have not been operated on. They may be acyanotic after the Fontan operation. At 5-year follow-up, 80% or more of Fontan survivors are in New York Heart Association functional class I or II, with successful pregnancy reported in a small number of patients. When patients of all ages are considered together, 10-year survival rates vary from 60 to 70%. Late deaths are due to reoperation, arrhythmia, ventricular failure, protein-losing enteropathy, and liver dysfunction. Yearly follow-up with specialized imaging is recommended.

Anomalies of Pulmonary Venous Return

In partial anomalous pulmonary venous return, one or more, but not all four, pulmonary veins are not connected to the left atrium. The most common pattern has the right pulmonary veins connected to the superior vena cava, usually with a sinus venosus ASD.

In total anomalous pulmonary venous return, all the pulmonary veins connect abnormally to either the right atrium or one of the systemic veins above or below the diaphragm. Concurrent obstruction of the pulmonary veins is present when drainage occurs below the diaphragm and variable when drainage occurs above it. An ASD is essential to sustain life. One third of cases occur with major complex cardiac malformations. Surgical treatment is indicated.

In cor triatriatum, the pulmonary veins drain into an accessory chamber that is usually connected to the left atrium through an opening of variable size. The hemodynamic consequences are determined by the size of this opening and are similar to those of mitral stenosis.

Dextrocardia and Mesocardia

In dextrocardia, the heart is on the right side of the thorax with or without situs inversus. When the heart is right sided with inverted atria, the stomach is right sided, and the liver is left sided, the combination is dextrocardia with situs inversus. The heart usually functions normally, and the diagnosis is often fortuitous. The heart sounds are louder on the right side of the chest, and the liver is palpable on the left. The chest radiograph shows a right-sided cardiac apex with a lower left hemidiaphragm and a right-sided stomach bubble. The ECG shows an inverted P and T wave in lead I with a negative QRS deflection and a reverse pattern between aVR and aVL. A mirror-image progression is seen from V_1 to a right-sided V_6 lead. An echocardiogram should be performed to ensure that intracardiac anatomy is normal.

When dextrocardia with situs solitus occurs, the ventricles are inverted, but not the viscera and therefore not the atria. Associated severe cardiac malformations are typical. In mesocardia, the heart is centrally located in the chest with normal atrial and visceral anatomy. The apex is central or rightward displaced

on the chest radiograph. Typically, no associated cardiac malformations are present.

SPECIALIZED ISSUES

Pulmonary Hypertension and Its Complications

Pulmonary hypertension (Chapter 69) secondary to structural disease of the heart or circulation can occur with or without an increase in pulmonary vascular resistance. Pulmonary vascular obstructive disease occurs when pulmonary vascular resistance rises and becomes fixed and irreversible. *Eisenmenger physiology* designates the physiologic response of shunt lesions in which a right-to-left shunt occurs in response to an elevation in pulmonary vascular resistance.

In the most common congenital anomalies, pulmonary hypertension is a result of increased pulmonary blood flow because of a native left-to-right shunt. Examples include ASD, a large-sized VSD, PDA, and a variety of complex lesions. The rate at which pulmonary hypertension progresses to become pulmonary vascular obstructive disease varies from one lesion to another and depends at least in part on the source of pulmonary blood flow. Pulmonary hypertension typically develops in patients with an ASD after the fourth decade; Eisenmenger syndrome is a late complication seen in only 5 to 10% of cases. In contrast, in patients with a large VSD or persistent PDA, progressive elevation in pulmonary vascular resistance occurs rapidly because the pulmonary vascular bed is exposed not only to the excess volume of the left-to-right shunt but also to systemic arterial pressures. As a result, Eisenmenger complex develops in approximately 10% of patients with a large VSD during the first decade.

The term *Eisenmenger syndrome*[16] should be reserved for patients in whom pulmonary vascular obstructive disease is present and pulmonary vascular resistance is fixed and irreversible. These findings, in combination with the absence of left-to-right shunting, render the patient inoperable.

The clinical manifestations of Eisenmenger syndrome include dyspnea on exertion, syncope, chest pain, congestive heart failure, and symptoms related to erythrocytosis and hyperviscosity. On physical examination, central cyanosis and digital clubbing are hallmark findings. Systemic oxygen saturations typically vary between 75 and 85%. The pulse pressure narrows as the cardiac output falls. Examination of jugular venous pressure can reveal a dominant *a* wave reflecting a noncompliant right ventricle until tricuspid insufficiency is severe enough to generate a large *v* wave. A prominent right ventricular impulse is felt in the left parasternal border in end expiration or in the subcostal area in end inspiration. A palpable pulmonary artery is commonly felt. The pulmonary component of the second heart sound is increased and can be felt in most cases. Pulmonary ejection sounds are common when the pulmonary artery is dilated with a structurally normal valve. Right atrial gallop is heard more frequently when the *a* wave is dominant. A murmur of tricuspid insufficiency is common, but the inspiratory increase in the murmur (Carvallo sign) disappears when right ventricular failure occurs. In diastole, a pulmonary insufficiency murmur is often heard. The 12-lead ECG shows evidence of right atrial enlargement, right ventricular hypertrophy, and right axis deviation. Chest radiographic findings include a dilated pulmonary artery segment, cardiac enlargement, and diminished pulmonary vascular markings. Echocardiography confirms the right-sided pressure overload and pulmonary artery enlargement as well as the tricuspid and pulmonary insufficiency. Cardiac catheterization is indicated if doubt exists about the potential reversibility of the elevated pulmonary vascular resistance in a patient who might otherwise benefit from surgery.

Cyanosis occurs when persistent venous-to-arterial mixing results in hypoxemia. Adaptive mechanisms to increase oxygen delivery include an increase in oxygen content, a rightward shift in the oxyhemoglobin dissociation curve, a higher hematocrit, and an increase in cardiac output. When cyanosis is not relieved, chronic hypoxemia and erythrocytosis result in hematologic, neurologic, renal, and rheumatic complications.

TREATMENT AND PROGNOSIS

In patients with Eisenmenger syndrome, pulmonary vasodilator therapy (e.g., bosentan 62.5 mg twice daily for 4 weeks, then 125 mg twice daily) may improve hemodynamics and exercise capacity after 4 months of use. Chronic oxygen therapy is unlikely to benefit hypoxemia caused by right-to-left shunting in the setting of a fixed pulmonary vascular resistance. Oxygen therapy may be considered for cyanotic patients during long-distance flights.

Indications for phlebotomy are symptomatic hyperviscosity in an iron-replete patient and prevention of excessive bleeding perioperatively. In the iron-replete state, moderate to severe hyperviscosity symptoms typically occur when hematocrit levels exceed 65%. If no evidence of dehydration is present, removal of 500 mL of blood during a 30- to 45-minute period should be followed by quantitative volume replacement with normal saline or dextran (E-Fig. 55-3). The procedure may be repeated every 24 hours until symptomatic improvement occurs.

Treatment of spontaneous bleeding is dictated by its severity and the abnormal hemostatic parameters (E-Fig. 55-4). For severe bleeding, platelet transfusions, fresh-frozen plasma, vitamin K, cryoprecipitate, and desmopressin have been used. Reduction in erythrocyte mass also improves hemostasis, so cyanotic patients undergoing surgery should have prophylactic phlebotomy if the hematocrit is greater than 65%.

Symptomatic hyperuricemia and gouty arthritis (Chapter 252) can be treated as necessary with colchicine, probenecid, or allopurinol. Nonsteroidal anti-inflammatory drugs are best avoided, given the baseline hemostatic anomalies in these patients.

Endocarditis Prophylaxis

Prolonged survival of patients with complex congenital heart disease has resulted in a population at increased risk for infective endocarditis (Chapter 61), which usually involves left-sided heart valves.[17] Adults with congenital heart disease should be informed about the risks of endocarditis. Any unexplained fever requires blood cultures to be drawn before antibiotics are initiated. Thorough transthoracic and transesophageal echocardiograms should be performed to assess the presence of vegetations. If infection of prosthetic material is suspected, early consultation with a specialist who has access to a congenital heart surgeon should be initiated because of the potential for rapid deterioration. The risk of endocarditis is highest in patients with cyanotic congenital heart disease and prosthetic material.

Antibiotic prophylaxis before dental procedures that involve manipulation of the gingiva, periapical regions of the teeth, or mucosal tissue is indicated in patients with previous infective endocarditis, unrepaired cyanotic lesions, palliative shunts or conduits, prosthetic valves or prosthetic materials used for valve repair, repaired congenital heart disease with prosthetic material or transcatheter device within 6 months of intervention, and repaired congenital heart disease with residual lesions at or adjacent to the site of a prosthetic patch or device (Chapter 61). It is also reasonable to consider prophylaxis against endocarditis before vaginal delivery at the time of membrane rupture in such patients. Prophylaxis is not indicated for nondental procedures in the absence of active infection.

Exercise

The goal of exercise evaluation is to assess the functional results of therapeutic interventions and to provide guidelines for exercise prescriptions. Patients with residual hemodynamic lesions or unrepaired congenital cardiac anomalies should be evaluated on an annual basis with a physical examination, an ECG, and a cardiac ultrasonographic examination if indicated. Pertinent additional tests may include Holter monitoring and exercise testing. Attention should be directed to the detection of pulmonary hypertension; arrhythmias; myocardial dysfunction; and symptoms such as exercise-induced dizziness, syncope, dyspnea, or chest pain.

Patients beyond 6 months after repair of a single shunt lesion without pulmonary hypertension, arrhythmias, or evidence of myocardial dysfunction can participate in all sports (E-Table 55-1).[18] With residual shunts, if the peak pulmonary artery pressure is less than 40 mm Hg in the absence of ventricular dysfunction or significant arrhythmias, patients can enjoy a free range of activity. Patients with elevated pulmonary vascular resistance are at risk of sudden death during intense exercise; although most self-limit their activity, participation in competitive sports is contraindicated. Patients with aortic and pulmonary stenosis should be counseled as recommended earlier, according to gradient severity. For patients with uncomplicated aortic coarctation, athletic participation is permitted if the arm-leg blood pressure gradient is 20 mm Hg or less at rest and the peak systolic blood pressure during exercise is normal. For patients after tetralogy of Fallot repair, repair of transposition of the great arteries, and the Fontan operation, exercise recommendations vary according to residual ventricular function and the presence or absence of arrhythmias.

Older Patients

Overall survival is similar to the general population in patients without cyanosis, univentricular physiology, genetic disorders, ventricular dysfunction, residual hemodynamic lesions, or acquired late complications. However, median survival is only 56 years in patients with one or more of these risk factors. Among

E-TABLE 55-1 EXERCISE RECOMMENDATIONS IN ADULTS WITH CONGENITAL HEART DISEASE

CONDITION	UNRESTRICTED	LOW-MODERATE INTENSITY*	PROHIBITED
ASD†	No PHT; no arrhythmia; normal ventricular function	PA pressure >40 mm Hg *with* normal ETT; no arrhythmia	Eisenmenger
VSD†	Small; no PHT; no arrhythmia; normal ventricular function	Moderate VSD	Eisenmenger
PDA†	Small; no PHT; no arrhythmia; normal ventricular function	PA pressure >40 mm Hg *with* normal ETT; no arrhythmia	Eisenmenger
Coarctation‡	Gradient ≤20 mm Hg arm to leg; normal BP at rest and exercise	Gradient ≥20 mm Hg arm to leg *with* normal BP and normal ETT	Gradient ≥50 mm Hg arm to leg *or* aortic aneurysm
PS	Gradient <40 mm Hg; no arrhythmia; normal ventricular function	Gradient 40-60 mm Hg	Gradient ≥70 mm Hg *or* ventricular arrhythmia
AS	Gradient, <30 mm Hg; normal ECG; normal ETT; asymptomatic	Gradient 30-50 mm Hg *with* normal ECG, normal ETT; asymptomatic	Gradient >50 mm Hg *or* ventricular arrhythmia
TOF after repair	Normal RV pressure; no shunt; no arrhythmia	Increased RV pressure *or* moderate PR *or* SVT	RV pressure ≥65% systemic *or* ventricular arrhythmia on ETT
Mustard or Senning		No cardiomegaly, arrhythmia, or syncope; normal ETT	Cardiomegaly *or* arrhythmia at rest or exercise
c-TGA unoperated	No cardiomegaly; mild TR; no arrhythmia; normal ETT	Moderate RV dysfunction, moderate TR; no arrhythmia	Severe TR *or* uncontrolled arrhythmia
Ebstein anomaly	Mild Ebstein; no arrhythmia; operated with mild TR	Moderate TR *with* no arrhythmia	Severe Ebstein *or* uncontrolled arrhythmia
Fontan		Normal O_2 saturation *with* near-normal ETT and ventricular function	Moderate-severe MR or TR *or* uncontrolled arrhythmia

*Based on peak dynamic and static components of exercise during competition for individual sports (see credit line).

†Unoperated or 6 months after surgery.

‡Unoperated or 1 year after surgery.

women who become pregnant, fetal growth retardation is about 30% more common if the congenital heart condition is simple, but complex congenital lesions are associated with a 60% increased risk of fetal growth retardation and an 80-fold increased risk of maternal death.

The increasing number of older adults are surgical survivors who are subject to developing the full range of age-related cardiac conditions as well as late complications from their surgically repaired congenital anomaly.[19] Careful attention to blood pressure (Chapter 64), lipid levels (Chapter 190), and other preventive approaches (Chapter 40), including physical activity (Chapter 14), diet (Chapter 13), and smoking cessation (Chapter 363), is critically important. Neurodevelopmental problems in childhood and adolescence also may contribute to detectable cognitive decline (Chapter 371) and dementia in adulthood.

56 ANGINA PECTORIS AND CHRONIC ISCHEMIC HEART DISEASE

WILLIAM E. BODEN

DEFINITION

Angina pectoris and myocardial ischemia most commonly result from an obstruction or stenosis of one or more of the epicardial coronary arteries by atheromatous plaque, but it is increasingly recognized that both angina and ischemia can occur in the absence of epicardial coronary artery obstruction—particularly in women, who may exhibit microvascular angina and ischemia. Both coronary stenosis and obstruction can result when a plaque ruptures acutely to cause severe myocardial ischemia, thereby culminating in a myocardial infarction or an acute coronary syndrome (Chapters 57 and 58) with associated symptoms of angina, dyspnea, heart failure (Chapters 45 and 46), and arrhythmic complications (Chapters 50, 52 and 53) that may result in sudden cardiac death.

Angina pectoris results from an imbalance in myocardial oxygen supply and demand when an increase in activity or emotional stress increases cardiac workload, or "demand," with a concomitant increase in heart rate, blood pressure, and contractility, which, in turn, leads to an increase in left ventricular (LV) wall tension. However, stenotic coronary arteries are unable to augment antegrade flow, or "supply," adequately in response to this increase in demand. Such an imbalance classically results in chest discomfort (Chapter 39) of varying intensity and duration. Angina pectoris is generally defined as a discomfort in the chest or adjacent areas that occurs predictably and reproducibly at a certain level of exertion and is relieved with rest or nitroglycerin.

Chronic angina may result from epicardial coronary obstruction, vasospasm of the epicardial coronary arteries or microcirculation, or a noncoronary or nonvascular process, such as myocardial energy derangements, blood rheology abnormalities, or extravascular microcirculatory compression. Stable angina and chronic myocardial ischemia have been variably termed "chronic coronary syndromes," "stable ischemic heart disease," or "chronic coronary disease." Given the multiplicity of causes and precipitants of angina and ischemia in the nonacute setting, the term "chronic ischemic heart disease" is favored as being more accurately descriptive and inclusive of these multiple pathogenetic processes and triggers.

Grading of Angina Pectoris

The Canadian Cardiovascular Society (CCS) angina grading scale is a widely used four-point ordinal scale that classifies angina pectoris from mild (class I: angina occurring only during strenuous or prolonged physical activity) to severe (class IV: inability to perform any activity without angina, or angina at rest) and includes the full spectrum of angina from chronic stable to unstable (see Table 39-5). Operationally, the CCS angina scale permits clinicians to categorize patients as mild or stable (generally CCS classes I and II) versus severe or unstable (typically CCS classes III and IV). For classification purposes, subjects with stable ischemic heart disease generally exhibit CCS class I to II symptoms, which are typically provoked by exertion. Other grading systems include a specific activity scale, which is based on the metabolic cost of specific activities, and an anginal score, which integrates the clinical features and tempo of angina with electrocardiographic changes and offers independent prognostic information beyond that provided by age, sex, ventricular function, and coronary anatomy.

EPIDEMIOLOGY

More than 85 million American adults (more than 1 in 3) have at least one type of cardiovascular disease, which includes more than 17 million persons with coronary heart disease (Chapter 40), including 7.6 million who have survived a myocardial infarction (MI), nearly 10 million with angina pectoris, 5.7 million with heart failure, and 6.6 million with stroke (of all types). Among adults aged 60 to 79 years, approximately 25% of men and 16% of women have coronary heart disease, and among persons older than age 80 years, the percentages increase to 37% and 23%, respectively.[1] The Global Burden of Disease Study estimates that cardiovascular diseases are the leading cause of death globally. An estimated 18 million people died from cardiovascular disease in 2019, representing 32% of all global deaths.[2]

In 2019, before the severe acute respiratory syndrome coronavirus 2 pandemic, coronary heart disease accounted for 365,000 of the 650,000 or so U.S. deaths due to heart disease, or about 55%. The number of coronary heart disease deaths is expected to rise in the coming decade as a consequence of the aging of the U.S. population as well as the epidemic rise in obesity (Chapter 201), type 2 diabetes (Chapter 210), and metabolic syndrome, which may give rise to an increasing risk for premature coronary artery disease in younger generations.

PATHOBIOLOGY

Angina is the most frequent clinical expression of myocardial ischemia. Ischemia, which rapidly develops when a mismatch arises between myocardial oxygen needs and myocardial oxygen supply, can be manifested clinically in many ways besides angina, from no symptoms (e.g., silent myocardial ischemia) to unstable angina, MI, or sudden cardiac death. It may remain stable for many years in selected patients or may be rapidly progressive with an abrupt change in frequency and tempo during days to weeks. Conversely, atherosclerosis, which is the most common cause of myocardial ischemia, may evolve for years without any manifestations of ischemia.

Chronic angina and ischemia may be due to a variety of pathogenetic mechanisms, the most common of which is an obstructed or stenotic coronary artery. Alternative mechanisms include microvascular dysfunction, vasoconstriction at the site of a dynamic stenosis, or mural thrombosis, as well as noncoronary or nonvascular processes, such as derangements in myocardial energy supply or demand, abnormalities in blood rheology, and extravascular microcirculatory compression.[3,4]

Two major pathogenetic mechanisms may result in myocardial ischemia and angina in the chronic setting: so-called *demand angina*, which is caused by an increase in myocardial oxygen requirements and workload, and *supply angina*, which is caused by diminished oxygen delivery to myocardial tissue. Demand angina is a consequence of the increased myocardial oxygen requirements that occur with increased physical activity, emotion, or stress. In a patient with decreased myocardial perfusion owing to chronic atherosclerotic narrowing of a coronary artery, this increased demand may precipitate angina. Other extracardiac precipitants of angina include the excessive metabolic demands imposed by fever, thyrotoxicosis (Chapter 207), severe anemia (Chapter 144)

56 ANGINA PECTORIS AND CHRONIC ISCHEMIC HEART DISEASE

WILLIAM E. BODEN

DEFINITION

Angina pectoris and myocardial ischemia most commonly result from an obstruction or stenosis of one or more of the epicardial coronary arteries by atheromatous plaque, but it is increasingly recognized that both angina and ischemia can occur in the absence of epicardial coronary artery obstruction—particularly in women, who may exhibit microvascular angina and ischemia. Both coronary stenosis and obstruction can result when a plaque ruptures acutely to cause severe myocardial ischemia, thereby culminating in a myocardial infarction or an acute coronary syndrome (Chapters 57 and 58) with associated symptoms of angina, dyspnea, heart failure (Chapters 45 and 46), and arrhythmic complications (Chapters 50, 52 and 53) that may result in sudden cardiac death.

Angina pectoris results from an imbalance in myocardial oxygen supply and demand when an increase in activity or emotional stress increases cardiac workload, or "demand," with a concomitant increase in heart rate, blood pressure, and contractility, which, in turn, leads to an increase in left ventricular (LV) wall tension. However, stenotic coronary arteries are unable to augment antegrade flow, or "supply," adequately in response to this increase in demand. Such an imbalance classically results in chest discomfort (Chapter 39) of varying intensity and duration. Angina pectoris is generally defined as a discomfort in the chest or adjacent areas that occurs predictably and reproducibly at a certain level of exertion and is relieved with rest or nitroglycerin.

Chronic angina may result from epicardial coronary obstruction, vasospasm of the epicardial coronary arteries or microcirculation, or a noncoronary or nonvascular process, such as myocardial energy derangements, blood rheology abnormalities, or extravascular microcirculatory compression. Stable angina and chronic myocardial ischemia have been variably termed "chronic coronary syndromes," "stable ischemic heart disease," or "chronic coronary disease." Given the multiplicity of causes and precipitants of angina and ischemia in the nonacute setting, the term "chronic ischemic heart disease" is favored as being more accurately descriptive and inclusive of these multiple pathogenetic processes and triggers.

Grading of Angina Pectoris

The Canadian Cardiovascular Society (CCS) angina grading scale is a widely used four-point ordinal scale that classifies angina pectoris from mild (class I: angina occurring only during strenuous or prolonged physical activity) to severe (class IV: inability to perform any activity without angina, or angina at rest) and includes the full spectrum of angina from chronic stable to unstable (see Table 39-5). Operationally, the CCS angina scale permits clinicians to categorize patients as mild or stable (generally CCS classes I and II) versus severe or unstable (typically CCS classes III and IV). For classification purposes, subjects with stable ischemic heart disease generally exhibit CCS class I to II symptoms, which are typically provoked by exertion. Other grading systems include a specific activity scale, which is based on the metabolic cost of specific activities, and an anginal score, which integrates the clinical features and tempo of angina with electrocardiographic changes and offers independent prognostic information beyond that provided by age, sex, ventricular function, and coronary anatomy.

EPIDEMIOLOGY

More than 85 million American adults (more than 1 in 3) have at least one type of cardiovascular disease, which includes more than 17 million persons with coronary heart disease (Chapter 40), including 7.6 million who have survived a myocardial infarction (MI), nearly 10 million with angina pectoris, 5.7 million with heart failure, and 6.6 million with stroke (of all types). Among adults aged 60 to 79 years, approximately 25% of men and 16% of women have coronary heart disease, and among persons older than age 80 years, the percentages increase to 37% and 23%, respectively.[1] The Global Burden of Disease Study estimates that cardiovascular diseases are the leading cause of death globally. An estimated 18 million people died from cardiovascular disease in 2019, representing 32% of all global deaths.[2]

In 2019, before the severe acute respiratory syndrome coronavirus 2 pandemic, coronary heart disease accounted for 365,000 of the 650,000 or so U.S. deaths due to heart disease, or about 55%. The number of coronary heart disease deaths is expected to rise in the coming decade as a consequence of the aging of the U.S. population as well as the epidemic rise in obesity (Chapter 201), type 2 diabetes (Chapter 210), and metabolic syndrome, which may give rise to an increasing risk for premature coronary artery disease in younger generations.

PATHOBIOLOGY

Angina is the most frequent clinical expression of myocardial ischemia. Ischemia, which rapidly develops when a mismatch arises between myocardial oxygen needs and myocardial oxygen supply, can be manifested clinically in many ways besides angina, from no symptoms (e.g., silent myocardial ischemia) to unstable angina, MI, or sudden cardiac death. It may remain stable for many years in selected patients or may be rapidly progressive with an abrupt change in frequency and tempo during days to weeks. Conversely, atherosclerosis, which is the most common cause of myocardial ischemia, may evolve for years without any manifestations of ischemia.

Chronic angina and ischemia may be due to a variety of pathogenetic mechanisms, the most common of which is an obstructed or stenotic coronary artery. Alternative mechanisms include microvascular dysfunction, vasoconstriction at the site of a dynamic stenosis, or mural thrombosis, as well as noncoronary or nonvascular processes, such as derangements in myocardial energy supply or demand, abnormalities in blood rheology, and extravascular microcirculatory compression.[3,4]

Two major pathogenetic mechanisms may result in myocardial ischemia and angina in the chronic setting: so-called *demand angina*, which is caused by an increase in myocardial oxygen requirements and workload, and *supply angina*, which is caused by diminished oxygen delivery to myocardial tissue. Demand angina is a consequence of the increased myocardial oxygen requirements that occur with increased physical activity, emotion, or stress. In a patient with decreased myocardial perfusion owing to chronic atherosclerotic narrowing of a coronary artery, this increased demand may precipitate angina. Other extracardiac precipitants of angina include the excessive metabolic demands imposed by fever, thyrotoxicosis (Chapter 207), severe anemia (Chapter 144)

ABSTRACT

Angina pectoris and myocardial ischemia generally result from an inadequate supply of blood flow and oxygen to an area of myocardium, typically resulting from a mismatch of myocardial oxygen demand and supply. Both exertional angina and dyspnea are common symptoms in the chronic setting. Obstructive coronary artery disease, which may have either acute or chronic presentations, most commonly results from a significant stenosis of greater than 70% in one or more of the major epicardial coronary arteries secondary to an atherosclerotic plaque. In acute disease expressions, the plaque may rupture or fissure, whereas symptoms of angina and objective findings of chronic ischemia typically result from a slowly advancing atherosclerotic process that compromises the arterial lumen. Increasingly, attention is being directed to ischemic manifestations that may occur in the absence of epicardial coronary artery narrowing, such as is observed in patients (most often women) who may exhibit "microvascular angina" due to involvement of the arteriolar resistance vessels, thereby resulting in impaired coronary vasodilator reserve. Other chronic manifestations of myocardial ischemia include vasospastic angina and silent myocardial ischemia (as detected electrographically or by imaging) in the absence of angina. Multiple diagnostic tests include laboratory assessments and both noninvasive and invasive approaches, which are often used in combination to risk-stratify patients and inform treatment options. These treatments include aggressive secondary prevention with both disease-modifying pharmacologic agents and drugs directed at the relief of angina/ischemia as well as intensive lifestyle interventions, which together comprise optimal medical therapy. Revascularization is also indicated in patients whose symptoms are refractory to intensive medical therapy or in patients who cannot tolerate antianginal medications. To date, data from multiple randomized controlled trials have failed to demonstrate that a strategy of routine upfront revascularization (with either percutaneous coronary intervention or coronary artery bypass graft surgery) plus optimal medical therapy reduces the rates of death or myocardial infarction or improves quality of life as compared with an intensive medical therapy alone. Thus, in the chronic setting, revascularization is principally indicated to relieve symptoms when medical therapy fails or for patients in whom quality of life remains unacceptable with a conservative approach to management.

from blood loss, tachycardia from any cause (Chapters 50, 52, 53), hypoglycemia (Chapter 211), and pain (Chapter 26).

By contrast, supply angina may occur in patients with either acute coronary syndrome (Chapter 57) or chronic ischemic heart disease by transient reductions in myocardial oxygen delivery as a consequence of coronary vasoconstriction with resulting dynamic coronary stenosis. In the presence of coronary luminal narrowing due to atherosclerosis, superimposed platelet thrombi and leukocytes may elaborate vasoconstrictor substances, such as serotonin and thromboxane A_2, whereas endothelial damage in diseased coronary arteries may decrease production of vasodilator substances such as nitric oxide and adenosine. The result is an abnormal physiologic vasoconstrictor response to exercise and other stimuli, such as exogenously administered adenosine, or the paradoxical vasoconstrictor response to the typical flow-mediated reactive hyperemia associated with brachial artery compression. Some patients with normal coronary angiograms or non–flow-limiting stenoses may exhibit dynamic obstruction alone, which can cause myocardial ischemia and result in angina at rest (Prinzmetal [variant] angina). Conversely, in patients with flow-limiting coronary stenoses, only a minor increase in dynamic obstruction can reduce blood flow sufficiently to cause myocardial ischemia.

The pathophysiologic basis for angina and myocardial ischemia has important implications for the selection of anti-ischemic agents. In patients with *demand angina*—in which increases in myocardial oxygen requirements are triggered by increases in heart rate, blood pressure, and contractility—therapeutic agents that reduce heart rate and wall tension, such as β-blockers or non-dihydropyridine calcium antagonists, will often provide the most clinical benefit. By comparison, nitrates and calcium antagonists with more potent vasodilatory properties (particularly the dihydropyridines) will be more beneficial to alleviate angina and ischemia mediated by coronary vasoconstriction and reductions in myocardial oxygen delivery.

Although the most common cause of chronic ischemic heart disease is atherosclerotic coronary artery narrowing and flow-limiting obstruction to epicardial blood flow, obstructive coronary artery disease may also have nonatherosclerotic causes, including congenital abnormalities of the coronary arteries (Chapter 55), coronary artery dissection, myocardial bridging, coronary arteritis in association with systemic vasculitides (Chapter 249), and radiation-induced coronary disease (Chapter 18). Importantly, myocardial ischemia and angina pectoris may occur commonly in the absence of obstructive coronary artery disease, a syndrome that is termed ischemia with nonobstructive coronary arteries (INOCA).[5] Angina and ischemia may also be associated with aortic valve disease, principally aortic stenosis (Chapter 60), hypertrophic cardiomyopathy (Chapter 47), and dilated cardiomyopathy.

CLINICAL MANIFESTATIONS

History

It is important to recognize that there are many causes of chest discomfort (see Table 39-2), that angina-like chest pain may not represent ischemic heart disease (Fig. 56-1), that ischemic heart disease causes symptoms other than anginal pain (Table 56-1), and that nonatherosclerotic coronary artery abnormalities may cause ischemic chest pain (Table 56-2).

Angina pectoris has four cardinal clinical features: the character of the discomfort, its site and distribution, its provocation, and its duration. The character of anginal discomfort is typically described as a pressure sensation that conveys a feeling of strangling and anxiety (Chapter 39), but patients may also use descriptors such as heaviness, squeezing, constricting, viselike, suffocating, and crushing. In some patients, especially women and the elderly, the quality of the sensation is more vague and atypical. Some patients may describe the discomfort as a burning sensation in the mid-epigastrium or as an uncomfortable, numb sensation. *Anginal equivalents* (i.e., symptoms of myocardial ischemia other than angina), such as dyspnea, fatigue, lightheadedness or dizziness, and gastric eructations, also may be manifestations of ischemic heart disease.

The site and distribution of anginal discomfort are predominantly midsternal or retrosternal but can be precordial. Radiation is common, usually to the left side of the neck and shoulder and down the ulnar surface of the left arm; radiation to the right arm is less common. Throat tightness or discomfort is a very important angina equivalent and should be a warning of coronary obstruction. Discomfort radiating to the jaw is common and must be distinguished from dental pain. Epigastric discomfort alone or in association with chest pressure may occur. Provocation of angina is classically caused by physical exertion or activity, emotional stress, exposure to the cold, sexual intercourse, or eating a large meal. Angina that occurs at rest or nocturnally often heralds a change in the pattern from stable to unstable and may indicate that there is an incipient plaque rupture leading to an acute coronary syndrome (ACS). Vasospastic (or Prinzmetal) angina may occur spontaneously at rest or nocturnally without provocation.

The typical duration of an episode of angina pectoris is brief. An episode usually begins gradually and reaches its maximal intensity during a period of

TABLE 56-1 NON–CHEST PAIN SYMPTOMS OF CHRONIC ISCHEMIC HEART DISEASE

DYSPNEA
Dyspnea on exertion
Dyspnea at rest
Paroxysmal nocturnal dyspnea
Temporal change of increasing exertional dyspnea with declining effort tolerance
NON–CHEST LOCATIONS OF DISCOMFORT (EITHER EXERTIONAL OR AT REST)
Neck or mandibular discomfort or pain
Throat tightness
Shoulder discomfort
Upper arm or forearm discomfort (more often left-sided)
Interscapular or infrascapular discomfort
MID-EPIGASTRIC OR ABDOMINAL
Mid-epigastric burning, often postprandially
Sharp abdominal pain (atypical, but more common in women)
Right upper quadrant discomfort (may mimic gallbladder disease or pancreatitis)
Nausea or vomiting (often associated with increased vagal tone secondary to inferior myocardial ischemia or infarction)
DIAPHORESIS
EXCESSIVE FATIGUE AND WEAKNESS
Often a discernible prodrome of increasing fatigue with declining effort tolerance
DIZZINESS AND SYNCOPE
Uncommon, unless precipitated or exacerbated by alterations in heart rate or rhythm (e.g., bradyarrhythmia, tachyarrhythmia, heart block), blood pressure (e.g., hypotension), or cardiac output (e.g., decreased cerebral perfusion)

minutes before abating. It is unusual for angina pectoris to peak and trough in less than a minute, and it is common that patients with exertional angina usually prefer to rest, to sit, or to stop walking during episodes that may be precipitated by the offending activity. Chest discomfort that persists for more than 15 to 20 minutes, especially at rest or nocturnally, is likely to represent ACS or MI. By contrast, features that suggest a noncardiac etiology of angina pectoris include pleuritic pain, pain reproduced by movement or palpation of the chest wall, sharp or constant pain lasting for many hours, pain or discomfort that a patient can localize to the chest wall with the tip of one finger, and very brief episodes of pain lasting seconds (Chapter 39). Typical angina pectoris is generally relieved within minutes by rest or the use of sublingual, oral, or cutaneous nitroglycerin. The response to sublingual nitroglycerin is often a helpful diagnostic tool, although some noncardiac pain (e.g., esophageal spasm) may also respond to nitroglycerin.

Although chest discomfort is usually the predominant symptom of ischemia, it is not invariably seen in all patients with chronic ischemic heart disease. Many individuals may complain predominantly or exclusively of dyspnea, diminishing exercise tolerance, fatigue, or weakness. Others will first present with an abnormal exercise test result or other evidence of myocardial ischemia without any symptoms (so-called *silent myocardial ischemia*). Some patients may present with cardiac arrhythmias or even sudden cardiac death.

Physical Examination

Many patients with chronic ischemic heart disease present with normal physical findings (Chapter 39), but a diligent physical examination may reveal findings that represent either the consequences of myocardial ischemia or evidence of risk factors for coronary heart disease. Inspection of the eyes may reveal a corneal arcus, and examination of the skin may show xanthomas (see E-Fig. 39-1). Retinal arteriolar changes are common in patients with coronary heart disease who have hypertension or diabetes mellitus (see Figs. 391-22 and 391-24).

The cardiac examination is generally of limited benefit in evaluating patients with chest discomfort or establishing a diagnosis of stable ischemic heart disease. During an episode of chest discomfort, myocardial ischemia may produce either a third or fourth heart sound.

Myocardial ischemia also can cause a transient holosystolic or mid-late systolic apical murmur due to reversible papillary muscle dysfunction that results in mitral regurgitation. These murmurs are more prevalent in patients with extensive coronary artery disease, especially with inferior or inferoposterior ischemia due to right coronary artery disease. It is important to distinguish such a murmur from the murmur of aortic stenosis or obstructive hypertrophic cardiomyopathy (see Tables 39-7 and 39-8). A displaced LV apical impulse, particularly if dyskinetic, is a sign of significant LV systolic dysfunction.

If patients have coexisting heart failure, an elevated jugular venous pressure, pulmonary rales, an S_3 gallop, and peripheral edema may be present (Chapter 45). The physical examination may reveal other implicating or contributing conditions, such as thyroid enlargement (Chapter 207) or severe anemia (Chapter 144).

DIAGNOSIS

In addition to a careful history and physical examination, assessment of patients with chronic ischemic heart disease includes the 12-lead electrocardiogram (ECG), measurement of biochemical and inflammatory markers, and noninvasive diagnostic testing (Chapter 44). The first goal is to assess the patient's probability of ischemia so that an appropriate evaluation can expedite effective therapy (Fig. 56-2). An acute syndrome with discomfort on minimal exertion or at rest requires urgent evaluation and treatment (Chapters 39 and 57), whereas a chronic syndrome with effort-related symptoms can be evaluated on an outpatient basis if an ECG does not show evidence of an acute myocardial infarction (Chapter 58), an acute coronary syndrome (Chapter 57), pericarditis (Chapter 62), or a worrisome arrhythmia (Chapters 51 to 53; Fig. 56-3).[6]

Resting Electrocardiogram

Although there may be focal, diagnostic findings of ST segment depression or T wave inversions (Fig. 56-4) on the resting ECG in patients with chronic ischemic heart disease, even those with extensive anatomic coronary artery disease may have a normal tracing at rest. In addition to myocardial ischemia, other conditions that can produce ST-T wave abnormalities include LV hypertrophy and dilation due to long-standing hypertension and valvular heart disease (e.g., aortic stenosis, hypertrophic cardiomyopathy), electrolyte abnormalities, neurogenic effects, and antiarrhythmic drugs. The presence of new ST-T wave abnormalities on the resting ECG, however, can be helpful in the diagnosis of coronary artery disease and may correlate with the severity of the underlying heart disease.

In addition to focal ST-T wave abnormalities, the ECG may reveal various conduction disturbances, most frequently left bundle branch block and left anterior fascicular block (Chapter 42). The finding of abnormal Q waves is relatively specific for the presence of previous MI but may not help determine when such an event occurred. Arrhythmias, especially ventricular premature beats (Chapter 53), may be present on the ECG but have a low sensitivity and specificity for coronary artery disease.

During a spontaneous episode of angina pectoris or during exertion or stress, the ECG becomes abnormal in 50% or more of patients with normal resting ECGs. The most common abnormality observed is focal ST segment depression, usually in one or more ECG lead groups, which signifies the presence of subendocardial ischemia. On occasion, transient but diminutive ST segment elevation and normalization of previous resting ST-T wave depression or inversion (pseudonormalization) may develop during chronic angina and ischemia, although ST segment elevation is far more commonly observed in ACS patients with plaque rupture.

Chest Radiography

Unless there is a history of prior MI, heart failure, or structural heart disease, the chest radiograph (Chapter 44) is usually normal in patients with stable angina and chronic ischemic heart disease. If an enlarged cardiac silhouette is present, it is generally indicative of a previous MI with LV dilation and cardiac remodeling. Other causes of cardiomegaly include long-standing hypertension (Chapter 64), concomitant valvular heart disease (Chapter 60), pericardial effusion (Chapter 62), and nonischemic cardiomyopathy (Chapter 47).

Laboratory Testing

In patients with new-onset or worsening symptoms, serial troponin measurements can distinguish MI and ACS from chronic ischemic heart disease (Chapters 57 and 58). The plasma levels of brain natriuretic peptide (BNP) and N-terminal pro-BNP, which increase in response to spontaneous or provoked ischemia, do not reliably distinguish stable from acute coronary syndromes but are associated with the risk of future cardiovascular events in patients who are at risk for coronary disease.

All patients with chronic angina should have biochemical evaluation of total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, triglycerides, serum creatinine (estimated glomerular filtration), and fasting blood glucose levels. In patients with known or suspected diabetes, a hemoglobin A_{1C} level should be obtained (Table 56-3). Other biochemical markers that are not routinely recommended but are associated with higher risk of future cardiovascular events include lipoprotein (a), apolipoprotein B, small dense LDL cholesterol, and lipoprotein-associated

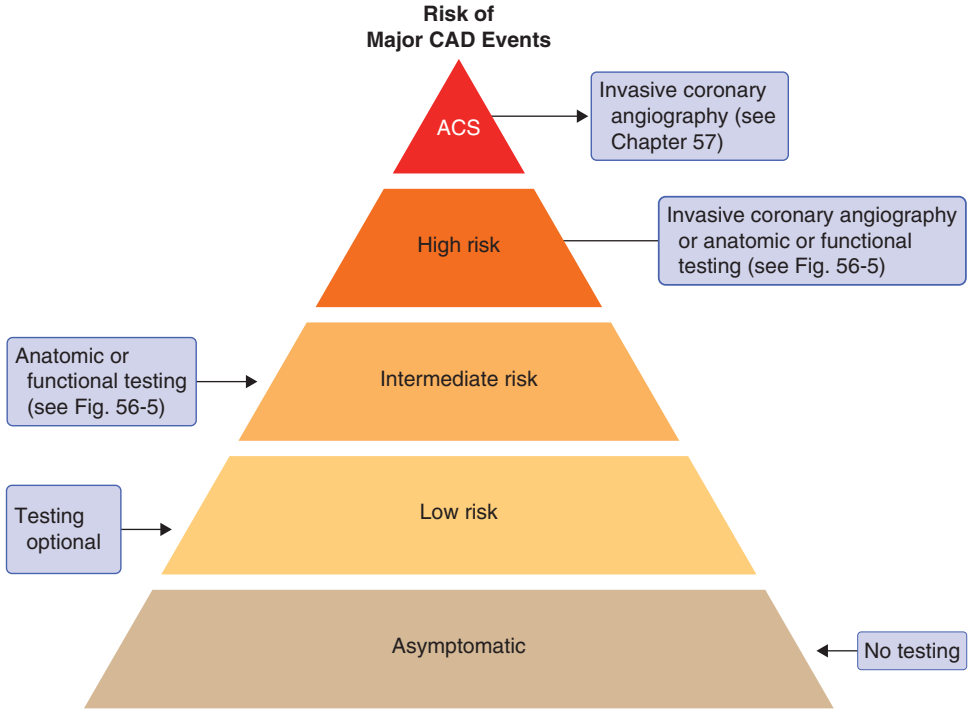

FIGURE 56-2. **Guide to when to consider noninvasive and invasive tests.** ACS = acute coronary syndrome (see Chapter 57). (From Gulati M, Levy PD, Mukherjee D, et al. 2021 AHA/ACC/ASE/CHEST/SAEM/SCCT/SCMR guideline for the evaluation and diagnosis of chest pain: a report of the American College of Cardiology/American Heart Association joint committee on clinical practice guidelines. *Circulation*. 2021;144:e368-e454.)

phospholipase A_2. Homocysteine levels correlate with the risk for development of coronary heart disease, but randomized trials have failed to demonstrate a reduction of clinical events when elevated homocysteine levels are reduced; as a result, routine screening for an elevated homocysteine level is not recommended.

High-sensitivity C-reactive protein, which is an acute-phase reactant of inflammation, has a strong and consistent relationship to the risk of future cardiovascular events, and an elevated level may warrant more aggressive diagnostic evaluation and therapy. Similarly, elevated levels of N-terminal pro-B-type natriuretic peptide can predict worse outcomes in patients with stable ischemic heart disease.

Differential Diagnosis of Angina

Many common noncardiac disorders may be manifested with clinical features that can be confused with angina pectoris (see Table 39-2). In some instances, symptoms may be indistinguishable from ischemic heart disease. For example, many patients with angina have coexisting esophageal disorders (Chapter 124), and both angina and esophageal discomfort may be relieved by nitroglycerin (Chapter 39). A distinguishing feature from angina is that esophageal discomfort is often relieved by antacids, proton pump inhibitors, or food.

Costochondritis can mimic angina but can typically be distinguished by the presence of well-localized pain on palpation. However, pressure, if it is applied too firmly to the anterior chest wall during examination of a patient with suspected angina pectoris, may elicit symptoms of discomfort even in normal subjects. Cervical radiculopathy may cause pain radiating to the shoulders, neck, or upper arms and can be confused with angina. However, this condition typically causes a constant ache that is often exacerbated by neck movement or rotation and may be accompanied by a focal sensory deficit or radiculopathy.

Pulmonary hypertension (Chapter 69) can cause exertional chest discomfort that may share many of the characteristics of angina pectoris. It is believed that right ventricular ischemia during physical exertion may cause this discomfort along with associated symptoms of exertional dyspnea, dizziness, and syncope. Findings on physical examination typically include a parasternal lift, a loud (and sometimes palpable) pulmonary component of the second heart sound, and findings of right ventricular hypertrophy on electrocardiography.

Chest discomfort may also be an important presenting clinical feature of pulmonary embolism (Chapter 68). Physical findings typically include tachycardia and tachypnea, an accentuated pulmonic component of the second heart sound, and occasionally a right-sided S_4 gallop. Pleuritic discomfort suggests pulmonary infarction, whereas a history of pain exacerbated by inspiration or deep breathing, along with a pleural friction rub, usually helps distinguish it from angina pectoris.

Acute pericarditis (Chapter 62) may be confused with the discomfort of angina pectoris, but pericarditis tends to cause chest pain that is generally sharp, is not relieved by rest or nitroglycerin, is exacerbated by movement or deep breathing, and is associated with a pericardial friction rub that may be evanescent. Aortic dissection (Chapter 63), which may be manifested with acute, severe chest pain, may be confused with an acute MI but generally not with angina.

Pretest Probability in Patients with Angina or Ischemic Equivalents

When symptoms of angina or exertional dyspnea prompt consideration of coronary heart disease and the need for additional cardiac evaluation, the clinician should first make a probability estimate of the likelihood that obstructive coronary disease is present. A number of validated risk assessment models exist that, in general, are useful in calculating this probability as follows:

- Low Pretest Probability: less than 10% pretest probability of coronary heart disease;
- Intermediate Pretest Probability: between 10% and 90% pretest probability of coronary heart disease;
- High Pretest Probability: greater than 90% pretest probability of coronary heart disease.

Recent evidence suggests that the pretest probability of detecting obstructive coronary disease among middle-aged men and women with typical angina has declined appreciably, to 32% and 44% in men aged 50 to 59 and 60 to 69 years, respectively, and to just 13% and 16% in women aged 50 to 59 and 60 to 69 years, respectively (see Fig. 56-1). These data reinforce the observation that epicardial coronary obstruction may be less common than previously believed and that other causes of chronic myocardial ischemia, such as coronary vasospasm, microvascular angina, and ischemia with nonobstructive coronary arteries, may be as frequent, if not more frequent.

Noninvasive Testing

Noninvasive stress testing with a standard electrocardiographic treadmill or bicycle exercise, radionuclide imaging (Chapter 44), stress echocardiography (Chapter 43), or newer diagnostic modalities such as cardiac magnetic resonance (CMR; Chapter 44) and positron emission tomography (PET; Chapter 44)

Pretest likelihood of CAD	Low →	No testing necessary →	Option for CAC for ASCVD risk stratification		(see Chapter 44)
	Intermediate-high →	Younger patient (age < 65 years)	**OR**	Less obstructive CAD suspected →	CCTA favored (see Chapter 44)
	Intermediate-high →	Older patient (age ≥ 65 years)	**OR**	More obstructive CAD suspected →	Stress testing favored

	Favors use of CCTA	Favors use of stress imaging
Goal	• Exclude obstructive CAD • Detect nonobstructive CAD	• Ischemia-guided management
Availability and expertise	• High-quality imaging and expert interpretation routinely available	• High-quality imaging and expert interpretation routinely available
Likelihood of obstructive CAD	• Age <65 years	• Age ≥65 years
Prior test results	• Prior functional study inconclusive	• Prior CCTA inconclusive
Other compelling indications	• Patient unable to exercise • Anomalous coronary arteries • Require evaluation of aorta or pulmonary arteries	• Suspect scar (especially if PET or stress CMR available) • Suspect coronary microvascular dysfunction (when PET or CMR available)

FIGURE 56-3. Approach to choosing diagnostic testing in suspected angina pectoris or chronic ischemic heart disease. ASCVD = atherosclerotic cardiovascular disease; CAC = coronary artery calcium; CAD = coronary artery disease; CCTA = coronary computed tomography angiography; CMR = cardiovascular magnetic resonance; ETT = exercise tolerance test; LV = left ventricular; MPI = myocardial perfusion imaging; PET = positron emission tomography; SPECT = single-photon emission computed tomography. (From Gulati M, Levy PD, Mukherjee D, et al. 2021 AHA/ACC/ASE/CHEST/SAEM/SCCT/SCMR guideline for the evaluation and diagnosis of chest pain: a report of the American College of Cardiology/American Heart Association joint committee on clinical practice guidelines. *Circulation*. 2021;144:e368-e454.)

are useful and clinically important options for establishing the diagnosis and prognosis in patients with chronic ischemic heart disease (Fig. 56-5). The predictive accuracy of these tests is defined not only by their sensitivity and specificity but also by the prevalence of disease (or pretest probability) in the population under study. Noninvasive testing should be performed only if the incremental information is likely to alter the planned management strategy. Thus, the value of noninvasive stress testing is limited in patients with a very low likelihood of ischemic heart disease (Chapter 44) and is greatest when the pretest likelihood is intermediate because the test result is likely to have the greatest effect on the post-test probability of coronary artery disease and, hence, on clinical decision making.[7]

Each noninvasive test has a sensitivity and specificity (Table 56-4) that, when combined with a patient's pretest probability (see Table 56-1), can yield a post-test probability that may essentially rule in or rule out significant for coronary artery disease (Fig. 56-6).[8] The choice among tests depends on the patient's characteristics (see Figs 56-3 and 56-5). Stress testing can be performed carefully in patients with mild aortic valve stenosis or hypertrophic cardiomyopathy but generally should be avoided in patients with severe disease.

Cardiac Computed Tomographic Angiography

Cardiac computed tomographic angiography (CCTA; Chapter 44) is a highly sensitive method to detect coronary calcification (see Fig. 44-9), which is strongly associated with coronary atherosclerosis, and can also provide noninvasive angiography of the proximal coronary arteries. Although coronary calcification is a highly sensitive (approximately 90%) finding in patients with coronary artery disease, the specificity for identifying patients with obstructive coronary artery disease is much lower (approximately 50%). Because of the potential unnecessary testing from false-positive results, CCTA is currently not recommended as a routine screening approach for suspected obstructive coronary artery disease in individuals who are asymptomatic or are at low risk (<10% 10-year estimated risk of coronary events).

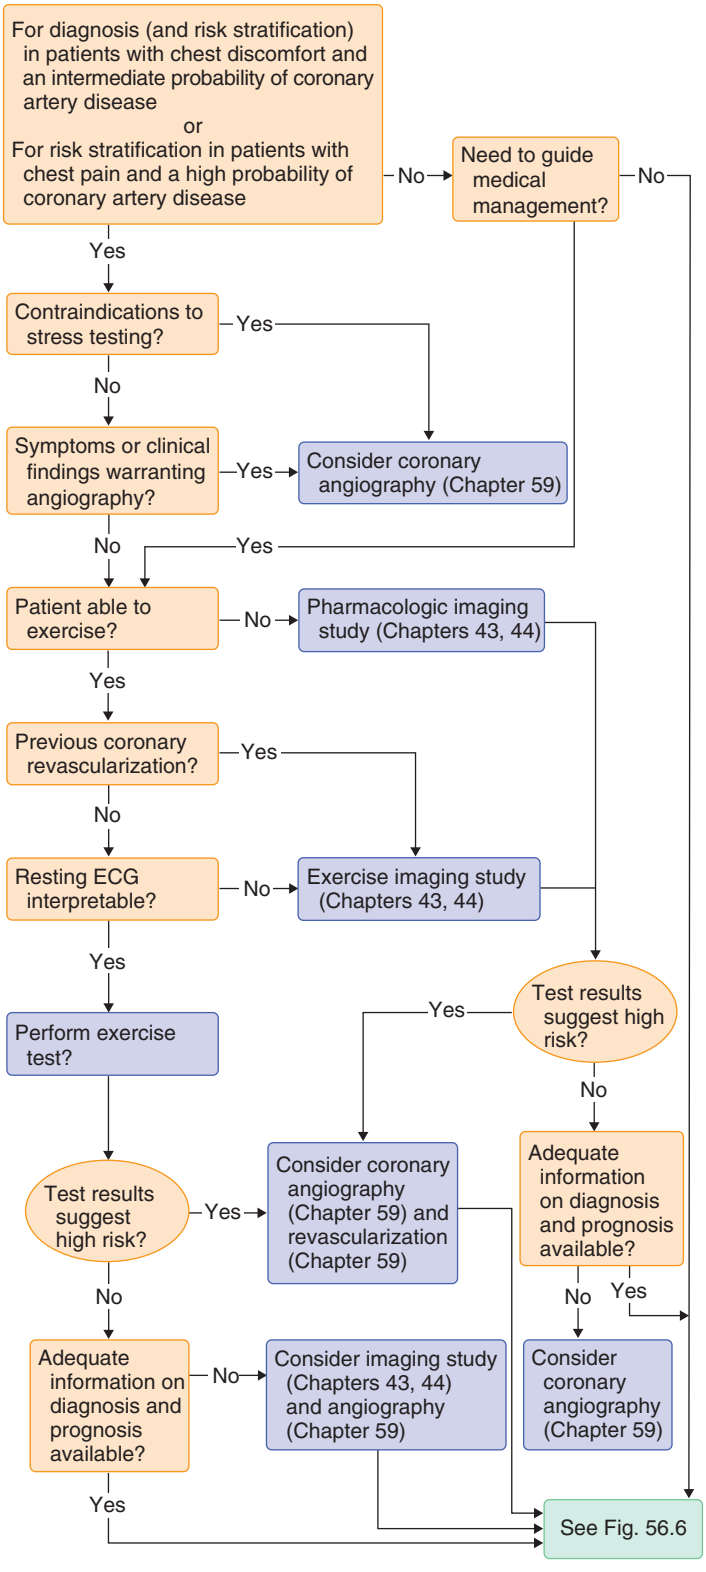

FIGURE 56-5. **Approach to the use of stress testing and angiography for the evaluation of chronic stable angina.** ECG = electrocardiogram. (Modified from American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Management of patients with chronic stable angina. *ACC/AHA/ACP-ASIM Pocket Guidelines*. Philadelphia: Elsevier Science; 2000.)

By contrast, selective screening of intermediate-risk patients may be reasonable because a high calcium score may reclassify such individuals as higher risk and thereby lead to more intensive risk factor modification and treatment.[9] In symptomatic patients who have an intermediate pretest probability of obstructive coronary artery disease, stress myocardial perfusion imaging and CCTA are equivalent in predicting the composite end point of death, MI, or hospitalization for ACS.[A1,A2] A negative CCTA portends a very favorable prognosis. Since CCTA identifies both obstructive and nonobstructive coronary artery disease, however, it appears to provide better overall prognostic information[A3,A4] and has replaced functional testing in some recent guidelines. CCTA is also a diagnostic alternative to invasive coronary angiography for patients who have stable chest pain and an intermediate probability of obstructive coronary disease.[A5]

Exercise Electrocardiography

An exercise ECG is the preferred test in patients who have suspected angina pectoris and are considered to have a moderate probability of coronary artery disease if the resting ECG is interpretable (i.e., ST segments are not obscured by structural heart disease or medication), provided subjects are capable of achieving an adequate workload. Interpretation of the exercise ECG should include the exercise capacity achieved (duration and metabolic equivalents of the external workload), the magnitude and extent of ST segment deviation, the clinical and hemodynamic responses to exercise, and the rapidity with which the heart rate returns to normal after exercise (recovery phase).

The exercise test protocol is usually adjusted to a patient's tolerance, aiming for 6 to 12 minutes of exercise time (i.e., Bruce protocol stages II to IV) to achieve maximal oxygen consumption and to elicit objective evidence of inducible ischemia, if present. Exercise stress testing is generally safe,

with death or MI occurring in less than one case per 2500 tests, when such provocative testing is avoided in patients with ACS, severe aortic stenosis, severe hypertension, or uncontrolled heart failure. Other contraindications are acute MI, symptomatic arrhythmias, acute pulmonary embolism, and suspected acute aortic dissection. Relative contraindications are hypertension above 200 mm Hg systolic or 110 mm Hg diastolic, significant aortic stenosis, hypertrophic cardiomyopathy, and high-degree atrioventricular block.

Concomitant antianginal therapy (notably the use of β-blockers) reduces the sensitivity of exercise testing as a screening tool. If the purpose of the exercise test is to diagnose ischemia, it should be performed, whenever possible, before β-blockers are initiated or 2 to 3 days after their discontinuation.

TABLE 56-4 APPROXIMATE SENSITIVITIES AND SPECIFICITIES OF COMMON NONINVASIVE TESTS TO DIAGNOSE CORONARY ARTERY DISEASE

TEST	SENSITIVITY (%)	SPECIFICITY (%)
Stress ECG	58	62
Stress echocardiography	85	82
CCTA	97	78
SPECT	87	70
PET	90	85
Stress CMR	90	80

CCTA = coronary computed tomography angiography; CMR = stress cardiac magnetic resonance; ECG = electrocardiogram; PET = positron emission tomography; SPECT = single-photon emission computed tomography (exercise stress SPECT with or without dipyridamole or adenosine); stress echocardiography = exercise stress echocardiography.

Adapted from Knuuti J, Ballo H, Juarez-Orozco LE, et al. The performance of non-invasive tests to rule-in and rule-out significant coronary artery stenosis in patients with stable angina: a meta-analysis focused on post-test disease probability. *Eur Heart J*. 2018;39:3322-3330.

Nuclear Cardiology Imaging

Stress myocardial perfusion imaging (Chapter 44) with single-photon emission computed tomography (SPECT) with simultaneous electrocardiographic testing (see Fig. 44-8) is particularly helpful in the diagnosis of coronary artery disease in patients with abnormal resting ECGs and among those in whom ST segment responses cannot be interpreted accurately, such as patients with repolarization abnormalities caused by LV hypertrophy, those with left bundle branch block, and those receiving digitalis. Its sensitivity and specificity are superior to exercise electrocardiography alone in detecting coronary artery disease (especially multivessel disease), in identifying regional perfusion defects that may localize to and correlate with diseased vessels, and in delineating the magnitude and extent of ischemic and infarcted myocardium. Treadmill testing is preferred for patients who can perform such physical activity because of the additional diagnostic and prognostic information achieved with graded exercise. In the 40 to 50% of patients who are unable to exercise adequately, however, myocardial perfusion imaging with pharmacologic vasodilator stress with dipyridamole, adenosine, or regadenoson may be the preferred approach to noninvasive testing.

Stress Echocardiography (Chapter 43)

Stress two-dimensional echocardiography with exercise or pharmacologic stress can detect regional ischemia by identifying new wall motion abnormalities (see Fig. 43-7). Additional clinical information about associated structural heart disease, chamber dimensions, and valve function can be readily obtained. Exercise echocardiography can detect the presence of coronary artery disease with an accuracy similar to that achieved with stress myocardial perfusion imaging and is useful for localizing and quantifying ischemic myocardial segments. Pharmacologic stress is usually performed with dobutamine in patients who are unable to exercise and in those unable to achieve adequate heart rates with exercise.

Stress Cardiac Magnetic Resonance Imaging (Chapter 44)

Pharmacologic stress perfusion with CMR imaging is becoming increasingly available in many centers and may provide additional diagnostic capability in detecting the presence of structural heart disease, in addition to suspected coronary artery disease. CMR with gadolinium enhancement is the most accurate way to diagnose a scar from a prior MI (see Fig. 44-13). Preliminary

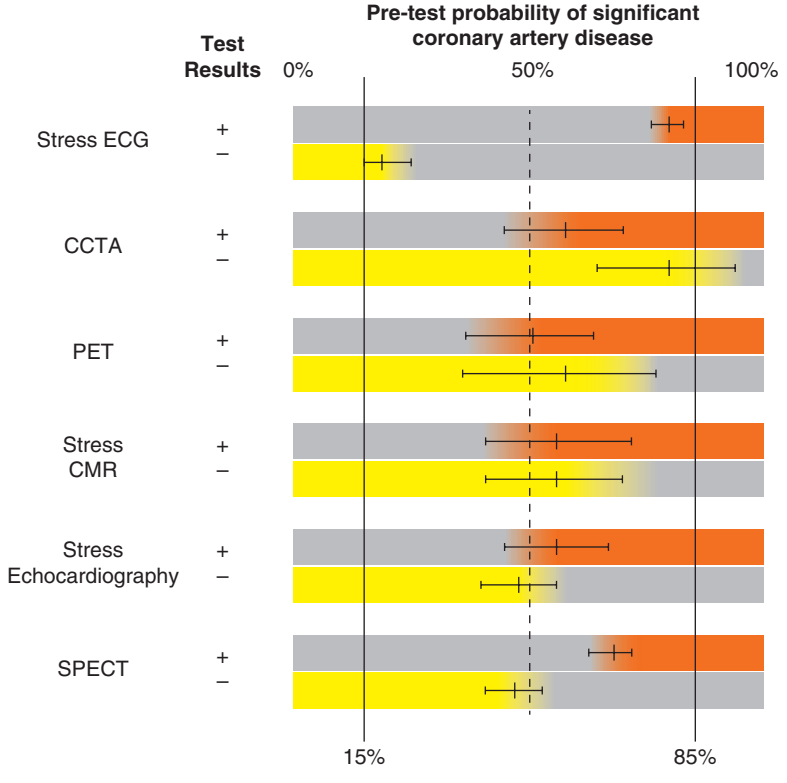

FIGURE 56-6. Ability of noninvasive tests to rule in or rule out significant coronary artery disease. TABLE 56-5 CORONARY ANGIOGRAPHY FOR DIAGNOSIS AND RISK STRATIFICATION IN PATIENTS WITH CHRONIC ANGINA AND STABLE ISCHEMIC HEART DISEASE

FOR INITIAL DIAGNOSTIC INDICATION
Recommended on the Basis of Evidence or General Consensus
Patients with suspected angina and evidence of intermediate-high risk, moderate-severe ischemia on noninvasive testing, or a changing angina pattern who have survived sudden cardiac death or serious ventricular arrhythmia
Weight of Evidence or Opinion Is in Favor
Uncertain diagnosis after noninvasive testing, and the benefit of a more certain diagnosis outweighs the risk and cost of coronary angiography
Inability to undergo noninvasive testing because of disability, illness, or morbid obesity
Occupational requirement for a definitive diagnosis
Suspected nonatherosclerotic cause of myocardial ischemia
Suspicion of a coronary spasm
High pretest probability of left main or three-vessel disease
Recurrent hospitalization for chest pain in the absence of definitive diagnosis
Overriding desire for a definitive diagnosis and a greater than low probability of CAD
Not Recommended
Significant comorbidity in patients in whom the risk of coronary arteriography outweighs the benefit of the procedure
Overriding personal desire for a definitive diagnosis and a low probability of CAD
FOR INITIAL RISK STRATIFICATION OR TREATMENT INDICATION
Recommended on the Basis of Evidence or General Consensus
With disabling (CCS class III and class IV) chronic stable angina despite medical therapy
With high-risk criteria on noninvasive testing regardless of anginal severity
Patients with angina who have survived sudden cardiac death or serious ventricular arrhythmia
Angina and symptoms and signs of congestive heart failure
Clinical characteristics that indicate a high likelihood of severe CAD
Weight of Evidence or Opinion Is in Favor
Significant left ventricular dysfunction (EF < 45%), CCS class I or class II angina, and demonstrable ischemia but less than high-risk criteria on noninvasive testing
High-risk criteria suggesting ischemia on noninvasive testing
Inadequate prognostic information after noninvasive testing
Clinical characteristics that indicate a high likelihood of severe CAD
CCS class I or class II angina, preserved left ventricular function (EF > 45%), and less than high-risk criteria on noninvasive testing
CCS class III or class IV angina that improves to class I or class II with medical therapy
CCS class I or class II angina but intolerance (unacceptable side effects) to adequate medical therapy
Not Recommended
CCS class I or class II angina in patients who respond to medical therapy and who have no evidence of ischemia on noninvasive testing
Patients who prefer to avoid revascularization after adequate explanation

CAD = coronary artery disease; CCS = Canadian Cardiovascular Society; EF = ejection fraction.
Modified from Gibbons RJ, Abrams J, Chatterjee K, et al. ACC/AHA 2002 guideline update for the management of patients with chronic stable angina—summary article: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Patients with Chronic Stable Angina). *Circulation*. 2003;107:149-158.

TABLE 56-6 USING THE RESULTS OF NONINVASIVE RISK STRATIFICATION TO GUIDE CLINICAL DECISION MAKING

HIGH RISK (>3% ANNUAL MORTALITY RATE)
Severe resting left ventricular dysfunction (LVEF < 35%)
High-risk treadmill score (≤−11)*
Severe exercise left ventricular dysfunction (exercise LVEF <35%)
Stress-induced large perfusion defect (particularly if anterior)
Stress-induced multiple perfusion defects of moderate size
Large, fixed perfusion defect with left ventricular dilation or increased lung uptake (^{201}Tl)
Stress-induced moderate perfusion defect with left ventricular dilation or increased lung uptake (^{201}Tl)
Echocardiographic wall motion abnormality (involving more than two segments) developing at a low dose of dobutamine or at a low heart rate (<120 beats/min)
Stress echocardiographic evidence of extensive ischemia
INTERMEDIATE RISK (1-3% ANNUAL MORTALITY RATE)
Mild to moderate resting left ventricular dysfunction (LVEF = 35-49%)
Intermediate-risk treadmill score (−11 < score < 5)*
Stress-induced moderate perfusion defect without left ventricular dilation or increased lung intake (^{201}Tl)
Limited stress echocardiographic ischemia with a wall motion abnormality only at higher doses of dobutamine involving two segments or less
LOW RISK (<1% ANNUAL MORTALITY RATE)
Low-risk treadmill score (≥5)*
Normal or small myocardial perfusion defect at rest or with stress†
Normal stress echocardiographic wall motion or no change of limited resting wall motion abnormalities during stress†

*Score = (duration of exercise in minutes) − (5 × mm of ST segment depression) − (4 × angina score), where 0 = no angina, 1 = nonlimiting angina, and 2 = angina that causes discontinuation of the test.
†Although the published data are limited, patients with these findings will probably not be at low risk in the presence of either a high-risk treadmill score or severe resting left ventricular dysfunction (LVEF < 35%).
LVEF = left ventricular ejection fraction; Tl = thallium.
From Gibbons RJ, Abrams J, Chatterjee K, et al. ACC/AHA 2002 guideline update for the management of patients with chronic stable angina—summary article: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines (Committee on the Management of Patients with Chronic Stable Angina). *J Am Coll Cardiol*. 2003;41:159-168.

data suggest that cardiovascular magnetic resonance imaging may be equally sensitive but more specific than fractional flow reserve (see "Diagnostic Coronary Angiography") for determining which patients will benefit from revascularization.[A6]

Diagnostic Coronary Angiography

Despite the continued evolution of noninvasive diagnostic testing, invasive coronary angiography (Chapter 59) remains the "gold standard" for anatomic definition of obstructive coronary artery disease. Among patients who have a clinical diagnosis of stable angina and chronic myocardial ischemia and who are referred for coronary angiography, a 70% or more luminal diameter narrowing is found in one (about 25%), two (about 25%), or all three (about 25%) epicardial coronary arteries in about 75% of cases; another 5 to 10% of patients have obstruction of the left main coronary artery; and the remaining 15 to 20% have no flow-limiting coronary obstructions. These data emphasize the persisting role of coronary angiography for diagnostic purposes (Table 56-5), but angiography is also helpful for risk stratification in patients with clear-cut angina and chronic ischemic heart disease. In patients with less severe coronary stenoses (i.e., 50 to 70% on angiography), coronary intravascular ultrasonography can substantially enhance the quantification of obstruction and vulnerability of the coronary atheroma to future instability. Alternatively, an invasive physiologic approach with use of a pressure wire positioned proximal and distal to a coronary stenosis can measure the severity of the stenosis and determine whether functionally significant flow reduction (i.e., a decreased fractional flow reserve [FFR] <0.8) is present. This technique may be useful when there is a borderline (50 to 60%) visual coronary stenosis at angiography, particularly if such a stenosis subtends an ischemic myocardial segment observed on noninvasive testing. An FFR below 0.8 is generally considered to represent a sufficiently important reduction in coronary flow to justify proceeding to percutaneous coronary intervention (Chapter 59) to reduce symptoms and the subsequent need for urgent revascularization.[A7] By contrast, an FFR of 0.8 or higher would indicate that myocardial revascularization of the stenotic coronary artery would be of little benefit clinically.

Risk Stratification

Clinical and noninvasive criteria can be used in a complementary fashion to refine the estimate of risk for the individual patient with chronic ischemic heart disease (Table 56-6). Clinical characteristics that include age, male sex, diabetes mellitus, previous MI, and symptoms typical of angina are predictive of the presence of coronary artery disease. Heart failure and LV dysfunction (generally defined by an ejection fraction <50%), the severity and extent of angina, and associated symptoms such as dyspnea are also important predictors of outcome in patients with chronic ischemic heart disease.

The simple classification of disease into single-, double-, or triple-vessel or left main coronary artery disease remains the most widely used approach (Table 56-8). Additional prognostic information is provided by the severity and extent of coronary luminal narrowing and its location. For example, high-grade lesions of the left main coronary artery or its equivalent, as defined by severe proximal left anterior descending and proximal left circumflex coronary artery disease, are particularly life-threatening. The SYNTAX trial has permitted the

TABLE 56-7 TREATMENT OF PATIENTS WITH STABLE ANGINA

GENERAL MEASURES
Rule out and control aggravating conditions
Associated noncardiac diseases
Associated cardiac disease
Use of drugs aggravating angina
Smoking cessation
Dietary counseling for body weight and lipid control
Exercise prescription
Treat to targets
Hypertension
Blood lipids
Diabetes
PHARMACOLOGIC THERAPY: RECOMMENDATIONS FOR PHARMACOTHERAPY TO PREVENT MI AND DEATH AND TO REDUCE SYMPTOMS
Recommended on the Basis of Evidence or General Consensus
Aspirin in the absence of contraindications
β-Blockers as initial therapy in the absence of contraindications in patients with prior MI or without prior MI
Angiotensin-converting enzyme inhibitor in all patients with CAD who also have diabetes or left ventricular systolic dysfunction
Low-density lipoprotein–lowering therapy in patients with documented or suspected CAD, with a target <55 mg/dL using high-potency statins, ezetimibe, and PCSK9 inhibitors
Sublingual nitroglycerin or nitroglycerin spray for the immediate relief of angina
Calcium-channel antagonists or long-acting nitrates as initial therapy for reduction of symptoms when β-blockers are contraindicated
Calcium-channel antagonists or long-acting nitrates in combination with β-blockers when initial treatment with β-blockers is not successful
Calcium-channel antagonists and long-acting nitrates as a substitute for β-blockers if initial treatment with β-blockers leads to unacceptable side effects
Weight of Evidence or Opinion Is in Favor
Rivaroxaban 2.5 mg twice daily added to low-dose (81-100 mg daily) aspirin
Clopidogrel when aspirin is contraindicated
Long-acting non-dihydropyridine calcium-channel antagonists instead of β-blockers as initial therapy
Weight reduction and increased physical activity in persons with metabolic syndrome
Consider fibric acid derivatives for high-risk patients with elevated triglycerides if LDL-cholesterol is at target on statin therapy
Angiotensin-converting enzyme inhibitor in patients with CAD or other vascular disease
Not Recommended
Dipyridamole
Chelation therapy

CAD = coronary artery disease; HDL = high-density lipoprotein; LDL = low-density lipoprotein; MI = myocardial infarction; PCSK9 = proprotein convertase subtilisin/kexin type 9.

TABLE 56-8 CURRENT RECOMMENDATIONS FOR MYOCARDIAL REVASCULARIZATION IN PATIENTS WITH CHRONIC STABLE ANGINA

CABG SURGERY VERSUS MEDICAL THERAPY
Among patients with medically refractory angina pectoris, CABG surgery is indicated for symptom improvement.
Among patients with medically stable angina pectoris, CABG surgery is indicated to prolong life in left main coronary artery disease or three-vessel disease (regardless of left ventricular function) and, possibly, to help symptoms.
CABG surgery may be indicated for prolongation of life if the proximal left anterior descending coronary artery is involved (regardless of the number of diseased vessels).
CABG surgery may reduce the composite end point of death, myocardial infarction, or stroke in diabetic patients with extensive multivessel (two- to three-vessel) coronary artery disease compared with medical therapy.
CABG surgery can reduce symptoms, cardiovascular events, and death in diabetic patients with stable angina.
PCI VERSUS MEDICAL THERAPY
For the initial management of patients with stable ischemic heart disease, PCI does not reduce the risk of death, myocardial infarction, or other major cardiovascular events when it is added to optimal medical therapy.
Among patients with symptomatic angina pectoris, PCI is indicated to improve symptoms.
PCI may be indicated in the presence of severe myocardial ischemia, regardless of symptoms. PCI does not appear to improve survival compared with medical treatment among patients with one- or two-vessel disease.
In the absence of symptoms of myocardial ischemia, PCI is not indicated (merely for the presence of an anatomic stenosis).
PCI VERSUS CABG SURGERY
For single-vessel disease, PCI and CABG surgery provide excellent symptom relief, but repeated revascularization procedures are required more frequently after PCI. Intracoronary stenting is preferred to regular PCI, but direct comparison with CABG surgery is limited.
For treating diabetic patients with two- or three-vessel disease, CABG surgery is the treatment of choice.
For nondiabetic patients, multivessel PCI and CABG surgery are acceptable alternatives. The choice of PCI or CABG surgery for initial treatment depends primarily on local expertise and the patient's and physician's preferences.
In general, PCI is preferred for patients at low risk and CABG surgery for patients at high risk.

CABG = coronary artery bypass graft; PCI = percutaneous coronary intervention.

identification of subsets of coronary artery disease patients into three tertiles of low-, moderate-, and high-risk anatomic findings based on multiple lesional characteristics (see Table 56-7). Although the plaque that is causing the most severe chronic stenosis is not necessarily the one that will subsequently rupture to cause an acute coronary syndrome or acute MI, the underlying extent and severity of the coronary stenoses are nevertheless potent predictors of the likelihood of a critical plaque rupture somewhere in the epicardial coronary arterial circulation.

TREATMENT

Comprehensive management of angina and chronic ischemic heart disease (Fig. 56-7) entails multiple therapeutic approaches to the identification and treatment of associated diseases that can precipitate or worsen angina and ischemia (Table 56-8): cardiac risk factor identification and intervention; application of pharmacologic and nonpharmacologic interventions for secondary prevention; pharmacologic and symptomatic management of angina and ischemia; and myocardial revascularization with percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) surgery, when indicated (Table 56-8).[10,11] A multidimensional management approach integrates all of these considerations, often simultaneously, in each patient. Among pharmacotherapies, three drug classes are classified as being "disease modifying" in that they have been demonstrated to reduce mortality and morbidity in patients with chronic ischemic heart disease and preserved LV function: antiplatelet agents such as aspirin; inhibitors of the renin-angiotensin-aldosterone system, especially angiotensin-converting enzyme (ACE) inhibitors; and effective lipid-lowering agents, principally statins (Chapter 40). In patients who have type 2 diabetes, the use of either a sodium-glucose cotransporter-2 inhibitor or a glucose-like peptide-1 agonist can reduce cardiac events (Chapter 210). Other therapies, such as nitrates, β-blockers, calcium antagonists, and ranolazine, can reduce symptomatic myocardial ischemia, ameliorate or prevent angina, and improve exercise performance, but they have not been shown to reduce mortality in patients with chronic ischemic heart disease.

Medical Therapy

Careful attention to lifestyle and the management of coronary risk factors is essential (Fig. 56-8). Such secondary prevention strategies can reduce the risk of progressive coronary disease, morbidity, and mortality.

Drugs That Alter Lipid Metabolism

Each 1% increase in the LDL cholesterol level results in a 2 to 3% increase in the risk for coronary events (Chapter 40). Large, randomized clinical trials in patients with ischemic heart disease have shown a consistent and significant reduction in mortality and cardiac events with statin therapy (Chapter 190). Patients with stable angina and documented ischemic heart disease should routinely be treated with statins[A8] (see Table 190-2). Current U.S. guidelines

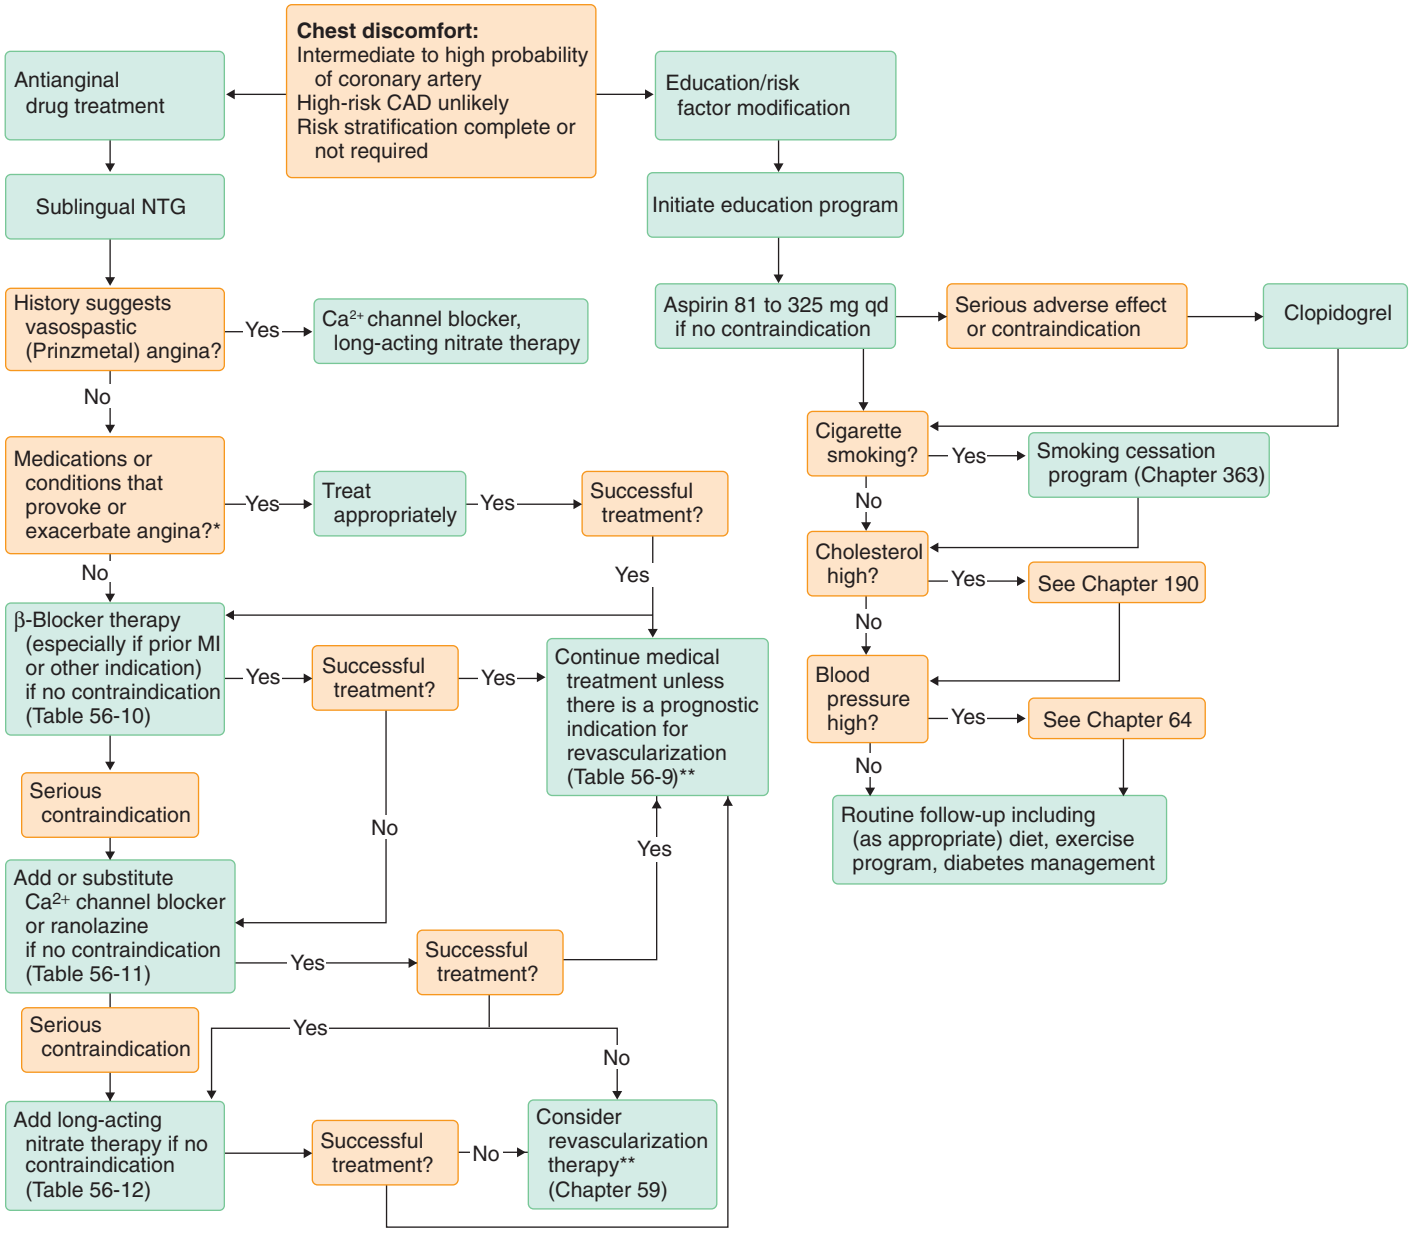

FIGURE 56-7. Algorithm for the oral treatment of stable angina. Both pathways (Antianginal Drug Treatment and Education/Risk Factor Modification) must be completed. *Conditions that exacerbate or provoke angina: medications: vasodilators, excessive thyroid replacement, vasoconstrictors; other medical problems: profound anemia, uncontrolled hypertension, hyperthyroidism, hypoxemia; other cardiac problems: tachyarrhythmias, bradyarrhythmias, valvular heart disease (especially AS), hypertrophic cardiomyopathy. **At any point in this process, based on coronary anatomy, severity of anginal symptoms, and patient preferences, it is reasonable to consider evaluation for coronary revascularization. Unless a patient is documented to have left main, three-vessel, or two-vessel CAD with significant stenosis of the proximal left anterior descending coronary artery, there is no demonstrated survival advantage associated with revascularization in low-risk patients with chronic stable angina; thus, medical therapy should be attempted in most patients before considering PTCA or CABG. AS = aortic stenosis; CABG = coronary artery bypass graft; CAD = coronary artery disease; MI = myocardial infarction; NTG = nitroglycerin; PTCA = percutaneous transluminal coronary angioplasty; qd = once daily. (Modified from American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Management of Patients with Chronic Stable Angina. *ACC/AHA/ACP-ASIM Pocket Guidelines*. Philadelphia: Elsevier Science; 2000.)

recommend high-potency statin therapy (e.g., atorvastatin up to 80 mg per day or rosuvastatin up to 40 mg per day) with periodic monitoring of LDL levels to a target of less than 70 mg/dL, whereas European guidelines recommend a more stringent LDL target of less than 55 mg/dL. With the documentation of additional benefit from ezetimibe and PCSK9 antagonists, most U.S. cardiologists have also adopted these more intensive targeted levels.[12]

Ezetimibe added to statins lowers LDL and reduces subsequent cardiovascular events in patients who have survived an acute coronary syndrome,[A9] even when statins have reduced LDL levels to 50 to 100 mg/dL. PCSK9 inhibitors, which can reduce LDL levels by 60% and LDL levels to less than 30 mg/dL in most patients, are an effective option for patients with elevated LDL levels despite statins, with or without ezetimibe, and further reduce dyslipidemic residual risk, especially in high-risk patients (Chapter 190).[A10]

A pure eicosapentaenoic acid derivative (an icosapent ethyl ester) can significantly reduce cardiovascular death, MI, and stroke as well as all-cause mortality when added to statins in patients who have ischemic heart disease, well-controlled LDL levels (40 to 100 mg/dL), and elevated baseline triglyceride levels (135 to 500 mg/dL).[A11] However, bile acid sequestrants, fibrates, and various fish oil preparations (Chapters 190) targeted to reduce the triglyceride level or raise the HDL cholesterol level have failed to reduce clinical events when added to statins.[A12] Drug therapies directed specifically at raising low levels of HDL with either niacin or cholesteryl ester transfer protein inhibitors have been uniformly disappointing and are not recommended.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors and angiotensin receptor blockers (see Table 64-7) reduce cardiac events, cardiovascular mortality, and all-cause mortality in patients with risk factors for or with previously diagnosed coronary artery disease, including high-risk patients with vascular disease or diabetes and patients with chronic ischemic heart disease and no clinical evidence of heart failure. However, the incremental benefit of such agents in otherwise well-treated patients without high-risk features remains less clear.[A13]

Antiplatelet Agents and Anticoagulants

Aspirin reduces the risk of adverse cardiovascular events in patients with angina and chronic ischemic heart disease, and in the absence of contraindications,

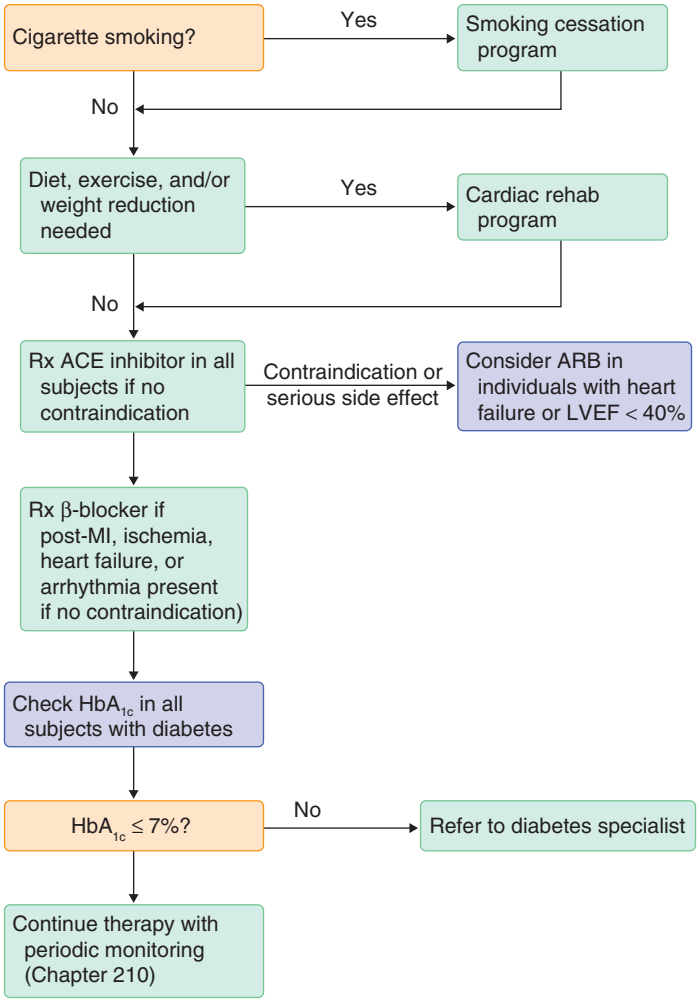

FIGURE 56-8. Approach to lifestyle interventions and pharmacotherapy. ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; HbA_{1c} = hemoglobin A_{1c}; LVEF = left ventricular ejection fraction; MI = myocardial infarction; Rx = prescribe.

should be administered routinely. In such patients, low-dose aspirin (81 mg daily) is as effective as 325 mg daily, with a similar bleeding risk but overall better adherence.[A14]

Although dual antiplatelet therapy with clopidogrel, prasugrel, or ticagrelor (Chapter 70) is of proven benefit when combined with aspirin to reduce the composite end point of death, MI, or stroke in ACS patients and in patients who undergo PCI,[13] especially with drug-eluting stents (Chapters 57, 58, and 59), these agents have not been shown to be superior to low-dose (75 to 162 mg/day) aspirin alone in patients who have stable angina and chronic ischemic heart disease, because any reduction in cardiovascular events is at least offset by an increase in major bleeding events.[A15] For patients who cannot tolerate aspirin or have aspirin insensitivity, clopidogrel (75 mg once daily), prasugrel (10 mg once daily), and ticagrelor (60 mg twice daily) are indicated. A direct-acting anticoagulant (see Table 70-6) is required in patients who have atrial fibrillation (Chapter 52).

Low-dose rivaroxaban (2.5 mg twice daily) combined with low-dose aspirin (81 to 100 mg daily) is superior to aspirin alone for reducing the composite primary endpoint of cardiovascular death, MI, or stroke,[A16] including a 23% reduction in death in patients with stable coronary artery disease,[A17] although it causes more bleeding. Warfarin is generally as effective as aspirin for preventing coronary events in patients with angina and is preferred to aspirin for patients with concomitant atrial fibrillation (Chapter 52), but has it been superseded by direct-acting anticoagulants, except in patients with prosthetic heart valves.

Therapeutic Agents to Reduce Angina and Ischemia

The goal of antianginal therapy is to reduce symptoms of cardiac ischemia and to improve quality of life.[14] β-Blockers, which prevent the binding of catecholamines to the β-adrenergic receptor, lower heart rate and myocardial contractility, thereby reducing myocardial workload, myocardial oxygen demand, and ischemia and anginal symptoms. β-Blockers raise the ischemic threshold and delay or prevent the onset of angina with exercise. β-Blockers also reduce the rate of secondary cardiac events and sudden cardiac death in post-MI patients, but to date there have been no placebo-controlled outcome trials in angina patients. All β-blockers appear to be equally effective in patients with chronic stable angina (Table 56-9). The β-blocker dose should be titrated to a target resting heart rate of 50 to 60 beats per minute as tolerated by the patient.

Calcium-channel blockers (Table 56-10) reduce afterload by their peripheral vasodilatory effects and thus lower myocardial workload and myocardial oxygen demand. Calcium-channel blockers also reduce coronary vascular resistance and inhibit coronary vasospasm by preventing coronary arterial smooth muscle contraction. This favorable reduction in myocardial oxygen demand, coupled with an increase in myocardial oxygen supply, results in a reduction in angina and ischemia. Non-dihydropyridine calcium-channel blockers, such as verapamil and diltiazem, also reduce heart rate. Conversely, dihydropyridine calcium-channel antagonists, such as nifedipine and amlodipine, have greater effect on vascular smooth muscle, are better peripheral and coronary vasodilators, and hence may have advantages for use in the hypertensive patient with angina. In randomized clinical trials, calcium-channel blockers and β-blockers are generally equally effective in relieving angina, improving time to onset of angina, and improving time to ischemic ST depression during exercise. Because calcium-channel blockers have not been shown to reduce death or MI in patients with stable or previously unstable ischemic heart disease, these agents are usually used in patients who cannot tolerate β-blockers or who require additional pharmacotherapy to control their symptoms. When calcium-channel blockers are used with β-blockers, care must be taken not to cause symptomatic bradycardia with verapamil and diltiazem. When calcium-channel blockers are used alone, diltiazem is often preferred because dihydropyridine calcium-channel blockers can increase the heart rate.

Nitrates (Table 56-11) continue to be widely prescribed for antianginal treatment and are effective when they are administered sublingually, orally, or topically. They act as vasodilators by entering vascular smooth muscle, where they are metabolized to nitric oxide, which relaxes vascular smooth muscle, including in coronary arteries. These effects reduce angina by improving coronary blood flow. Nitrates also lower preload because of their venodilatory effects, with a resulting reduction in LV end-diastolic pressure and wall tension, which in turn lowers subendocardial oxygen demand. When nitrates are used in patients with stable angina, they improve exercise tolerance, time to onset of angina, and ST segment depression during treadmill exercise testing. Long-acting nitrates, which are frequently combined with β-blockers and calcium-channel blockers, have additive antianginal and anti-ischemic effects in patients with stable ischemic heart disease. Sublingual nitroglycerin or oral spray can terminate an angina attack and can be used as prophylaxis to prevent exertional angina. Long-acting nitrates administered orally or transdermally are used to prevent angina and to improve exercise tolerance. For avoidance of nitrate tolerance or tachyphylaxis, an 8- to 12-hour nitrate-free interval daily is recommended. Nitroglycerin and nitrates can cause vasodilation-induced headache, a decrease in blood pressure, and, more rarely, severe hypotension with bradycardia due to activation of the vagal Bezold-Jarisch reflex. Because the vasodilation by nitroglycerin is markedly exaggerated and prolonged in the presence of the phosphodiesterase inhibitors sildenafil (Viagra), vardenafil (Levitra), tadalafil (Cialis), and avanafil (Stendra), these agents and nitrates should not be used concurrently.

Ranolazine (initiated at a dose of 500 mg twice daily and titrated up to a maximal dose of 1000 mg twice daily) acts by reducing intracellular calcium overload in ischemic myocytes by inhibiting late inward sodium current entry. The net effect of reduced late inward sodium current is a reduction in LV wall tension and myocardial oxygen demand, thereby reducing angina and ischemia. Ranolazine increases exercise tolerance in patients with stable angina, reduces episodes of recurrent ischemia, and provides additional antianginal benefit in patients who are already receiving intensive antianginal therapy with β-blockers and calcium-channel blockers, but it has not been documented to reduce the composite primary end point of cardiac death, MI, or recurrent ischemia in a trial of patients after an acute coronary syndrome.[A18]

Treating Inflammation

Low-dose colchicine (0.5 mg daily) can reduce the composite primary outcome of cardiac death, MI, stroke, and ischemia-driven revascularization by about 30% compared with placebo, but the reduction in cardiac deaths has been at least counterbalanced by an increase in noncardiovascular death.[A19,A20] Injections of a monoclonal antibody (canakinumab) targeting interleukin-1beta (IL-1β), administered in combination with standard of care (including lipid-lowering therapy) in patients with a prior MI and an hsCRP greater than or equal to 2 mg/L, reduces the primary composite end point of nonfatal MI, stroke, and cardiovascular death by 15% during a median 3.7 years of follow-up.[A21] Whether the treatment of inflammatory pathways will become a part of standard secondary prevention care remains uncertain.

Myocardial Revascularization

Coronary revascularization with CABG surgery (but not PCI) (Chapter 59) prolongs life, reduces major cardiovascular events, and improves health status, quality of life, and functional capacity in selected patients with chronic, stable ischemic heart disease who meet certain anatomic criteria: the presence of

TABLE 56-9 CLINICAL USE OF B-BLOCKERS

significant left main coronary artery disease, three-vessel coronary artery disease, or multivessel coronary artery disease in patients who have an LV ejection fraction below 50% or have diabetes.[15]

Comparisons of PCI with Optimal Medical Therapy

Numerous randomized clinical trials have compared PCI with medical therapy in stable angina patients. PCI improves angina symptoms but does not reduce the risk of death, MI, or other major cardiovascular events when it is added to optimal medical therapy as an initial management strategy in patients with chronic ischemic heart disease,[A22–A26] including patients with a chronic total occlusion of a major coronary artery.[A27] As a result, optimal medical therapy to control symptoms is a justifiable and more cost-effective initial management strategy for patients with chronic ischemic heart disease, even if they have diabetes,[16] with revascularization reserved only for patients in whom medical therapy is ineffective in controlling anginal symptoms.[17]

For patients who have stable angina and coronary lesions with reduced fractional flow reserve below 0.8 in one or more visually stenotic arteries (≥50% stenosis), initial PCI significantly reduces the need for hospitalization for urgent revascularization but has not been shown to reduce the composite end point of MI or death.[A28] Thus, intensive secondary prevention with proven pharmacotherapies combined with lifestyle modification is of paramount importance in reducing major cardiovascular events in such patients and must be considered the foundation of treatment.

Comparisons of CABG with Medical Therapy

Randomized trials comparing CABG with medical therapy indicate that a greater severity of ischemia, a greater extent of anatomic coronary disease, and the presence of LV systolic dysfunction favor a greater magnitude of survival benefit of CABG over medical therapy. CABG prolongs survival in patients with significant left main coronary artery disease irrespective of symptoms, in patients with multivessel coronary artery disease and impaired LV function (ejection fraction < 50%), and in patients with two- or three-vessel coronary artery disease that includes the proximal left anterior descending coronary artery. Patients with extensive multivessel coronary artery disease appear to derive a survival benefit from CABG surgery, particularly if they also have diabetes, whereas PCI may be considered appropriate for symptom relief, particularly in patients with one- or two-vessel coronary artery disease. It is also worth emphasizing, however, that the randomized trials of CABG surgery compared with medical therapy were conducted more than 40 years ago, and subsequent improvements in both medical therapy and CABG surgery make it increasingly difficult to extrapolate these earlier findings to contemporary clinical practice.

Comparisons of PCI with CABG Surgery for Multivessel Coronary Artery Disease

In patients with isolated left main disease, PCI appears to be approximately equivalent to CABG for the combined end point of death, stroke, or myocardial infarction, but there may be a survival advantage with CABG.[A29] In patients with severe three-vessel disease or left main disease with additional stenoses, however, CABG is superior to PCI, especially in patients with diabetes.[A30] In terms of death and MI, as well as the composite of death, MI, and stroke, CABG surgery is superior to both PCI and optimal medical therapy in reducing the composite outcome of death or MI in stable ischemic heart disease patients who have diabetes and two- and three-vessel coronary disease during a 5-year follow-up,[A31] but not at 10 years.[A32]

These data emphasize that, among patients who remain symptomatic despite intensive treatment or who have substantial ischemia or extensive coronary artery disease, revascularization with either PCI or CABG is appropriate. If, however, the goal of revascularization is to improve survival or reduce clinical events, CABG surgery is generally superior to PCI in symptomatic patients who have stable ischemic heart disease and who have more anatomically complex disease, including three-vessel or left main coronary artery disease and in diabetic patients with multivessel coronary disease for at least 5 years (see Table 56-8; Chapter 58).[18,19] Although PCI appears to provide equivalent survival outcomes in lower-risk patients (principally in patients with one- or two-vessel coronary disease), repeated procedures are more often needed during follow-up.

Refractory Angina

Occasional patients may have refractory angina despite medications and revascularization.[20] One alternative is enhanced external counterpulsation (EECP), which is generally administered as 35 sequential treatments (1 hour daily; 5 days/week) during 7 weeks. EECP does not reduce ischemia on myocardial perfusion imaging, and the mechanisms underlying its effects are poorly understood. Possible mechanisms include durable hemodynamic changes that reduce myocardial oxygen demand, improvement in myocardial perfusion by diastolic augmentation of retrograde coronary flow, and improved endothelial function. Although EECP increased the time to ST segment depression during exercise testing, reduced angina, and improved health-related quality of life for at least 1 year in one randomized, double-blind study of patients with chronic stable angina, its role in the treatment of angina remains unclear. In patients who have refractory angina despite medical therapy and are not candidates for revascularization, reduction of coronary venous return via the coronary sinus can potentially redistribute flow to areas of ischemic myocardium and is an experimental approach to reducing symptoms and improving quality of life.

OTHER ANGINAL SYNDROMES

VARIANT ANGINA OR PRINZMETAL ANGINA

The diagnosis of variant or Prinzmetal angina is based on the documentation of transient ST segment elevation during an episode of chest pain in the absence of a severe, fixed coronary stenosis.[21] Prinzmetal variant angina typically is caused by an occlusive spasm superimposed on a coronary artery stenosis that otherwise does not limit blood flow significantly. In some patients, however, no underlying stenoses are seen. Associated Raynaud phenomenon and migraine headache have been described in some patients, suggesting that the syndrome may be part of a more generalized vasospastic disorder.

The chest discomfort occurs predominantly at rest, although approximately one third of patients may also experience pain during exercise. There is a predilection for the pain to wake the patient in the early morning hours when sympathetic activity is increasing. The syndrome is often cyclical; periods of exacerbation with repetitive episodes of chest pain may persist only for seconds or be more prolonged and severe, alternating with periods with few or no symptoms. The symptoms are typically relieved by nitroglycerin. The ST segment elevation accompanying the pain signifies transmural ischemia due to total abrupt occlusion of a nonsignificant epicardial coronary stenosis in the absence of adequate collateral circulation. The subsequent rapid reperfusion may explain the high prevalence of severe life-threatening arrhythmias.

Coronary angiography, with a provocative test for spasm, such as injection of acetylcholine into the affected coronary artery, usually precipitates the

syndrome. Such testing is useful to establish the diagnosis and to assess the response to therapy, especially in patients with normal or nearly normal coronary angiograms, in whom the diagnosis is otherwise unclear. Dihydropyridine calcium-channel blockers (e.g., amlodipine, 5 to 10 mg orally per day) are preferred in patients with Prinzmetal angina.

MICROVASCULAR ANGINA WITH NORMAL CORONARY ANGIOGRAPHY

Angina can occur despite normal coronary arteries, even after an acetylcholine challenge.[22] The majority of patients who have angina or ischemia with nonobstructive coronary arteries on angiography have occult coronary abnormalities that can be detected by cardiac MR imaging[23] (Chapter 44) or by a detailed coronary catheterization. Such detailed testing may reveal increased coronary resistance and an inability to increase coronary resistance and to increase coronary flow in response to stimuli such as exercise, adenosine, dipyridamole, and atrial pacing.

Symptoms occur most frequently at rest and often in relation to emotional stress. Periods of exacerbation commonly alternate with symptom-free periods. The syndrome is more frequent in women, and some patients have an altered perception of pain or hypersensitivity to certain stimuli.

The diagnosis requires objective documentation of ischemia based on ST-T segment changes, a metabolic abnormality, a transient regional perfusion defect or new wall motion abnormality on echocardiography, or endothelial dysfunction that limits blood flow reserve. Abnormal endothelium-dependent vasoreactivity can be associated with regional myocardial perfusion defects on SPECT and PET imaging.

β-Blockers or heart rate–lowering calcium-channel blockers may be useful, particularly when a relative tachycardia, hypertension, or decreased heart rate variability on Holter monitoring is present. Nitroglycerin can relieve symptoms in approximately 50% of patients, and long-acting nitrates are also sometimes helpful.

The prognosis is generally favorable and not different from that of a general age-matched population in the absence of coronary artery disease.[24,25] However, some studies have indicated that an ischemic response to exercise is associated with increased mortality.

SILENT MYOCARDIAL ISCHEMIA

Up to 20% of patients with ischemic heart disease may not present with angina and are often described as having silent myocardial ischemia. Some patients are totally asymptomatic despite obstructive coronary artery disease, which may be severe. Others have silent ischemia after a prior documented MI. The third and most common form occurs in patients who may also exhibit the usual forms of chronic stable angina, unstable angina, and Prinzmetal angina. When monitored, these patients, who typically have silent ischemia episodes in addition to symptomatic ischemia, are sometimes referred to as having *mixed angina*. This mixed angina is estimated to be present in approximately one third of all treated patients with angina, although an even higher prevalence has been reported in diabetic patients. In these patients, about 85% of ambulant ischemic episodes occur without chest pain, and 66% of angina episodes are not accompanied by ST segment depression, suggesting that overt angina pectoris is merely the "tip of the ischemic iceberg." Pharmacologic agents that reduce or abolish episodes of symptomatic ischemia also reduce or abolish episodes of silent ischemia.

PROGNOSIS

Modern treatments have improved the prognosis of patients with chronic ischemic heart disease to an annual mortality rate of 1 to 3% and a 1 to 2% rate of major ischemic events. The 1-year rate of cardiovascular death is now 1.9% (95% confidence interval [CI], 1.7 to 2.1), with a 2.9% (95% CI, 2.6 to 3.2) rate of all-cause mortality and a 4.5% (95% CI, 4.2 to 4.8) rate of the combined outcome of cardiovascular death, MI, or stroke. Even in patients who have refractory angina and are not candidates for revascularization, modern medical treatment is associated with a 1-year mortality of only 4% and a 9-year mortality of 30%.

In a large majority of patients, anginal symptoms greatly improve or even resolve, often without any change in medical therapy.[26] Recurrent angina is a common subsequent complaint in many patients with chronic ischemic heart disease, even those who were initially treated successfully with PCI. About 30% of patients continue to experience angina one or more times per week, with associated greater physical limitation and worse quality of life, and almost 80% of patients who underwent initially successful PCI for chronic angina still take one or more antianginal agents at 1 year. Exercise rehabilitation may slightly increase exercise capacity but otherwise does not have any clear prognostic implications.[A33]

Patients with chronic stable angina require follow-up on a regular basis (in general, at least every 6 to 12 months). At each visit, a detailed history and physical examination should be performed to discern any important developments such as:

- A change in physical activity
- Any change in the frequency, severity, or pattern of angina
- Tolerance of and adherence to the prescribed medical regimen
- Modification of cardiac risk factors
- The development of new or worsened comorbid illnesses

In addition to a lipid profile and blood glucose level, an ECG should be obtained if medications have changed, and echocardiography as well as electrocardiography is indicated if there are new findings on the history or physical examination. However, routine noninvasive surveillance is not needed in stable patients.

Selection of optimal treatment requires a full understanding of the potential risks and benefits of each treatment approach. In patients who have stable symptoms and who have not had an adequate trial of medical therapy, there is no need to proceed to an invasive evaluation before multifaceted medical therapy and lifestyle intervention are implemented for at least 3 to 6 months.[27] Such an initial approach of aggressive medical therapy and lifestyle intervention is strongly recommended and supported by professional guidelines. Finally, it is important to emphasize that the results of randomized trials involving both pharmacotherapy and revascularization must be individualized for specific patients, while a multidisciplinary approach to clinical decision making can ensure that all therapeutic options are fully and transparently discussed so that patients are offered the most appropriate evidence-based treatment recommendations that are tailored to the level of ischemic risk and coronary anatomic findings.

ACUTE CORONARY SYNDROME: UNSTABLE ANGINA AND NON–ST ELEVATION MYOCARDIAL INFARCTION

RICHARD A. LANGE AND DEBABRATA MUKHERJEE

DEFINITION

The term *acute coronary syndrome* is used to describe the continuum of myocardial ischemia (unstable angina pectoris) or infarction (with or without concomitant ST segment elevation). The patient with *unstable angina* has cardiac chest pain that is new, worsening (i.e., more severe, prolonged, or frequent than previous episodes of angina), or occurring at rest, *without* serologic evidence of myocyte necrosis—that is, no elevation of serum concentrations of troponin. The patient with cardiac chest pain *with* serologic evidence of myonecrosis and without ST elevation is said to have a *non–ST elevation myocardial infarction* (MI). Because unstable angina and non–ST elevation MI are characterized by the absence of ST elevation, they are collectively termed *non–ST elevation acute coronary syndrome* (Fig. 57-1). The patient with acute-onset cardiac chest pain, serologic evidence of myonecrosis, and persistent (>20 minutes) ST segment elevation is said to have an *ST elevation MI* (Chapter 58).

EPIDEMIOLOGY

Almost 1.2 million individuals in the United States are hospitalized annually with acute coronary syndrome, of whom approximately two thirds have non–ST elevation acute coronary syndrome. More than half of patients with non–ST elevation acute coronary syndrome are older than 65 years, and almost half are women. Non–ST elevation acute coronary syndrome is more common in individuals with one or more risk factors for atherosclerosis (Chapter 40), peripheral vascular disease, or a chronic inflammatory disorder, such as rheumatoid arthritis, psoriasis, or infection.

Most patients with non–ST elevation acute coronary syndrome have so-called type 1 MI, which is precipitated by rupture of a coronary arterial atherosclerotic plaque, with subsequent platelet aggregation and thrombus formation, leading in turn to diminished blood flow in the involved artery. Type 2 MI is myocardial injury in the milieu of a mismatch between oxygen supply and demand. Substantial reductions in oxygen supply, for example, can be caused by severe systemic arterial hypotension, anemia, or hypoxemia; dramatic increases in oxygen demand can be caused by tachycardia, severe systemic arterial hypertension, or thyrotoxicosis. In patients thought to have type 2 MI, therapy should be directed at the underlying cause.

PATHOBIOLOGY

The precipitating event in almost all patients with non–ST elevation acute coronary syndrome is coronary arterial atherosclerotic plaque rupture or erosion, with subsequent platelet aggregation and thrombus formation, leading to subtotal occlusion of the involved artery (type 1 MI). In an occasional patient, total thrombotic occlusion of the artery leads to non–ST elevation acute coronary syndrome rather than to ST elevation MI when extensive collateral blood supply perfuses the region of myocardium that is distal to the occluded artery.

Some patients have a mismatch between myocardial oxygen supply and demand caused by a secondary process other than coronary artery disease (type 2 MI). For example, intense vasospasm of a segment of an epicardial coronary artery, due to focal endothelial dysfunction (i.e., Prinzmetal angina) or drug ingestion (caused, for example, by cocaine, chemotherapeutic agents, or one of the serotonin receptor agonist "triptans"), causes a transient or sustained compromise of coronary arterial blood flow, with resultant non–ST elevation acute coronary syndrome. Spontaneous coronary arterial dissection, which occurs most often in peripartum women and patients with vasculitis, also may result in non–ST elevation acute coronary syndrome.

Plaque Rupture

Coronary arterial atherosclerotic plaque rupture (Chapter 41) or erosion is the initiating event in most patients with non–ST elevation acute coronary syndrome. Several factors may play a role in the deterioration of the protective fibrous cap that separates the atheroma in the vessel wall from the coronary arterial lumen. Local and systemic inflammation, mechanical features, and anatomic changes contribute to the transformation of a stable atherosclerotic plaque to a so-called vulnerable plaque, the rupture of which triggers platelet adherence, activation, and aggregation, with subsequent thrombus formation.

The deposition of oxidized low-density lipoprotein in the coronary arterial wall stimulates an inflammatory response, which results in the accumulation of macrophages and T lymphocytes at the plaque border. These inflammatory cells secrete cytokines (e.g., tissue necrosis factor, interleukin-1, interferon-γ), which inhibit collagen synthesis and deposition, as well as enzymes (e.g., matrix metalloproteinases and cathepsins), which promote collagen and elastin degradation, thereby rendering the overlying fibrous cap vulnerable to rupture.

Systemic inflammation may play a role in plaque rupture, as evidenced by the predisposition of individuals with chronic gingivitis, psoriasis, systemic lupus erythematosus, rheumatoid arthritis, and chronic or acute infection to develop acute coronary syndrome. Angiographic and angioscopic studies of the coronary arteries of acute coronary syndrome patients often demonstrate plaque ulceration and thrombosis at more than one site, thereby suggesting that a systemic and diffuse inflammatory process is present.

The mechanical characteristics and location of coronary arterial plaques appear to influence their stability. For example, thin fibrous caps are more likely to erode or to rupture than are thick ones. Sites of low shear stress, such as vessel bifurcations, have reduced production of endothelial vasodilator substances (i.e., nitric oxide and prostacyclin), accelerated accumulation of lipids and inflammatory cells, increased degradation of the extracellular matrix, and thinning of the fibrous cap, all of which contribute to plaque instability.

Detailed histologic examination of evolving atherosclerotic plaques reveals a rich neovascularization that is the result of angiogenic peptides, such as fibroblast growth factors, vascular endothelial growth factor, placental growth factor, oncostatin M, and hypoxia-inducible factor, which are secreted by smooth muscle cells, inflammatory cells, and platelets. This neovascularization

ACUTE CORONARY SYNDROME: UNSTABLE ANGINA AND NON–ST ELEVATION MYOCARDIAL INFARCTION

RICHARD A. LANGE AND DEBABRATA MUKHERJEE

DEFINITION

The term *acute coronary syndrome* is used to describe the continuum of myocardial ischemia (unstable angina pectoris) or infarction (with or without concomitant ST segment elevation). The patient with *unstable angina* has cardiac chest pain that is new, worsening (i.e., more severe, prolonged, or frequent than previous episodes of angina), or occurring at rest, *without* serologic evidence of myocyte necrosis—that is, no elevation of serum concentrations of troponin. The patient with cardiac chest pain *with* serologic evidence of myonecrosis and without ST elevation is said to have a *non–ST elevation myocardial infarction* (MI). Because unstable angina and non–ST elevation MI are characterized by the absence of ST elevation, they are collectively termed *non–ST elevation acute coronary syndrome* (Fig. 57-1). The patient with acute-onset cardiac chest pain, serologic evidence of myonecrosis, and persistent (>20 minutes) ST segment elevation is said to have an *ST elevation MI* (Chapter 58).

EPIDEMIOLOGY

Almost 1.2 million individuals in the United States are hospitalized annually with acute coronary syndrome, of whom approximately two thirds have non–ST elevation acute coronary syndrome. More than half of patients with non–ST elevation acute coronary syndrome are older than 65 years, and almost half are women. Non–ST elevation acute coronary syndrome is more common in individuals with one or more risk factors for atherosclerosis (Chapter 40), peripheral vascular disease, or a chronic inflammatory disorder, such as rheumatoid arthritis, psoriasis, or infection.

Most patients with non–ST elevation acute coronary syndrome have so-called type 1 MI, which is precipitated by rupture of a coronary arterial atherosclerotic plaque, with subsequent platelet aggregation and thrombus formation, leading in turn to diminished blood flow in the involved artery. Type 2 MI is myocardial injury in the milieu of a mismatch between oxygen supply and demand. Substantial reductions in oxygen supply, for example, can be caused by severe systemic arterial hypotension, anemia, or hypoxemia; dramatic increases in oxygen demand can be caused by tachycardia, severe systemic arterial hypertension, or thyrotoxicosis. In patients thought to have type 2 MI, therapy should be directed at the underlying cause.

PATHOBIOLOGY

The precipitating event in almost all patients with non–ST elevation acute coronary syndrome is coronary arterial atherosclerotic plaque rupture or erosion, with subsequent platelet aggregation and thrombus formation, leading to subtotal occlusion of the involved artery (type 1 MI). In an occasional patient, total thrombotic occlusion of the artery leads to non–ST elevation acute coronary syndrome rather than to ST elevation MI when extensive collateral blood supply perfuses the region of myocardium that is distal to the occluded artery.

Some patients have a mismatch between myocardial oxygen supply and demand caused by a secondary process other than coronary artery disease (type 2 MI). For example, intense vasospasm of a segment of an epicardial coronary artery, due to focal endothelial dysfunction (i.e., Prinzmetal angina) or drug ingestion (caused, for example, by cocaine, chemotherapeutic agents, or one of the serotonin receptor agonist "triptans"), causes a transient or sustained compromise of coronary arterial blood flow, with resultant non–ST elevation acute coronary syndrome. Spontaneous coronary arterial dissection, which occurs most often in peripartum women and patients with vasculitis, also may result in non–ST elevation acute coronary syndrome.

Plaque Rupture

Coronary arterial atherosclerotic plaque rupture (Chapter 41) or erosion is the initiating event in most patients with non–ST elevation acute coronary syndrome. Several factors may play a role in the deterioration of the protective fibrous cap that separates the atheroma in the vessel wall from the coronary arterial lumen. Local and systemic inflammation, mechanical features, and anatomic changes contribute to the transformation of a stable atherosclerotic plaque to a so-called vulnerable plaque, the rupture of which triggers platelet adherence, activation, and aggregation, with subsequent thrombus formation.

The deposition of oxidized low-density lipoprotein in the coronary arterial wall stimulates an inflammatory response, which results in the accumulation of macrophages and T lymphocytes at the plaque border. These inflammatory cells secrete cytokines (e.g., tissue necrosis factor, interleukin-1, interferon-γ), which inhibit collagen synthesis and deposition, as well as enzymes (e.g., matrix metalloproteinases and cathepsins), which promote collagen and elastin degradation, thereby rendering the overlying fibrous cap vulnerable to rupture.

Systemic inflammation may play a role in plaque rupture, as evidenced by the predisposition of individuals with chronic gingivitis, psoriasis, systemic lupus erythematosus, rheumatoid arthritis, and chronic or acute infection to develop acute coronary syndrome. Angiographic and angioscopic studies of the coronary arteries of acute coronary syndrome patients often demonstrate plaque ulceration and thrombosis at more than one site, thereby suggesting that a systemic and diffuse inflammatory process is present.

The mechanical characteristics and location of coronary arterial plaques appear to influence their stability. For example, thin fibrous caps are more likely to erode or to rupture than are thick ones. Sites of low shear stress, such as vessel bifurcations, have reduced production of endothelial vasodilator substances (i.e., nitric oxide and prostacyclin), accelerated accumulation of lipids and inflammatory cells, increased degradation of the extracellular matrix, and thinning of the fibrous cap, all of which contribute to plaque instability.

Detailed histologic examination of evolving atherosclerotic plaques reveals a rich neovascularization that is the result of angiogenic peptides, such as fibroblast growth factors, vascular endothelial growth factor, placental growth factor, oncostatin M, and hypoxia-inducible factor, which are secreted by smooth muscle cells, inflammatory cells, and platelets. This neovascularization

ABSTRACT

The term acute coronary syndrome is used to describe the continuum of myocardial ischemia (unstable angina pectoris) or infarction (with or without concomitant ST segment elevation). The patient with unstable angina has cardiac chest pain that is new, worsening (i.e., more severe, prolonged, or frequent than previous episodes of angina), or occurring at rest, without serologic evidence of myocyte necrosis—that is, no elevation of serum concentrations of troponin or the MB isoenzyme of creatine kinase (CK-MB). The patient with cardiac chest pain with serologic evidence of myonecrosis and without ST elevation is said to have a non–ST elevation myocardial infarction (MI). Because unstable angina and non–ST elevation MI are characterized by the absence of ST elevation, they are collectively termed the non–ST elevation acute coronary syndrome.

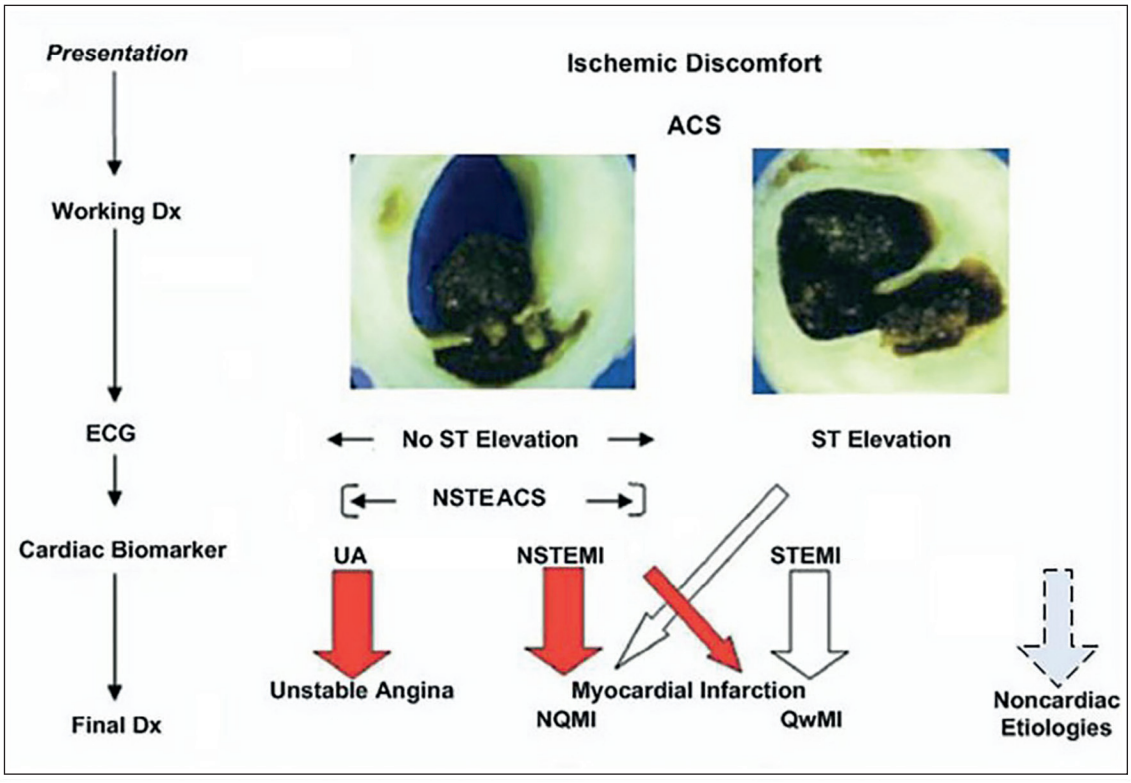

FIGURE 57-1. Acute coronary syndrome (ACS). Symptomatic, morphologic, electrocardiographic, and serologic findings in patients with various kinds of ACS. Patients with ACS usually complain of chest pain. If the involved coronary artery is totally occluded by a fresh thrombus (shown on the *right*), the patient's electrocardiogram (ECG) reveals ST segment elevation, cardiac biomarkers subsequently are elevated, and the patient is diagnosed with an ST elevation myocardial infarction (STEMI). In some cases, initial ST elevation can lead to non-Q wave myocardial infarction. If the involved coronary artery is partially occluded by fresh thrombus (shown on the *left*), the patient's ECG does not show ST segment elevation. If cardiac biomarkers are not elevated, the patient is diagnosed with unstable angina (UA). If cardiac biomarkers remain negative or are not elevated during hospitalization, the final diagnosis remains unstable angina. If cardiac biomarkers are elevated, the patient is diagnosed with a non–ST elevation MI (NSTEMI). Most patients presenting with NSTEMI develop NQMI, but a few may develop QwMI. Dx = diagnosis; NQMI = non–Q wave myocardial infarction; NSTEACS = non-ST elevation acute coronary syndrome; QwMI = Q wave myocardial infarction; UA = unstable angina.

contributes to the growth of atheroma and to leukocyte trafficking, plaque hemorrhage, and destabilization.

Thrombus Formation

Platelets play a pivotal role in the pathobiology of the acute coronary syndrome. After erosion or rupture of a vulnerable plaque, circulating platelets *adhere* to the exposed subendothelial proteins, after which they are *activated*. With activation, the platelets change shape from discoid to stellate, thereby increasing the surface area on which thrombin formation can occur. The platelets then release the contents of their intracellular granules (i.e., thromboxane, serotonin, adenosine diphosphate [ADP], von Willebrand factor, fibrinogen) into the immediate environment and promote focal vasoconstriction of the adjacent arterial segment and activation of nearby platelets. Platelets also increase the number of glycoprotein IIb/IIIa receptors on their surface and the affinity of these receptors to bind circulating fibrinogen. The result is platelet *aggregation*, which occurs as fibrinogen binds to the glycoprotein IIb/IIIa receptors of adjacent platelets, thereby creating a "platelet plug."

With formation of the platelet plug, the coagulation system activates and generates thrombin, which is a powerful stimulator of further platelet activation and aggregation. Thrombin also converts fibrinogen to fibrin, which is incorporated into the thrombus. Subtotal coronary arterial occlusion by this platelet-rich thrombus compromises blood flow in the involved artery, thereby resulting in an imbalance of oxygen supply and demand of the myocytes perfused by the artery. Distal embolization of platelet-rich thrombi from the site of a ruptured plaque may contribute to the compromise in blood flow. If the supply-demand imbalance is transient, the involved myocytes become ischemic but do not die because the ischemia is of insufficient duration to cause necrosis. The patient typically complains of cardiac chest pain at rest, but serologic evidence of myonecrosis, as evidenced by elevated serum concentrations of troponin, is absent; a diagnosis of *unstable angina* is made. In contrast, if the supply-demand imbalance is sustained, ischemic myocytes begin to die, and infarction occurs. The patient typically complains of cardiac chest pain at rest, and serologic evidence of myonecrosis confirms the diagnosis of *non–ST elevation MI*.

CLINICAL MANIFESTATIONS

Symptoms

The patient with non–ST elevation acute coronary syndrome typically complains of retrosternal pressure, squeezing, or heaviness that may be intermittent and recurrent or persistent (Chapter 39). If the episodes are intermittent and recurrent, the duration of each episode may range from only a few minutes to several hours. The chest pain may radiate to the left arm, neck, or jaw, and it may be accompanied by diaphoresis, nausea, abdominal pain, dyspnea, or syncope.

Atypical presentations are not uncommon and may include aching or vague chest discomfort, epigastric pain, acute-onset indigestion, unexplained fatigue, or dyspnea. Such atypical complaints are often observed in younger (25 to 40 years of age) and older (>75 years of age) patients; women; and patients with diabetes mellitus, chronic renal insufficiency, or dementia.

Physical Examination

The patient with non–ST elevation acute coronary syndrome often has normal findings on physical examination. On occasion, evidence of left ventricular dysfunction (Chapter 45), such as basilar rales or a ventricular gallop, hypotension, or peripheral hypoperfusion, may accompany an acute episode or appear shortly thereafter. An important goal of the physical examination is to exclude other potential causes of the patient's symptoms, including both noncardiac causes (i.e., costochondritis, pneumothorax, pulmonary embolism, pneumonia) and other cardiac disorders not attributable to myocardial ischemia (i.e., aortic dissection, pericarditis, severe systemic arterial hypertension, arrhythmias; Chapter 49). Accordingly, differences in blood pressure between the upper and lower limbs, decreased lung sounds, friction rubs, and pain on sternal palpation suggest a diagnosis other than non–ST elevation acute coronary syndrome. Other findings on physical examination—such as an elevated blood pressure, tachycardia, pallor, or increased sweating or tremor—point toward precipitating conditions, such as uncontrolled hypertension (Chapter 64), arrhythmias (Chapters 52 and 53), anemia (Chapter 144), or thyrotoxicosis (Chapter 207).

DIAGNOSIS

The patient with suspected acute coronary syndrome should be evaluated promptly because an expedient and accurate diagnosis permits the timely initiation of appropriate therapy, which can reduce the rate of complications.[1] The initial assessment should be directed at determining whether the patient's symptoms are likely to be caused by myocardial ischemia, MI, or some other disorder. The likelihood of acute coronary syndrome can be estimated from the history, physical examination, and electrocardiogram (ECG). In the acute setting, the presence or absence of traditional risk factors for atherosclerosis is less important for determining the presence or absence of acute coronary syndrome than are the patient's symptoms, ECG findings, and serologic evidence of myonecrosis. As a result, these long-term risk factors are not integral in determining whether an individual should be evaluated, hospitalized, or treated for acute coronary syndrome. Conditions that increase the likelihood that the symptomatic patient is experiencing myocardial ischemia or MI include older age, diabetes mellitus, extracardiac vascular disease, and chest pain radiating to the left arm, neck, or jaw as the presenting symptom. Myocardial ischemia is highly likely if anginal symptoms are accompanied by ECG abnormalities (i.e., Q waves, ST segment depression or elevation ≥1 mm in magnitude, or T wave inversion in multiple precordial leads) or elevated serum concentrations of troponin.

In a patient with known coronary artery disease, typical symptoms are likely to be caused by myocardial ischemia or MI rather than by another condition, particularly if the patient confirms that the symptoms are similar to previous anginal episodes. Conversely, a young individual who has a normal ECG and no risk factors for atherosclerosis is unlikely to be having acute coronary syndrome even when complaining of chest pain with features consistent with ischemia or infarction.

It is important to inquire about the use of cocaine and methamphetamines in the patient with suspected acute coronary syndrome, especially in those who are younger than 40 years or have few traditional risk factors for atherosclerosis. These drugs can increase myocardial oxygen demand and concomitantly decrease oxygen supply by causing vasospasm and thrombosis. A urine toxicologic analysis should be considered when substance abuse is suspected as a cause of acute coronary syndrome.

Electrocardiogram

An ECG, which should be performed and interpreted within 10 minutes or less of the patient's arrival at a facility, is particularly valuable if it is obtained during a symptomatic episode. If the patient has persistent (>20 minutes) ST segment elevation, prompt reperfusion therapy should be initiated (Chapter 58). Transient ST segment abnormalities that develop during a symptomatic episode at rest and resolve when the patient is asymptomatic strongly suggest non–ST elevation acute coronary syndrome. ST segment depression (or transient ST segment elevation) and T wave abnormalities occur in up to 50% of patients.

A completely normal ECG does not exclude the possibility of non–ST elevation acute coronary syndrome; in fact, about 5% of patients who are discharged from the emergency department and ultimately diagnosed with acute coronary syndrome have a normal ECG. Ischemia or infarction in the territory of the left circumflex coronary artery often escapes detection with a standard 12-lead ECG, but it may be detected with right-sided leads (V_4R and V_3R) or posterior leads (V_7 to V_9). In the patient whose initial ECG is normal, serial ECGs (e.g., 15- to 30-minute intervals during the first hour) should be performed routinely and during symptomatic episodes, and they should be compared with previous tracings to identify new ST segment or T wave abnormalities. Deep (>2 mm), symmetrical T wave inversion in the anterior chest leads is often associated with a hemodynamically significant stenosis of the left main or proximal left anterior descending coronary artery.

Serum Biomarkers

Unfortunately, the initial history, physical examination, and ECG alone cannot confirm or exclude an acute coronary syndrome. By comparison, modern high-sensitivity assays can detect troponin (Chapter 58) in the blood within 2 hours of the onset of symptoms in patients with non–ST elevation MI.

Risk Assessment and Triage

The greatest safety comes from continued observation or admission of patients who have a positive troponin level on presentation or at serial testing, have evidence of ischemia on their ECG, or have symptoms indicative of an acute exacerbation of prior coronary disease.[2,3] Because a single normal serum troponin measurement is insufficient to exclude MI in a patient with a very recent onset of symptoms, patients with suspected MI based on the clinical presentation or with ischemic ECG changes may be observed, either in the emergency department or in a chest pain evaluation unit, with a repeated troponin measurement (and a repeated ECG) at 3 or so hours after the onset of symptoms or whenever chest pain recurs.[4] A negative high-sensitivity troponin level at 2 to 3 hours after the onset of symptoms is sufficient to identify patients who do not have ST elevation or non–ST elevation MI (Fig. 57-2),[A1,A2] and patients with negative results and no ECG findings of ischemia have a sufficiently low risk (a 0.4% 30-day risk of MI or death) that they can safely complete the remainder of their evaluation as outpatients if they have no other need for hospitalization.[5–8] Noninvasive cardiac testing performed within 3 days of the initial presentation is associated with a modestly reduced subsequent risk of serious cardiac events, but its value in patients with normal troponin levels is likely small.[9]

Serum troponin concentrations can be measured with point-of-care instruments at the patient's bedside by desktop devices or handheld rapid qualitative assays.[10] The advantage of point-of-care systems for avoiding delays must be weighed against their higher costs and the need for stringent quality control. In addition, point-of-care assays are qualitative or semiquantitative and observer dependent, whereas the central laboratory provides more accurate quantitative information concerning biomarker concentrations.

Noninvasive Testing

A chest radiograph may identify pulmonary causes of chest pain and may show a widened mediastinum in aortic dissection (Chapter 63). The patient considered to have a low likelihood for acute coronary syndrome (on the basis of the history, physical examination, ECG, and serum biomarkers) should undergo timely stress testing (Chapter 39). Although stress testing does not absolutely establish or exclude the presence of coronary artery disease, it has the advantage of also defining a patient's exercise tolerance, which helps tailor therapeutic decisions. Alternatively, multidetector coronary computed tomographic angiography, which has a high (>98%) negative predictive value to exclude coronary artery disease when it is performed and interpreted at experienced centers, can help reduce the length of hospital stay when the findings are normal in emergency department patients at low to intermediate risk of possible acute coronary syndrome. However, coronary computed tomographic angiography does not have incremental value in patients with a negative troponin assay and a nonischemic ECG.[A3] Conversely, the patient who is believed to be at higher risk or who continues to have typical ischemic chest pain with ECG abnormalities or elevated cardiac biomarkers should not undergo stress testing or coronary computed tomographic angiography but rather should either undergo coronary angiography or be rendered symptom free with medical therapy before stress testing.

An echocardiogram may be helpful in the patient with chest pain if the ECG is nondiagnostic (i.e., minimal ST segment or T wave abnormalities). If left ventricular hypokinesis or akinesis is observed during an episode of chest pain and then improves when symptoms resolve, myocardial ischemia is likely. In the patient with anterior T wave inversion of uncertain etiology, hypokinesis of the left ventricular anterior wall suggests that the observed T wave abnormality is due to a severe stenosis of the left anterior descending coronary artery. Because echocardiography can help evaluate and identify alternative causes for the patient's chest pain (i.e., myocarditis [Chapter 47], aortic dissection [Chapter 63], or pulmonary embolism [Chapter 68]), it is recommended in patients whose diagnosis is uncertain.

Coronary Angiography

Coronary angiography (Chapter 59) should be performed in patients who are thought to be at high risk for death, MI, or recurrent ischemia in the ensuing days, weeks, and months (see later); in patients who have spontaneous or inducible myocardial ischemia despite appropriate medical therapy; and in patients who have a confusing or difficult clinical presentation and a subsequent inconclusive noninvasive evaluation. The results of angiography help determine whether revascularization is appropriate and, if so, whether it should be attempted by coronary artery bypass grafting or percutaneous coronary intervention (PCI) (Chapter 59).

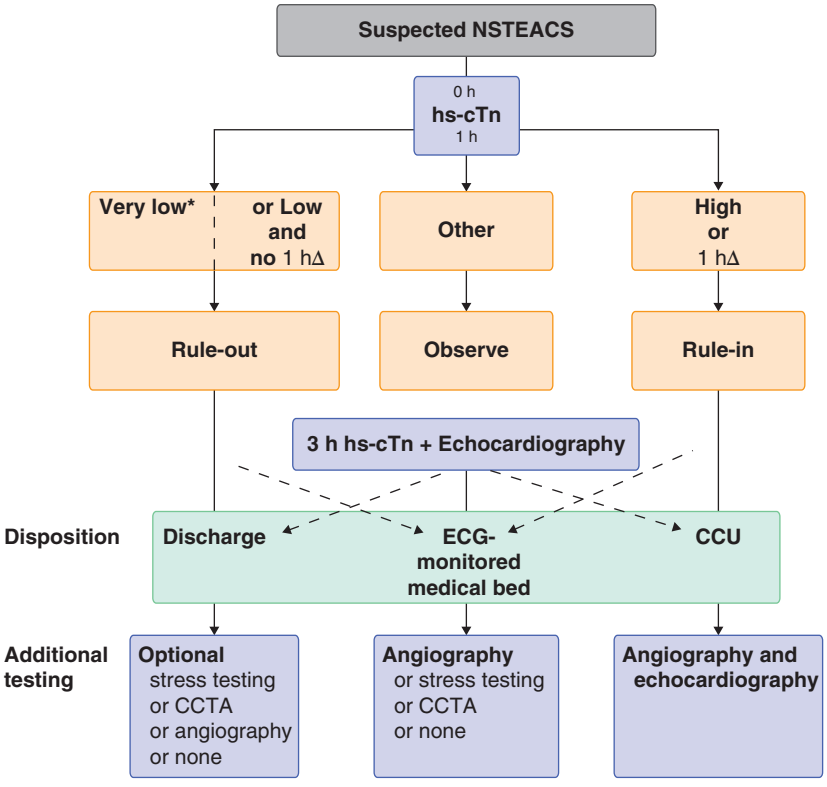

FIGURE 57-2. Initial triage for patients with symptoms suggestive of a non-ST elevation acute coronary syndrome (NSTEACS) using high-sensitivity cardiac troponin assays. 0 h/1 h rule-out and rule-in algorithm using high-sensitivity cardiac troponin assays in hemodynamically stable patients presenting with suspected NSTEACS to the emergency department. 0 h and 1 h refer to the time from the first blood test. NSTEMI can be ruled out at presentation if the hs-cTn concentration is very low. NSTEMI can also be ruled out by the combination of low baseline levels and the lack of a relevant increase within 1 h (no 1hΔ). Patients have a high likelihood of NSTEMI if the hs-cTn concentration at presentation is at least moderately elevated or hs-cTn concentrations show a clear rise within the first hour (1hΔ). CCTA = coronary computed tomography angiography; CCU = coronary care unit; hs-cTn = high-sensitivity cardiac troponin; NSTEACS = non-ST elevation acute coronary syndrome; NSTEMI = non-ST elevation myocardial infarction. *Only applicable if chest pain onset >3 h. (Adapted from Collet JP, Thiele H, Barbato E, et al. 2020 ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation. *Eur Heart J*. 2021;42:1289-1367.)

In patients with non–ST elevation acute coronary syndrome, coronary angiography demonstrates significant stenosis of the left main coronary artery in about 15% of patients, of all three major epicardial coronary arteries in about 30 to 35% of patients, of two of the three epicardial arteries in about 20 to 30% of patients, and of one major epicardial artery in 20 to 30% of patients. About 15% of patients have no coronary arterial narrowing of hemodynamic significance. Women with non–ST elevation acute coronary syndrome are likely to have less extensive coronary artery disease than men have, and patients with non–ST elevation MI usually have more extensive disease than those with unstable angina.

On angiography, the coronary arterial lesion responsible for signs and symptoms (the so-called culprit lesion) typically is asymmetrical or eccentric, with scalloped or overhanging edges and a narrow base or neck, features that reflect underlying plaque disruption and thrombus formation. Although obvious thrombus is visible by angiography in only one third of patients, coronary angioscopy shows plaque rupture with overlying thrombus in the majority. Interestingly, the culprit lesion often is not severely stenotic when it is assessed on recently performed angiograms; in fact, two thirds of culprit lesions previously had less than 50% luminal diameter narrowing (and therefore would not have been considered appropriate for revascularization).

After the initial triage decision is made, therapeutic interventions are based on the risk of adverse events in the ensuing hours, days, weeks, and months—estimated by either the Thrombolysis in Myocardial Infarction (TIMI) or Global Registry of Acute Coronary Events (GRACE) risk algorithm—balanced against the risk of a bleeding complication from intensive medical therapy (Table 57-1) or an adverse event from an invasive cardiac procedure. On the basis of this initial assessment, the patient's therapy should be tailored to minimize the likelihood of adverse events.

Although serum markers of myonecrosis represent only one of the TIMI or GRACE risk variables, the presence of this variable alone identifies the patient as being at high risk. However, although elevated serum markers indicate myonecrosis, they provide no insight into its cause because myonecrosis can occur with disease entities other than coronary artery disease (e.g., pulmonary embolism, decompensated heart failure, severe hypertension or tachycardia, anemia, sepsis). Thus, in evaluation of the patient with possible acute coronary syndrome, the presence of elevated serum markers should be assessed in conjunction with other variables.

Increasing age is associated with a higher incidence of both ischemic events and of complications from intensive medical therapy and invasive cardiac procedures. Even though elderly individuals are at increased risk of treatment-related complications, they nonetheless derive a greater absolute and relative benefit from such intensive therapy compared with younger individuals. Apart from this initial risk assessment, the patient's general medical and cognitive status, anticipated life expectancy, and, most important, personal preferences should be evaluated and considered.

Differential Diagnosis

The current universal definition of MI recognizes five different types (Table 57-2),[11] including ST elevation (Chapter 58) MI or non–ST elevation MI related to an acute coronary thrombosis (type 1); MI caused by a mismatch between myocardial supply and demand (type 2); MI associated with sudden cardiac arrest but not documented antemortem (type 3, Chapter 50); and MI associated with a percutaneous coronary intervention (type 4) or coronary artery bypass graft surgery (type 5, Chapter 59). The use of high-sensitivity troponin assays increases the detection of all five types.

Cardiac injury with troponin elevation but without other evidence of ischemia can also occur after cardiac and noncardiac procedures (Chapter 401). Several cardiac and noncardiac conditions, some of which are potentially life-threatening, may mimic non–ST elevation acute coronary syndrome. The patient with a pulmonary embolism (Chapter 68) will often complain of chest pain and dyspnea and may have ECG abnormalities and an elevated serum troponin concentration. Aortic dissection (Chapter 63) should be considered and excluded because the therapies for non–ST elevation acute coronary syndrome are contraindicated in patients with this condition. Stroke (Chapter 376) and subarachnoid hemorrhage (Chapter 377) may be accompanied by ECG abnormalities, left ventricular segmental wall motion abnormalities, and elevated serum biomarker concentrations. Underlying chronic cardiac conditions, such as valvular heart disease (i.e., aortic stenosis, aortic regurgitation) and hypertrophic cardiomyopathy (Chapter 47), may be associated with symptoms similar to those of non–ST elevation acute coronary syndrome, elevated serum biomarker concentrations, and ECG abnormalities. Myocarditis (Chapter 47), pericarditis (Chapter 62), and myopericarditis often cause chest pain that resembles angina, ECG abnormalities, and elevated serum biomarker concentrations; an influenza-like or upper respiratory tract infection (including severe acute respiratory syndrome coronavirus 2) often precedes or accompanies these conditions. Patients with "stress cardiomyopathy" (takotsubo syndrome) typically have chest pain, ST segment abnormalities and deeply inverted T waves, and mildly elevated serum biomarker concentrations (Chapter 47). In rural areas without emergency medicine specialists or cardiologists, diagnostic support from a tertiary center can improve diagnostic accuracy.[A4]

TABLE 57-1 RISK VARIABLES FOR ISCHEMIC EVENTS AND BLEEDING COMPLICATIONS

RISK VARIABLES PREDICTIVE OF DEATH, MYOCARDIAL INFARCTION, OR RECURRENT ISCHEMIA
Thrombolysis in Myocardial Infarction (TIMI) Score*
Age >65 yr
Three or more risk factors for atherosclerosis
Known coronary artery disease (previous coronary arteriography or myocardial infarction)
Two or more episodes of anginal chest pain at rest in the 24 hr before hospitalization
Use of aspirin in the 7 days before hospitalization
ST segment deviation ≥0.5 mV
Elevated serum concentrations of troponin or CK-MB
Global Registry of Acute Coronary Events (GRACE)†
Age
Heart failure (Killip) class
Heart rate
Systolic blood pressure
ST segment deviation
Cardiac arrest during presentation
Serum creatinine concentration
Elevated serum markers of myonecrosis
RISK FACTORS FOR BLEEDING COMPLICATIONS WITH INTENSIVE THERAPY†
Female gender
Older age
Renal insufficiency
Low body weight
Tachycardia
Systolic arterial pressure (high or low)
Anemia
Diabetes mellitus

*Individuals with three or more of these variables are considered to be at high risk, whereas those with none, one, or two are considered to be at low risk.

†Each variable is assigned a numerical score on the basis of its specific value, and the eight scores are summed to yield a total score, which is applied to a reference nomogram to determine the patient's risk. The GRACE application tool is available online at www.outcomes-umassmed.org/grace. (From Brieger D, Fox KA, Fitzgerald G, et al. Predicting freedom from clinical events in non-ST-elevation acute coronary syndromes: the Global Registry of Acute Coronary Events. *Heart*. 2009;95:888-894.)

†The patient's bleeding risk can be estimated with the tool available at https://reference.medscape.com/calculator/53/crusade-score-for-post-mi-bleeding-risk. (From Subherwal S, Bach RG, Chen AY, et al. Baseline risk of major bleeding in non-ST-segment-elevation myocardial infarction: the CRUSADE [Can Rapid risk stratification of Unstable angina patients Suppress ADverse outcomes with Early implementation of the ACC/AHA Guidelines] Bleeding Score. *Circulation*. 2009;119:1873-1882.)

TABLE 57-2 UNIVERSAL DEFINITION OF MYOCARDIAL INFARCTION

TYPE 1
Rise and/or fall of cardiac troponin values, with at least one value above the 99th percentile and at least one of the following: • Symptoms of acute myocardial ischemia • New ischemic ECG changes or development of new pathologic Q waves • New loss of viable myocardium or new regional wall motion abnormality consistent with an ischemic cause on imaging • Coronary thrombus on angiography, intracoronary imaging, or autopsy
TYPE 2
Rise and/or fall of cardiac troponin values, with at least one value above the 99th percentile, evidence of an imbalance between myocardial oxygen supply and demand unrelated to acute coronary thrombosis, and at least one of the following: • Symptoms of acute myocardial ischemia • New ischemic ECG changes or development of new pathologic Q waves • New loss of viable myocardium or new regional wall motion abnormality consistent with an ischemic cause on imaging
TYPE 3
• Cardiac death in a patient with symptoms suggestive of myocardial ischemia accompanied by presumed ischemic ECG changes or ventricular fibrillation, before blood samples for biomarkers can be obtained or increases in cardiac biomarkers can be identified • Myocardial infarction detected on autopsy
TYPE 4
Myocardial infarction associated with a percutaneous coronary intervention
TYPE 5
Myocardial infarction related to coronary artery bypass graft surgery

ECG = electrocardiogram.

Thygesen K, Alpert JS, Jaffe AS, et al. Fourth universal definition of myocardial infarction (2018). *Circulation*. 2018;138:e618-e651.

TREATMENT

The goals of treatment of the patient with non–ST elevation acute coronary syndrome are to prevent recurrent ischemia (by correcting the imbalance between myocardial oxygen supply and demand), to prevent thrombus propagation, and to stabilize the vulnerable plaque.[12,13] Antianginal medications, such as nitroglycerin (see Table 56-11), β-adrenergic blockers (see Table 56-9), and calcium-channel blockers (see Table 56-10), favorably affect myocardial oxygen supply and demand, thereby preventing recurrent ischemia. Antiplatelet and antithrombotic agents retard thrombus propagation, and statins promote plaque stabilization.

Once the patient's risk status is established, therapy is initiated and tailored to the patient's risk of sustaining a subsequent ischemic cardiac event or a treatment-related complication (Table 57-3). For example, the patient considered to be at low risk of a subsequent ischemic event does not benefit from intensive antithrombotic therapy or routine coronary angiography and revascularization. Conversely, in patients considered to be at high risk of sustaining an ischemic event, optimal therapy—including coronary angiography and revascularization (if appropriate)—results in a 20 to 40% decrease in the risk of recurrent ischemia and MI and an approximately 10% reduction in mortality, with about an 18-month postponement of recurrent MI or death.[A5] An invasive approach also appears to be preferable in patients over age 75 years.[A6]

Every patient with non–ST elevation acute coronary syndrome, regardless of their level of risk, should promptly receive antianginal medications, antiplatelet therapy, and a statin, unless contraindicated. A patient considered to be at low risk may receive unfractionated heparin, but more intensive anticoagulant therapy is not necessary because such therapy increases the risk of bleeding without further reducing the risk of an ischemic cardiac event. Routine coronary angiography and revascularization are not beneficial and should be reserved for the patient with recurrent ischemia despite intensive medical therapy.

Conversely, the high-risk patient should receive antianginal medications, antiplatelet therapy, a statin, intensive anticoagulant therapy, and coronary angiography followed by revascularization (if indicated). In the patient whose coronary anatomy is suitable, revascularization reduces the incidence of ischemia and recurrent MI, and it also improves survival in certain patients (see later).

Antianginal Therapy

Nitroglycerin

Nitroglycerin (see Table 56-11), which is a venodilator at low doses and an arteriolar dilator at higher doses, may prevent recurrent ischemia in patients with unstable angina, but no studies of sufficient statistical power have determined whether it reduces the risk of MI in this population of patients. In patients who complain of recurrent symptoms, nitroglycerin should be given sublingually or by buccal spray (0.3 to 0.6 mg). Patients with ongoing or recurrent chest pain should receive intravenous nitroglycerin (5 to 10 μg/minute with use of nonabsorbable tubing), with escalation of the dose in increments of 10 μg/minute until symptoms resolve or adverse effects develop. Nitroglycerin's most common adverse effects are headache, nausea, dizziness, hypotension, and reflex tachycardia.

Nitrate tolerance can be avoided by periodically providing the patient with a nitrate-free period (i.e., a brief cessation of drug administration). Nitroglycerin should not be given to patients who have received a phosphodiesterase-5 inhibitor (i.e., sildenafil, tadalafil, or vardenafil) within the previous 24 to 48 hours, because severe hypotension may ensue.

β-Adrenergic Blockers

β-Adrenergic blockers diminish symptoms and the risk of MI in patients with acute coronary syndrome who are not already taking a β-blocker at the time of hospitalization. In the normotensive patient without ongoing chest pain or tachycardia and without contraindications to β-blockers, metoprolol should be initiated at 25 to 50 mg orally every 6 to 8 hours, with the dose increased (to 100 mg twice daily) as necessary to control heart rate, blood pressure, and symptoms. In high-risk patients and in patients with tachycardia or elevated systemic arterial pressure, metoprolol should be administered intravenously

TABLE 57-3 MANAGEMENT STRATEGIES FOR PATIENTS WITH ACUTE CORONARY SYNDROME

THERAPY	INITIATION	DURATION	DOSE, ROUTE, AND DURATION	BENEFIT VS. PLACEBO (REDUCED INCIDENCE OF …)
LOW-RISK PATIENT				
Antianginal				
β-Blocker*	Within 24 hr	Hospitalization ± indefinitely	Metoprolol, 25-50 mg orally twice daily, titrated up to 100 mg twice daily; or atenolol, 50-100 mg orally daily	Recurrent ischemia
Nitroglycerin	Immediately	Hospitalization ± indefinitely	0.3-0.6 mg sublingually or 5-10 μg/min IV initially and increased by 10 μg/min every 5 min	Not studied
Diltiazem or verapamil†	Immediately	Hospitalization ± indefinitely	30-90 mg orally four times daily or up to 360 mg of long-acting preparation orally daily	MI, recurrent ischemia
Lipid Lowering				
Statins (with other lipid-lowering medications as needed; see Chapter 190)	Immediately	Indefinitely	Atorvastatin, 40-80 mg; or rosuvastatin, 20-40 mg orally daily	Recurrent ischemia
Antiplatelet				
Aspirin	Immediately	Indefinitely	162-325 mg orally initial dose, then 81 mg orally daily	Death, MI
Clopidogrel	Immediately	1-12 mo	300 mg orally initial dose, then 75 mg orally daily	MI, recurrent ischemia
Anticoagulant				
Unfractionated heparin	Immediately	2-5 days	IV bolus of 60 U/kg, then 12 U/kg/hr IV adjusted to achieve an aPTT of 50 to 70 sec	Death or MI (combined)
HIGH-RISK PATIENT				
Antianginal				
β-Blocker*	Within 24 hr	Hospitalization ± indefinitely	Metoprolol, 25-50 mg orally twice daily, titrated up to 100 mg twice daily; or atenolol, 50-100 mg orally daily	Death, MI, recurrent ischemia
Nitroglycerin	Immediately	Hospitalization ± indefinitely	0.3-0.6 mg sublingually or 5-10 μg/min IV initially and increased by 10 μg/min every 5 min	Not studied
Diltiazem or verapamil†	Immediately	Hospitalization ± indefinitely	30-90 mg orally four times daily or up to 360 mg of long-acting preparation orally daily	MI, recurrent ischemia
Lipid Lowering				
Statin	Before hospital discharge	Indefinitely	Atorvastatin, 40-80 mg; or rosuvastatin, 20-40 mg orally daily	Recurrent ischemia
Antiplatelet				
Aspirin *and*	Immediately	Indefinitely	162-325 mg orally initial dose, then 81 mg orally	Death, MI
Clopidogrel *or*	Immediately	12 mo	300-600 mg orally initial dose, then 75 mg orally daily	MI, recurrent ischemia
Prasugrel *or*	At time of PCI	12 mo	60 mg orally initial dose, then 10 mg orally daily	Cardiovascular death, MI or stroke (combined)‡
Ticagrelor	Immediately	12 mo	180 mg orally initially, then 90 mg twice daily	Vascular death, MI or stroke (combined)‡
Glycoprotein IIb/IIIa inhibitor (eptifibatide, tirofiban, or abciximab)	At time of PCI	12-24 hr after PCI	Abciximab, IV bolus of 0.25 mg/kg, then 0.125 μg/kg/min IV (max. 10 μg/min) for 12 hr; or eptifibatide, IV bolus of 180 μg/kg, then 2.0 μg/kg/min IV for 18-24 hr; or tirofiban, 0.4 μg/kg/min IV for 30 min, then 0.1 μg/kg/min IV for 12 to 24 hr	MI
Anticoagulants				
Enoxaparin *or*	Immediately	Duration of hospitalization (up to 8 days); discontinue after successful PCI	1 mg/kg subcutaneously twice daily	MI, recurrent ischemia§
Unfractionated heparin *or*	Immediately	2 to 5 days; discontinue after successful PCI	IV bolus of 60 U/kg, then 12 U/kg/hr IV adjusted to achieve an aPTT of 50 to 70 sec	Death or MI (combined)
Bivalirudin *or*	Immediately (only in patients managed with an early invasive strategy)	Up to 72 hr; discontinue 4 hr after PCI	0.10 mg/kg loading dose followed by 0.25 mg/kg/hr	Bleeding#

TABLE 57-3 MANAGEMENT STRATEGIES FOR PATIENTS WITH ACUTE CORONARY SYNDROME—cont'd

THERAPY	INITIATION	DURATION	DOSE, ROUTE, AND DURATION	BENEFIT VS. PLACEBO (REDUCED INCIDENCE OF …)
Fondaparinux	Immediately	Duration of hospitalization (up to 8 days); if used during PCI, it must be coadministered with another anticoagulant with factor IIa activity	2.5-mg subcutaneous injection once daily	Bleeding[¶]
Invasive Management				
Coronary angiography followed by revascularization (if appropriate)	Up to 36-80 hr after hospitalization; within 24 hr in "very high risk" patients			MI, recurrent ischemia

*Avoid in the patient with signs of decompensated heart failure, evidence of low-output state, increased risk for cardiogenic shock, or other contraindications to β-blockade (e.g., PR interval >0.24 sec, second- or third-degree atrioventricular block without a cardiac pacemaker, active asthma, or reactive airway disease).
†Avoid in patients with clinically significant left ventricular dysfunction, increased risk for cardiogenic shock, PR interval >0.24 sec, or second- or third-degree atrioventricular block without a cardiac pacemaker.
‡Compared with clopidogrel.
§Compared with unfractionated heparin.
#As monotherapy compared with heparin and glycoprotein IIb/IIIa inhibitor combination.
¶Compared with enoxaparin.
aPTT = activated partial thromboplastin time; IV = intravenous; MI = myocardial infarction; PCI = percutaneous coronary intervention.

(three boluses of 5 mg each given 5 minutes apart) initially, after which an oral dose should be initiated. A reasonable target heart rate is 50 to 60 beats per minute at rest.

β-Blockers should not be administered to patients with decompensated heart failure, hypotension, hemodynamic instability, or advanced atrioventricular block. Because most patients with chronic obstructive pulmonary disease or peripheral vascular disease tolerate β-blockers without difficulty, these conditions should not automatically preclude their use.

Calcium-Channel Blockers

Calcium-channel blockers, which cause arterial vasodilation, increase coronary arterial blood flow and lower systemic arterial pressure. The non-dihydropyridine calcium-channel blockers diltiazem and verapamil slow heart rate and are recommended for the patient with a contraindication to a β-adrenergic blocker or persistent or recurrent symptoms despite treatment with nitroglycerin or a β-blocker. Oral diltiazem (30 to 90 mg four times daily of the short-acting preparation or up to 360 mg once daily of the long-acting preparation) is the preferred calcium-channel blocker because it reduces the incidence of myocardial ischemia and recurrent MI in patients with non–ST elevation acute coronary syndrome. Diltiazem is contraindicated in patients with left ventricular systolic dysfunction or pulmonary vascular congestion. Caution should be exercised when combining a β-blocker with diltiazem because the two drugs may act synergistically to depress left ventricular systolic function as well as sinus and atrioventricular nodal conduction. Patients with acute coronary syndrome should not be prescribed short-acting nifedipine unless they are already receiving a β-blocker because it may increase the risk of death. By comparison, the risks and benefits of long-acting dihydropyridines are not well defined.

Antiplatelet Agents

Patients with acute coronary syndrome should receive dual antiplatelet therapy (aspirin and a $P2Y_{12}$ ADP receptor inhibitor) acutely and for up to 1 year unless they have an aspirin allergy, active bleeding, or are at high risk of bleeding.[14] Aspirin (162 to 325 mg initially, then 81 mg daily, continued indefinitely; Chapter 70) reduces the risk of death or MI by about 50%. The choice of which ADP receptor antagonist to use in combination with aspirin is determined by each patient's characteristics (i.e., risk of bleeding), medication costs, and pharmacologic properties of the agent (see the following details). The patient who is allergic to or intolerant of aspirin should be treated with a $P2Y_{12}$ ADP receptor inhibitor (clopidogrel, ticagrelor, or prasugrel [if PCI treated]) alone. Patients who are treated with drug-eluting coronary stenting (see later) and who are at high risk of bleeding may discontinue $P2Y_{12}$ ADP receptor inhibitor therapy after 3 to 6 months.[A7] Among these three options, prasugrel and ticagrelor decrease ischemic events but increase bleeding compared with clopidogrel.[A8] De-escalation to clopidogrel or low-dose prasugrel (e.g., 5 mg rather than 10 mg daily) at 3 to 6 months can provide equivalent benefits with lower bleeding risks.[A9]

$P2Y_{12}$ ADP Receptor Inhibitors

Clopidogrel (Chapter 70) has antiplatelet activity that is synergistic with aspirin because the two agents inhibit different platelet-activating pathways. Clopidogrel is a prodrug that must be metabolized by the cytochrome P-450 system to the active form. Polymorphisms in the cytochrome P-450 isoform CYP2C19, which are present in 15 to 20% of individuals, slow metabolism of the prodrug to the active form, thereby reducing the magnitude of platelet inhibition. Drugs that are potent inhibitors of the CYP2C19 enzyme (e.g., omeprazole, esomeprazole, cimetidine, fluconazole, ketoconazole, voriconazole, etravirine, felbamate, fluoxetine, and fluvoxamine) should not be administered with clopidogrel because they affect the metabolism to its active form and reduce its antiplatelet effects. In patients with non–ST elevation acute coronary syndrome, the addition of clopidogrel (a loading dose of 300 to 600 mg, then 75 mg daily for up to 1 year) to aspirin reduces the composite end point of cardiovascular death, nonfatal MI, or stroke by 20% (2.1% reduction in absolute risk) compared with treatment with aspirin alone. The benefit of an aspirin-clopidogrel combination was seen as early as 24 hours after drug initiation and persisted for the 12 months of the study, despite an increase in minor bleeding.

Prasugrel (Chapter 70) has a greater antiplatelet effect and a more rapid onset of action than clopidogrel. In patients with acute coronary syndrome who are referred for PCI, prasugrel in combination with aspirin reduces ischemic events (i.e., a combination of cardiovascular death, nonfatal MI, and stroke) by 20% compared with concomitant clopidogrel and aspirin (2.2% absolute risk reduction) therapy. However, this benefit is obtained at a 0.5% increased risk of life-threatening bleeding and a 0.3% increased risk of fatal bleeding. Compared with ticagrelor, prasugrel can significantly reduce the 1-year risk of death, myocardial infarction, or stroke, with a slightly lower risk of bleeding.[A10] In combination with aspirin, it is administered as a 60-mg oral loading dose followed by a 10-mg daily maintenance dose. Diminishing the dose from 10 mg daily to 5 mg daily at 1 month may sustain its anti-ischemic benefits but reduce bleeding, thereby improving its net clinical benefit.[A11] Because prasugrel-associated bleeding complications are highest in patients with a previous stroke or transient ischemic attack, age older than 75 years, or a body weight of less than 60 kg, it should not be used in patients with any of these features.

Ticagrelor (Chapter 70) does not require hepatic activation, and it has more rapid onset and more pronounced platelet inhibition than clopidogrel. It is a reversible inhibitor of the $P2Y_{12}$ receptor, so platelet function returns more rapidly after discontinuation than with clopidogrel. In a randomized trial in non–ST elevation acute coronary syndrome patients, the addition of ticagrelor to aspirin reduced the composite end point of vascular death, nonfatal MI, or stroke by about 15% compared with treatment with clopidogrel and aspirin but increased non–procedure-related bleeding by an absolute 0.7%. In combination with aspirin, ticagrelor is administered as a 180-mg oral loading dose, followed by a 90-mg twice-daily maintenance dose. In patients who receive ticagrelor, the daily aspirin maintenance dose should be 100 mg or less, and ticagrelor

should not be used in patients with a history of intracranial hemorrhage. Even in patients more than 1 year after a non–ST elevation MI, treatment with ticagrelor at 60 or 90 mg twice daily in addition to aspirin significantly reduces the risk of cardiovascular death, MI, or stroke but not of overall death because of an increased risk of major bleeding.

Cangrelor, which is the only intravenous $P2Y_{12}$ receptor antagonist, is administered as a bolus (30 μg/kg before the PCI procedure), followed by an infusion (4 μg/kg per minute for at least 2 hours or through the duration of the intervention, whichever is longer), as an adjunct during PCI to reduce the risk of periprocedural MI, repeated coronary revascularization, and subacute thrombosis in patients who are not being treated with an oral $P2Y_{12}$ inhibitor and are not planned to receive a glycoprotein IIb/III inhibitor. To maintain platelet inhibition after discontinuation of the cangrelor infusion, oral options include clopidogrel (600 mg immediately after discontinuing cangrelor), prasugrel (60 mg immediately after discontinuing cangrelor), or ticagrelor (180 mg at any time during the cangrelor infusion or immediately after it).

Glycoprotein IIb/IIIa Inhibitors

Glycoprotein IIb/IIIa inhibitors (Chapter 70) block platelet aggregation in response to all potential agonists, so they are the most potent antiplatelet agents available. Three glycoprotein IIb/IIIa inhibitors, each of which must be administered parenterally, are available: abciximab is the Fab fragment of a monoclonal antibody to the receptor, eptifibatide is a peptide, and tirofiban is a peptidomimetic molecule.

Glycoprotein IIb/IIIa inhibitors reduce the incidence of recurrent ischemic events in patients with non–ST elevation acute coronary syndrome who undergo PCI but not in patients who are managed with medical therapy alone. When a glycoprotein IIb/IIIa inhibitor is administered to PCI patients, it should be initiated at the time of angiography because its routine administration beforehand carries an increased bleeding risk and no improvement in outcomes. The glycoprotein IIb/IIIa inhibitor infusion (see Table 57-3) typically is continued for 12 to 24 hours after PCI.

Anticoagulants

Anticoagulant therapy should be administered to all patients with acute coronary syndrome unless a contraindication, such as active bleeding, is present. For the patient in whom a noninvasive, ischemia-guided management strategy is selected, treatment with unfractionated heparin, low-molecular-weight heparin (LMWH), or fondaparinux is appropriate, with fondaparinux recommended for the patient at increased risk of bleeding. For the patient in whom an invasive management strategy is selected, unfractionated heparin and LMWH are the agents of choice. Although bivalirudin may be preferred in patients undergoing PCI, it is not used in the initial management of the patient with acute coronary syndrome.

Low-Molecular-Weight Heparin

LMWHs (Chapter 70), which are fragments of unfractionated heparin, exert a more predictable anticoagulant effect, have a longer half-life, and are less likely to cause thrombocytopenia compared with unfractionated heparin. Because they provide predictable and sustained anticoagulation with once- or twice-daily subcutaneous administration, monitoring of their anticoagulant effect is not required.

LMWH is superior to unfractionated heparin in preventing MI or death during hospitalization in non–ST elevation acute coronary syndrome patients who have elevated serum cardiac biomarkers, as well as in those considered to be at high risk for recurrent ischemia (see Table 57-1). In the low-risk patient, unfractionated heparin and LMWH have similar efficacy.

Two LMWHs, enoxaparin and dalteparin, are approved for the treatment of the patient with non–ST elevation acute coronary syndrome. The dose of enoxaparin is 1 mg/kg subcutaneously twice daily, and the dose of dalteparin is 120 IU/kg (maximum, 10,000 IU) subcutaneously twice daily. Therapy should be continued for the duration of the hospitalization, up to 8 days, or until revascularization is performed (whichever occurs first). In obese (>120 kg), thin (<60 kg), or renally impaired (creatinine clearance <30 mL/minute) patients, the LMWH dose should be adjusted to achieve an anti–factor Xa concentration of 0.5 to 1.5 IU/mL 4 to 6 hours after drug administration. LMWH should be avoided in the patient with a history of heparin-induced thrombocytopenia. In the patient with renal failure, treatment with LMWH has been associated with the development of hyperkalemia.

Heparin

Unfractionated heparin (Chapter 70) exerts its anticoagulant effect by accelerating the action of circulating antithrombin; it prevents thrombus propagation but does not lyse existing thrombi. In the patient with non–ST elevation acute coronary syndrome, the addition of heparin to aspirin reduces the rate of in-hospital ischemic events (i.e., death or MI) by 33%.

Unfractionated heparin should be initiated with an intravenous bolus of 60 U/kg, followed by a continuous infusion of approximately 12 U/kg/hour (maximum, 1000 U/hour), adjusted to maintain the activated partial thromboplastin time (aPTT) at 1.5 to 2.5 times control (i.e., 50 to 70 seconds) or a heparin concentration at 0.3 to 0.7 U/mL (by anti–factor Xa determinations). The infusion should be continued for 48 hours or until revascularization is performed, whichever occurs sooner. Frequent monitoring of the aPTT or heparin concentration is necessary because the anticoagulant response to a standard dose of unfractionated heparin varies widely among individuals; even when a weight-based nomogram (see Table 68-6) is followed, the aPTT is outside the therapeutic range more than one third of the time.

Mild thrombocytopenia occurs in 10 to 20% of patients treated with unfractionated heparin. In 1 to 5% of patients, a more severe form of thrombocytopenia develops. This antibody-mediated response usually occurs 4 to 14 days after the initiation of treatment (although it may appear more quickly in patients who received heparin within the preceding 6 months) and is associated with thromboembolic sequelae in 30 to 80% of patients (Chapter 158).

Fondaparinux

Fondaparinux (Chapter 70), which is a selective factor Xa inhibitor, does not require dose adjustment and monitoring. Fondaparinux does not cause thrombocytopenia. Fondaparinux is as effective as enoxaparin in preventing ischemic cardiac events but with 50% fewer major bleeding episodes (2.2% vs 4.1%). Because an increased incidence of catheter-related thrombosis has been reported after fondaparinux treatment, it is not recommended for patients who are likely to undergo coronary angiography. Fondaparinux is a desirable anticoagulant for the acute coronary syndrome patients who are managed in an ischemia-guided fashion, especially patients at higher risk of a bleeding complication with anticoagulant therapy, but not for other patients.

For the patient with acute coronary syndrome, fondaparinux is administered as a 2.5-mg subcutaneous injection once daily for up to 5 days or until hospital discharge. Its use is contraindicated in patients with severe renal impairment and in those who weigh 50 kg or less, and it should not be used as the sole anticoagulant during a PCI.

Bivalirudin

Bivalirudin, a direct thrombin inhibitor, is currently recommended as an alternative anticoagulant for patients undergoing PCI. In patients whose acute coronary syndrome is managed with an ischemia-guided strategy, its administration in a setting other than the cardiac catheterization laboratory is not recommended. In the patient undergoing PCI, bivalirudin (0.75 mg/kg intravenous bolus followed by an infusion of 1.75 mg/kg/hour for up to 4 hours after the PCI) is as effective as unfractionated heparin[A12] and as combination heparin and glycoprotein IIb/IIIa inhibitor therapy in preventing ischemic events, but it causes fewer major bleeding episodes. Bivalirudin is the anticoagulant of choice for the patient with acute coronary syndrome who has heparin-induced thrombocytopenia.

Direct-Acting Oral Anticoagulants

Adding a direct-acting oral anticoagulant (e.g., apixaban, rivaroxaban, and dabigatran) to a single antiplatelet agent appears to have little effect on bleeding or cardiovascular complications in patients with acute coronary syndrome. By comparison, adding one to dual antiplatelet therapy appears to increase significant bleeding about 2.2-fold with only a modest 14% reduction in adverse cardiac events.[A13] Factor Xa inhibition with low-dose rivaroxaban (2.5 mg twice daily) plus aspirin may be considered as a treatment option for maintenance treatment beyond 12 months after PCI for acute coronary syndrome inpatients at high thrombotic risk but without an increased risk for major or life-threatening bleeding.

Cholesterol Reduction

Prompt initiation of statin therapy is recommended in all patients with non–ST elevation acute coronary syndrome to promote plaque stabilization and to restore endothelial function. Moreover, when statin therapy is initiated during the patient's hospitalization (rather than at hospital discharge), long-term medical compliance is substantially improved. In the absence of contraindications, high-dose atorvastatin (40 to 80 mg daily) or rosuvastatin (20 to 40 mg daily) should be given orally regardless of the baseline serum low-density lipoprotein (LDL) cholesterol concentration. A lower dose is not as effective in reducing ischemic events, and the goal for LDL reduction is to 70 mg/dL or lower. If a statin alone does not achieve this goal, ezetimibe (10 mg daily) and/or an inhibitor of proprotein convertase subtilisin/kexin type 9 (e.g., alirocumab 300 mg or evolocumab 320 mg subcutaneously every 4 weeks; Chapter 190) should be added to achieve it. The addition of ezetimibe provides incremental benefit even in patients who have achieved an average LDL level of 70 mg/dL, especially if they have other high-risk characteristics such as diabetes or age over 70 years.[A14,A15]

Recurrent or Refractory Unstable Angina

In most patients hospitalized with non–ST elevation acute coronary syndrome, symptoms do not recur after the institution of appropriate antianginal therapy. The occasional patient with continued or recurrent chest pain despite optimal medical therapy is at high risk for an MI. For the patient with refractory myocardial ischemia or hemodynamic instability despite optimal medical therapy,

intra-aortic balloon counterpulsation can reduce the incidence of ischemic episodes until revascularization can be performed. Intra-aortic balloon function is synchronized with the patient's ECG so that it inflates during diastole and deflates during systole, thereby augmenting coronary arterial blood flow and reducing myocardial oxygen demand by decreasing afterload. Intra-aortic balloon counterpulsation causes lower limb ischemia in approximately 3% of patients in whom the device is placed, but this complication usually resolves with its removal.

Coronary Revascularization

Coronary revascularization is performed to relieve angina that is persistent or recurrent despite optimal medical therapy, to prevent recurrent ischemia or MI in patients at high risk for a subsequent ischemic event, and to improve survival in patients with suitable coronary arterial anatomy.

Coronary revascularization is successful in relieving symptoms in 90% of the patients with angina refractory to medical therapy. Whether coronary bypass surgery or PCI is the more appropriate method of revascularization is determined by the location and severity of coronary arterial stenoses and the presence of comorbid medical conditions that may affect the performance or safety of the revascularization procedure (Chapter 59).

The patient who has been rendered symptom free with optimal medical therapy should undergo an assessment to determine whether he or she is at high risk or relatively low risk of sustaining a cardiac ischemic event (death, MI, or recurrent ischemia) in the ensuing days, weeks, and months and a bleeding complication from intensive medical therapy or an invasive cardiac procedure. Patients who are at low risk of having a subsequent ischemic event (those with a normal serum troponin concentration; age younger than 75 years; and zero, one, or two TIMI risk variables) should be evaluated noninvasively for inducible ischemia before hospital discharge. If the patient has spontaneous or provocable ischemia, coronary angiography and, if appropriate, revascularization should be performed.

The acute coronary syndrome patient with a detectable serum troponin concentration, age older than 75 years, or three or more TIMI risk variables is considered to be at high risk for a subsequent event and should be referred for routine coronary angiography and revascularization (if appropriate) during the hospitalization because this management strategy reduces the incidence of subsequent ischemic cardiac events.[A16] In most patients, early (within 24 hours of hospitalization) invasive therapy is no better at preventing death, MI, or stroke than somewhat delayed (median, 60 hours) invasive management,[A17] although it is associated with a modest decrease in the occurrence of recurrent ischemia. In contrast, in the one third of patients considered to be at very high risk (GRACE risk score of >140, corresponding to an incidence of in-hospital death or MI of >20%), an early invasive management strategy is superior to a delayed strategy in reducing the incidence of death, MI, or stroke. The benefit of an invasive strategy appears to extend even to patients over age 80 years.[15]

The patient with clinical features or noninvasive test results suggestive of severe coronary artery disease (i.e., left ventricular dysfunction, hemodynamic instability, life-threatening ventricular arrhythmias, or extensive inducible ischemia) should be referred for coronary angiography (Table 57-4) to determine if left main or three-vessel coronary arterial disease is present because patients with these coronary anatomic findings derive a survival benefit with coronary revascularization compared with medical therapy (Chapter 59). In patients who are taking a $P2Y_{12}$ ADP receptor inhibitor and in whom coronary artery bypass grafting can be delayed, the drug should be discontinued (5 days for clopidogrel or ticagrelor and at least 7 days for prasugrel) to allow dissipation of the antiplatelet effect. The timing of coronary bypass surgery in patients treated with a $P2Y_{12}$ ADP inhibitor should balance a potential increased risk of bleeding against the risks of delaying surgery.

For PCI, a single-stage complete revascularization is probably preferred compared with staged revascularization of the culprit artery immediately followed by other significant stenoses later (Chapter 59).[A18] Stenting can be performed safely at centers without on-site cardiac surgery.

Complications

Patients with non–ST elevation acute coronary syndrome can develop recurrent ischemic events or any of the complications associated with ST elevation MI, including arrhythmias, heart failure, and mechanical complications (Chapter 58). However, the acute complications other than recurrent ischemia occur less often in patients with non–ST elevation acute coronary syndrome because the amount of myocardial damage usually is less.

Because intensive medical therapy in conjunction with invasive management can lead to life-threatening bleeding complications, the patient's risk of such should be assessed before these therapies are instituted. Female gender, older age, renal insufficiency, low body weight, tachycardia, high or low systolic arterial pressure, anemia, and diabetes mellitus predict an increased risk of major bleeding, often due to excessive dosing of antiplatelet or anticoagulant agents. The bleeding risk can be estimated with the tool available at https://www.mdcalc.com/calc/1784/crusade-score-post-mi-bleeding-risk.

TABLE 57-4 SELECTION OF INITIAL TREATMENT STRATEGY: INVASIVE VERSUS CONSERVATIVE

GENERALLY PREFERRED STRATEGY	PATIENT CHARACTERISTICS
Invasive	Recurrent angina or ischemia at rest or with low-level activities despite intensive medical therapy Elevated troponin level New or presumably new ST segment depression Signs or symptoms of heart failure or new or worsening mitral regurgitation High-risk findings from noninvasive testing Hemodynamic instability Sustained ventricular tachycardia PCI within 6 months Previous CABG High-risk score (e.g., TIMI, GRACE) Mild to moderate renal dysfunction Diabetes mellitus Reduced left ventricular systolic function (EF <40%)
Conservative	Low-risk score (e.g., TIMI [0 or 1] or GRACE [<109]) Low-risk, troponin-negative female patients Patient or physician preference in the absence of high-risk features

CABG = coronary artery bypass grafting; EF = ejection fraction; GRACE = Global Registry of Acute Coronary Events; PCI = percutaneous coronary intervention; TIMI = Thrombolysis in Myocardial Infarction.

Integrated Approach to Treatment

Although the treatment of the patient with non–ST elevation acute coronary syndrome should be individualized, taking into account the specific features of the disease and the particular circumstances of the patient, algorithms nonetheless provide a useful framework (Fig. 57-3). Smoking cessation (Chapter 363), cholesterol lowering (Chapter 190), and control of blood pressure (Chapter 64), obesity, and diabetes mellitus (Chapter 210) are important long-term prevention strategies. A polypill strategy with aspirin (100 mg daily), ramipril (2.5 to 10 mg daily), and atorvastatin (20 to 40 mg daily) is preferred to usual care for preventing recurrent myocardial ischemic events.[A19] Maintaining adherence long term with medical therapy appears to reduce the risk of a future ischemic event by up to 80%.

PROGNOSIS

Because the number of ECG leads demonstrating ST segment depression and the magnitude of such depression are indicative of the extent and severity of myocardial ischemia and MI, it is not surprising that ST segment depression correlates with the patient's prognosis. Compared with patients without ST segment depression, the patient with non–ST elevation acute coronary syndrome who has ST segment depression of 1 mm or greater in two or more leads is almost four times as likely to die within 1 year, and the patient with ST segment depression of 2 mm or greater in magnitude is almost six times as likely to die within 1 year. If ST segment depression of 2 mm or greater is present in more than one region of the ECG, the mortality is increased 10-fold. Even the 20% of patients with acute coronary syndrome who have only 0.5 to 1 mm of ST segment depression have an adverse prognosis. Patients with ST segment depression also have a higher risk for subsequent cardiac events compared with patients with only T wave inversions (>1 mm).

The magnitude of the serum troponin concentration predicts short-term (30 days) and long-term (1 year) risks of recurrent MI and death, independent of ECG abnormalities or markers of inflammatory activity. Patients with a high-sensitivity troponin level <5 ng/L are at low risk for an event in the next 30 days, but risks increase progressively into higher levels even if the levels are stable and therefore not indicative of acute coronary syndrome.

C-reactive protein measured with a highly sensitive assay, which is a widely used marker of inflammation, has no role in the diagnosis of acute coronary syndrome but is predictive of long-term (6 months) mortality among patients with troponin-negative non–ST elevation acute coronary syndrome. Elevated serum concentrations of natriuretic peptides (B-type natriuretic peptide [BNP] or its N-terminal prohormone [NT-pro-BNP]) are associated with

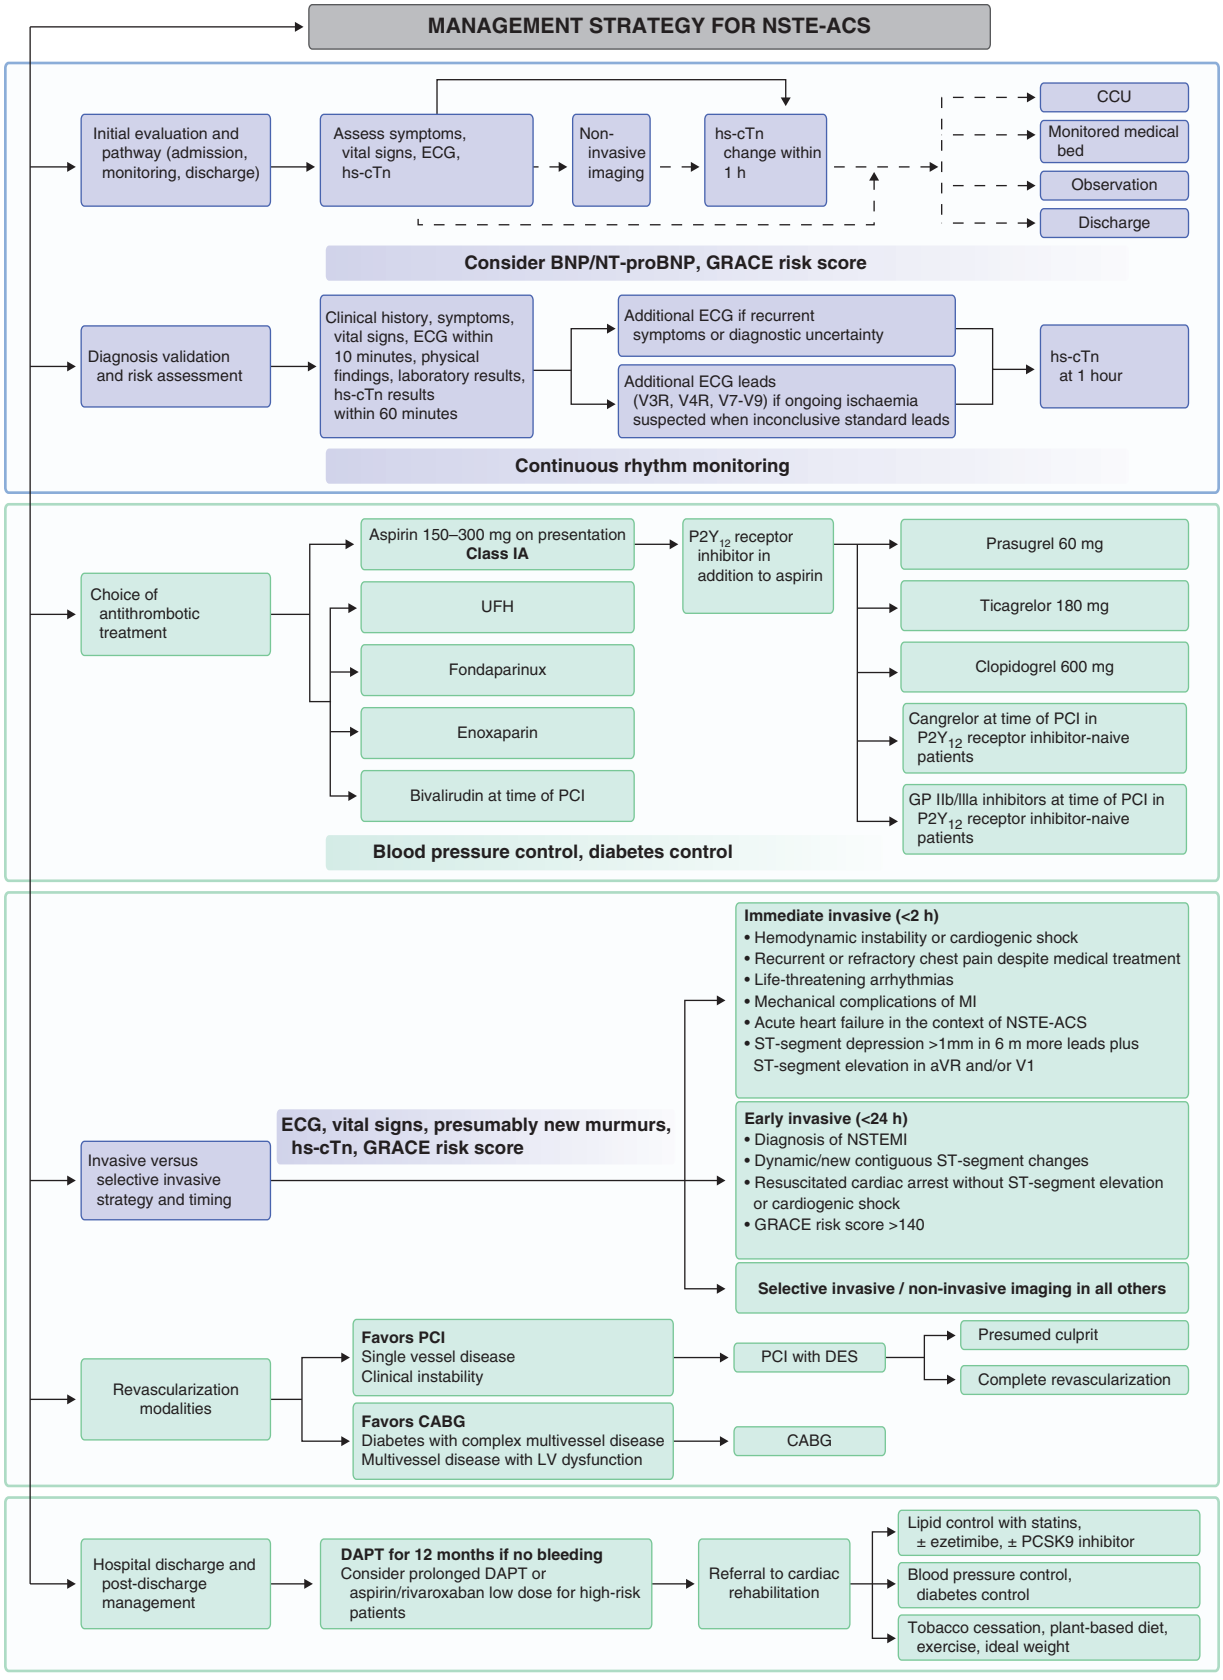

FIGURE 57-3. **Approach to the patient with non–ST elevation acute coronary syndrome (NSTE-ACS).** BNP = B-type natriuretic peptide; CABG = coronary artery bypass grafting; CCU = coronary care unit; DAPT = dual antiplatelet therapy; DES = drug-eluting stent; ECG = electrocardiogram/electrocardiography; GP = glycoprotein; GRACE = Global Registry of Acute Coronary Events; hs-cTn = high-sensitivity cardiac troponin; LV = left ventricular; MI = myocardial infarction; NSTE-ACS = non-ST elevation acute coronary syndrome; NSTEMI = non-ST elevation myocardial infarction; NT-proBNP = N-terminal pro-B-type natriuretic peptide; PCI = percutaneous coronary intervention; PCSK9 = proprotein convertase subtilisin kexin 9; UFH = unfractionated heparin. (Adapted from Collet JP, Thiele H, Barbato E, et al. ESC guidelines for the management of acute coronary syndromes in patients presenting without persistent ST-segment elevation. *Eur Heart J*. 2021;42:1289-1367.)

a three- to five-fold increased mortality in patients with non–ST elevation acute coronary syndrome, although they have limited value for diagnosis, initial risk stratification, and selection of an initial management strategy. Natriuretic peptide concentrations measured a few days after the onset of symptoms have better predictive value than those measured at the time of hospitalization. In patients with non–ST elevation acute coronary syndrome, a simultaneous assessment of troponin, high-sensitivity C-reactive protein, and BNP is superior to a single biomarker assessment at predicting short-term outcome.

In contrast to patients with ST elevation MI, in whom most events occur before or shortly after presentation to the hospital, patients with non–ST elevation acute coronary syndrome continue to be at high risk for such events during the ensuing days, weeks, and months. Although in-hospital mortality is higher in patients with ST elevation MI than among those with non–ST elevation acute coronary syndrome (7 vs. 5%, respectively), the mortality rates at 6 months are similar for the two conditions (12 vs. 13%, respectively). During long-term follow-up of hospitalized patients, rates of death are actually higher in those with non–ST elevation acute coronary syndrome than in those with ST elevation MI, with a two-fold difference after 4 years. As a result, treatment strategies for non–ST elevation acute coronary syndrome should address the issues related to both the acute event and longer-term treatment.

ST-ELEVATION ACUTE MYOCARDIAL INFARCTION AND COMPLICATIONS OF MYOCARDIAL INFARCTION

FREDERICK G.P. WELT AND JAMES C. FANG

DEFINITION

Conceptually, acute myocardial infarction (MI) is myocardial necrosis caused by ischemia. Practically, MI can be diagnosed and evaluated by clinical, electrocardiographic (ECG), biochemical, radiologic, and pathologic methods. Acute MI is classified based on whether the ECG shows ST-segment elevation (ST-elevation MI) or not (non–ST-elevation MI). Acute MI can be further classified into five types: type 1, acute MI due to coronary atherothrombosis; type 2, acute MI due to a demand/supply mismatch; type 3, acute MI causing (sudden) death without the opportunity for biomarker or ECG confirmation; type 4, acute MI related to a percutaneous coronary intervention (PCI) or thrombosis of a coronary stent[1]; and type 5, acute MI related to coronary bypass graft surgery (CABG). This chapter focuses primarily on type 1 ST-elevation MI. Non–ST-elevation MI is covered in Chapter 57.

ST-elevation MI is characterized by profound ("transmural") acute myocardial ischemia affecting relatively larger areas of myocardium. The underlying cause is essentially *complete* interruption of regional myocardial blood flow. In contrast, non–ST-elevation MI is characterized by *incomplete* blockage of coronary flow, for which different acute therapies are appropriate (Chapter 57).

EPIDEMIOLOGY

The age-adjusted risk of hospitalization and death from cardiovascular disease and MI has declined since the 1960s. Data from Medicare beneficiaries show a continued reduction in rates of hospitalization for MI in patients over age 65 years.[2]

The declines in cardiovascular disease and MI have been particularly noteworthy for ST-elevation MI, with rates falling by two-thirds since 2008. ST-elevation MI currently comprises 25% or less of acute coronary syndromes. This decline is attributable to changing demographics, lifestyles, and medical therapies.

Nevertheless, cardiovascular disease remains the number one cause of mortality in the United States, with 690,000 deaths in 2020 (21% of all deaths), and it has become a leading contributor to the burden of disease worldwide (Chapter 40) as developing countries adopt a more Western lifestyle. Coronary artery disease is the leading cardiovascular disease, causing about 600,000 first acute MIs, 200,000 recurrent MIs, and an estimated 170,000 "silent" MIs annually in the United States. Each year, about 365,000 Americans die from coronary heart disease, including about 100,000 attributable to acute MI.

The lifetime risk for coronary artery disease varies dramatically depending on age, sex, lipid profile (Chapter 190), blood pressure (Chapter 64), diabetes (Chapter 210), smoking status (Chapter 363), and family history. When all modifiable risk factors are optimal, the lifetime risk of coronary artery disease for a 45-year-old is estimated to be less than 5%; with two or more major risk factors, by comparison, it is 50% for men and 31% for women. All modifiable risk factors combined (including obesity, diet, physical activity, alcohol consumption, and psychosocial factors) account for over 90% of the population-attributable risk of acute MI globally. The genetic contribution to the risk of coronary artery disease is estimated to be about 40%, and polygenic risk scores based on common genetic variants can provide supplementary prognostic information.

Pathobiology

The usual initiating mechanism of acute MI is fissure or rupture of a vulnerable, lipid-laden atherosclerotic coronary plaque, thereby resulting in exposure of circulating blood to highly thrombogenic plaque core and matrix materials (Chapter 41). Based on both postmortem pathologic techniques and in vivo optical coherence tomography, up to one third of acute MIs may be due to superficial erosion of fibrous caps both in lesions with necrotic cores and in lesions that are predominantly fibrocellular (Chapter 41). A minority of lesions responsible for MI are characterized as a calcified nodule that fractures.[3] Regardless of

58 ST-ELEVATION ACUTE MYOCARDIAL INFARCTION AND COMPLICATIONS OF MYOCARDIAL INFARCTION

FREDERICK G.P. WELT AND JAMES C. FANG

DEFINITION

Conceptually, acute myocardial infarction (MI) is myocardial necrosis caused by ischemia. Practically, MI can be diagnosed and evaluated by clinical, electrocardiographic (ECG), biochemical, radiologic, and pathologic methods. Acute MI is classified based on whether the ECG shows ST-segment elevation (ST-elevation MI) or not (non–ST-elevation MI). Acute MI can be further classified into five types: type 1, acute MI due to coronary atherothrombosis; type 2, acute MI due to a demand/supply mismatch; type 3, acute MI causing (sudden) death without the opportunity for biomarker or ECG confirmation; type 4, acute MI related to a percutaneous coronary intervention (PCI) or thrombosis of a coronary stent[1]; and type 5, acute MI related to coronary bypass graft surgery (CABG). This chapter focuses primarily on type 1 ST-elevation MI. Non–ST-elevation MI is covered in Chapter 57.

ST-elevation MI is characterized by profound ("transmural") acute myocardial ischemia affecting relatively larger areas of myocardium. The underlying cause is essentially *complete* interruption of regional myocardial blood flow. In contrast, non–ST-elevation MI is characterized by *incomplete* blockage of coronary flow, for which different acute therapies are appropriate (Chapter 57).

EPIDEMIOLOGY

The age-adjusted risk of hospitalization and death from cardiovascular disease and MI has declined since the 1960s. Data from Medicare beneficiaries show a continued reduction in rates of hospitalization for MI in patients over age 65 years.[2]

The declines in cardiovascular disease and MI have been particularly noteworthy for ST-elevation MI, with rates falling by two-thirds since 2008. ST-elevation MI currently comprises 25% or less of acute coronary syndromes. This decline is attributable to changing demographics, lifestyles, and medical therapies.

Nevertheless, cardiovascular disease remains the number one cause of mortality in the United States, with 690,000 deaths in 2020 (21% of all deaths), and it has become a leading contributor to the burden of disease worldwide (Chapter 40) as developing countries adopt a more Western lifestyle. Coronary artery disease is the leading cardiovascular disease, causing about 600,000 first acute MIs, 200,000 recurrent MIs, and an estimated 170,000 "silent" MIs annually in the United States. Each year, about 365,000 Americans die from coronary heart disease, including about 100,000 attributable to acute MI.

The lifetime risk for coronary artery disease varies dramatically depending on age, sex, lipid profile (Chapter 190), blood pressure (Chapter 64), diabetes (Chapter 210), smoking status (Chapter 363), and family history. When all modifiable risk factors are optimal, the lifetime risk of coronary artery disease for a 45-year-old is estimated to be less than 5%; with two or more major risk factors, by comparison, it is 50% for men and 31% for women. All modifiable risk factors combined (including obesity, diet, physical activity, alcohol consumption, and psychosocial factors) account for over 90% of the population-attributable risk of acute MI globally. The genetic contribution to the risk of coronary artery disease is estimated to be about 40%, and polygenic risk scores based on common genetic variants can provide supplementary prognostic information.

Pathobiology

The usual initiating mechanism of acute MI is fissure or rupture of a vulnerable, lipid-laden atherosclerotic coronary plaque, thereby resulting in exposure of circulating blood to highly thrombogenic plaque core and matrix materials (Chapter 41). Based on both postmortem pathologic techniques and in vivo optical coherence tomography, up to one third of acute MIs may be due to superficial erosion of fibrous caps both in lesions with necrotic cores and in lesions that are predominantly fibrocellular (Chapter 41). A minority of lesions responsible for MI are characterized as a calcified nodule that fractures.[3] Regardless of

ABSTRACT

Acute myocardial infarction (MI) is defined as myocardial necrosis caused by an imbalance between oxygen supply and demand. ST-segment elevation MI (STEMI) is typically associated with abrupt cessation of flow in an epicardial coronary artery, usually as a result of atherothrombosis. Although the incidence of STEMI has declined in the last several decades, it remains a major source of morbidity and mortality. The hallmark of treatment for STEMI is rapid diagnosis and reperfusion with either fibrinolytic medications or, preferably, primary percutaneous coronary intervention (PCI). Rapid diagnosis is dependent on clinical suspicion based on symptoms and evaluation of the 12-lead ECG. Other confirmatory tests include markers of myocardial necrosis, including high sensitivity troponin assays. Considerable efforts have been made to design systems of care to ensure that STEMI patients receive prompt reperfusion therapy (within 90 minutes at hospitals with PCI programs). Postreperfusion care is centered around surveillance for immediate complications of MI and initiation of medical regimens designed to reduce secondary risks. Of particular concern is surveillance for malignant arrhythmias, recurrent ischemia, and the development of heart failure. Assessment of cardiac function is critical in the post-MI patient. Secondary prevention involves mitigation of risk from hyperlipidemia, hypertension, and diabetes as well as lifestyle modification. Prevention and treatment of heart failure are also closely linked to prognosis.

reperfusion

the initiating insult, platelets adhere, are activated, and aggregate at the site of injury. Thrombin is generated, thereby accelerating platelet activation, and the resulting fibrin traps red blood cells and leads to the formation of thrombus. A totally occluding thrombus typically leads to ST-elevation MI. By comparison, partial occlusion, or occlusion in the presence of collateral circulation, results in a non–ST-segment elevation acute coronary syndrome, often with ST depression or T-wave inversion (Chapter 57). Ischemia resulting from reduced coronary flow leads to myocardial cell injury or death, ventricular dysfunction, and cardiac arrhythmias. Myocardial necrosis begins after as little as 15 to 20 minutes of coronary occlusion and proceeds rapidly in a wave front from endocardium to epicardium. Partial myocardial salvage can be achieved by reperfusion within 3 to 6 hours, the degree of salvage being inversely proportional to the duration and extent of ischemia. The extent of myocardial necrosis also depends on metabolic demand and collateral blood supply.

About 10% of acute MIs are caused by conditions other than critical epicardial coronary atherosclerosis.[4] These other mechanisms include microvascular disease, endothelial dysfunction, coronary artery dissection,[5,6] coronary emboli, in situ thrombosis, vasculitis, primary vasospasm, infiltrative or degenerative disease, diseases of the aorta, congenital anomalies of a coronary artery, or trauma (Table 58-1).

CLINICAL MANIFESTATIONS

History

Acute MI may present with typical ischemic-type chest discomfort or atypically with dyspnea, nausea, epigastric discomfort, malaise, and/or unexplained weakness. Ischemic-type chest discomfort, usually the most prominent clinical symptom in acute MI, is perceived as a persistent (>10-20 minutes), diffuse, deep, and heavy retrosternal pressure or burning sensation; it rarely is perceived as sharp pain and generally not as stabbing pain (see Table 39-2 in Chapter 39). The discomfort associated with acute MI is qualitatively similar to that of angina pectoris but more severe and persistent (Chapters 39 and 56).

The primary location of typical ischemic pain is most consistently retrosternal, but it also can present left parasternal, left precordial, or across the anterior chest (Chapter 39). On occasion, discomfort is predominantly perceived in the anterior neck, jaw, arms, or epigastrium. It generally is somewhat diffuse; highly localized pain (finger point) is rarely angina or acute MI. The most characteristic pattern of radiation is to the left arm, but the right arm or both arms can be involved. The shoulders, neck, jaw, teeth, epigastrium, and interscapular areas also are sites of radiation. Discomfort above the jaws or below the umbilicus is not typical of acute MI. Associated symptoms often include nausea, vomiting, diaphoresis, weakness, dyspnea, restlessness, and apprehension.

The discomfort of acute MI is not reliably relieved by rest or nitroglycerin. The onset of acute MI usually is unrelated to exercise or other apparent precipitating factors. Nevertheless, acute MI may begin during or within a few hours following physical or emotional stress and is more common in this situation than is explained by chance.

It is estimated that at least 20% of acute MIs are painless ("silent") or atypical (unrecognized). Elderly patients, especially women, and patients with diabetes are particularly prone to painless or atypical MI, which is the presentation of MI in as many as one third to one half of such patients. Because the prognosis is worse in elderly and diabetic patients, diagnostic vigilance is required. In these patients, acute MI can be manifested as sudden dyspnea (which can progress to pulmonary edema), weakness, lightheadedness, nausea, and vomiting. Confusional states, sudden loss of consciousness, a new rhythm disorder, and an unexplained fall in blood pressure are other uncommon presentations. The differential diagnosis of ischemic chest discomfort also should include gastrointestinal disorders (e.g., reflux esophagitis; Chapter 124), musculoskeletal pain (e.g., costochondritis), anxiety or panic attacks, pleurisy or pulmonary embolism (Chapter 68), and acute aortic dissection (see Table 39-2 in Chapter 39 and Chapter 63).

Physical Examination

No physical findings are diagnostic or pathognomonic of acute MI. The physical examination often is entirely normal or may reveal only nonspecific abnormalities. An S_4 gallop frequently is found if it is carefully sought. Blood pressure often is initially elevated, but it may be normal or low. Signs of sympathetic hyperactivity (tachycardia, hypertension, diaphoresis, or any combination of these three) often accompany anterior wall MI, whereas parasympathetic hyperactivity (bradycardia, hypotension, or both) is more common with inferior wall MI.

The examination is best focused on an overall assessment of cardiac function. Adequacy of vital signs and peripheral perfusion should be noted. Signs of cardiac failure, both left and right sided (e.g., S_3 gallop, pulmonary congestion, elevated neck veins), should be sought, and observation for arrhythmias and mechanical complications (e.g., new murmurs) is essential. If hypoperfusion is present, determination of its primary cause (e.g., hypovolemia, right-sided heart failure, left-sided heart failure) is critical to management.

DIAGNOSIS

The diagnosis of acute MI has traditionally rested on the triad of ischemic-type chest discomfort, electrocardiographic abnormalities, and elevated serum cardiac biomarkers of necrosis. Acute MI was considered present when at least two of the three were present. With their increasing sensitivity and specificity, serum cardiac troponin levels (i.e., troponin I [TnI] and troponin T [TnT])

TABLE 58-1 CONDITIONS OTHER THAN CORONARY ATHEROSCLEROSIS THAT CAN CAUSE ACUTE MYOCARDIAL INFARCTION

Coronary emboli	Causes include aortic or mitral valve lesions, left atrial or ventricular thrombi, prosthetic valves, fat emboli, intracardiac neoplasms, infective endocarditis, and paradoxical emboli
Thrombotic coronary artery disease	Can occur with oral contraceptive use, sickle cell anemia and other hemoglobinopathies, polycythemia vera, thrombocytosis, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, antithrombin III deficiency and other hypercoagulable states, macroglobulinemia and other hyperviscosity states, multiple myeloma, leukemia, malaria, and fibrinolytic system shutdown secondary to impaired plasminogen activation or excessive inhibition
Coronary vasculitis	Seen with Takayasu disease, Kawasaki disease, polyarteritis nodosa, lupus erythematosus, scleroderma, rheumatoid arthritis, and immune-mediated vascular degeneration in cardiac allografts
Coronary vasospasm	Can be associated with variant angina, nitrate withdrawal, cocaine or amphetamine abuse, and angina with "normal" coronary arteries
Infiltrative and degenerative coronary vascular disease	Can result from amyloidosis, connective tissue disorders (e.g., pseudoxanthoma elasticum), lipid storage disorders and mucopolysaccharidoses, homocystinuria, diabetes mellitus, collagen vascular disease, muscular dystrophies, and Friedreich ataxia
Spontaneous coronary dissection	Over 90% of cases occur in younger women. The dominant predisposing cause is fibromuscular dysplasia (Chapter 63); other causes include various arteriopathies and pregnancy-related conditions. Precipitating factors include extreme physical and emotional stressors, intense hormonal therapy, and labor, delivery, and postpartum status. About 50% of cases present as an ST-elevation myocardial infarction, and the estimated 10-year rate of subsequent major adverse cardiac events is about 50%.
Coronary ostial occlusion	Associated with aortic dissection, luetic aortitis, aortic stenosis, and ankylosing spondylitis syndromes
Congenital coronary anomalies	Including Bland-White-Garland syndrome of anomalous origin of the left coronary artery from the pulmonary artery, left coronary artery origin from the anterior sinus of Valsalva, coronary arteriovenous fistula or aneurysms, and myocardial bridging with secondary vascular degeneration
Trauma	Associated with and responsible for coronary dissection, laceration, or thrombosis (with endothelial damage secondary to trauma such as angioplasty) and direct myocardial injury with radiation and cardiac contusion
Augmented myocardial oxygen requirements exceeding oxygen delivery	Encountered with aortic stenosis, aortic insufficiency, hypertension with severe left ventricular hypertrophy, pheochromocytoma, thyrotoxicosis, methemoglobinemia, carbon monoxide poisoning, shock, and hyperviscosity syndromes

have assumed a dominant role in confirming the diagnosis of acute MI in patients with suggestive clinical or electrocardiographic features.

Electrocardiography

In patients with a possible acute MI, a 12-lead ECG should be obtained immediately, with a goal of less than 10 minutes after arrival at a health care facility. Although the initial ECG is neither perfectly sensitive nor specific in patients who develop acute ST-elevation MI, it plays a critical role in initial stratification, triage, and management (Chapter 39).[7] In an appropriate clinical setting, a pattern of ST-segment elevation of 2 mm (0.2 mV) or more at the J point in V_2 to V_3 in men or 1.5 mm (0.15 mV) or more in women in the absence of left ventricular (LV) hypertrophy or 1 mm (0.1 mV) or more in two or more other contiguous chest or limb leads suggests coronary occlusion causing marked myocardial ischemia. In such patients, emergency reperfusion (primary angioplasty or fibrinolysis) should be performed unless it is contraindicated. Hyperacute T-wave changes may suggest the diagnosis in the early phase of ST-elevation MI before the onset of ST elevation. A new or presumably new left bundle branch block, which may obscure ST elevation analysis, may suggest an ST-elevation MI equivalent in the appropriate clinical setting. ST depression in two or more precordial leads V_1 to V_4 may indicate transmural posterior injury due to occlusion of the left circumflex coronary artery; extending ECG analysis to leads V_7 to V_9 (i.e., over the left posterior chest) can help confirm this diagnosis. Other ECG patterns (ST-segment depression, T-wave inversion, nonspecific changes, normal ECG) in association with ischemic chest discomfort are consistent with a non–ST-segment elevation acute coronary syndrome and are treated with different triage and initial management strategies (Chapter 57).

Electrocardiographic Evolution

Serial ECG tracings improve the sensitivity and specificity of the ECG for the diagnosis of acute MI and assist in assessing the outcomes of therapy. When typical ST-segment elevation persists for hours and is followed within hours to days by T-wave inversions and Q waves, the diagnosis of acute MI can be made with virtual certainty. The ECG changes in acute ST-elevation MI evolve through three overlapping phases: hyperacute or early acute, evolved acute, and chronic (stabilized).

Early Acute Phase

This earliest phase begins within minutes, persists, and evolves during hours. T waves increase in amplitude and widen over the area of injury (hyperacute pattern). ST segments evolve from concave to straightened to convex upward patterns (acute pattern). When prominent, the acute injury pattern of blended ST-T waves can take on a tombstone appearance (Figs. 58-1 and 58-2). ST-segment depressions that occur in leads opposite those with ST-segment elevation are known as reciprocal changes and are associated with larger areas of injury and a worse prognosis but also with greater potential for benefit from reperfusion therapy.

Other causes of ST-segment elevation must be considered and excluded (Table 58-2). These conditions include pericarditis (Chapter 62), left ventricular hypertrophy with J point elevation, and normal variant early repolarization (Chapter 42). Pericarditis (or perimyocarditis) is of particular concern because it can mimic acute MI clinically, but fibrinolytic therapy is *not* indicated and can be hazardous.

Evolved Acute Phase

During the second phase, ST-segment elevation begins to regress, T waves in leads with ST-segment elevation become inverted, and pathologic Q or QS

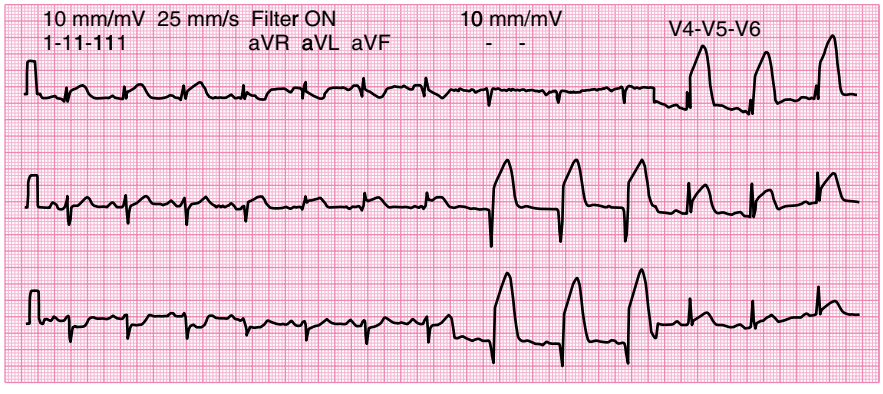

FIGURE 58-1. Electrocardiographic tracing shows an acute anterolateral myocardial infarction. Note ST-segment elevation in leads I, aVL, and V_1 to V_6 with Q waves in V_1 to V_4.

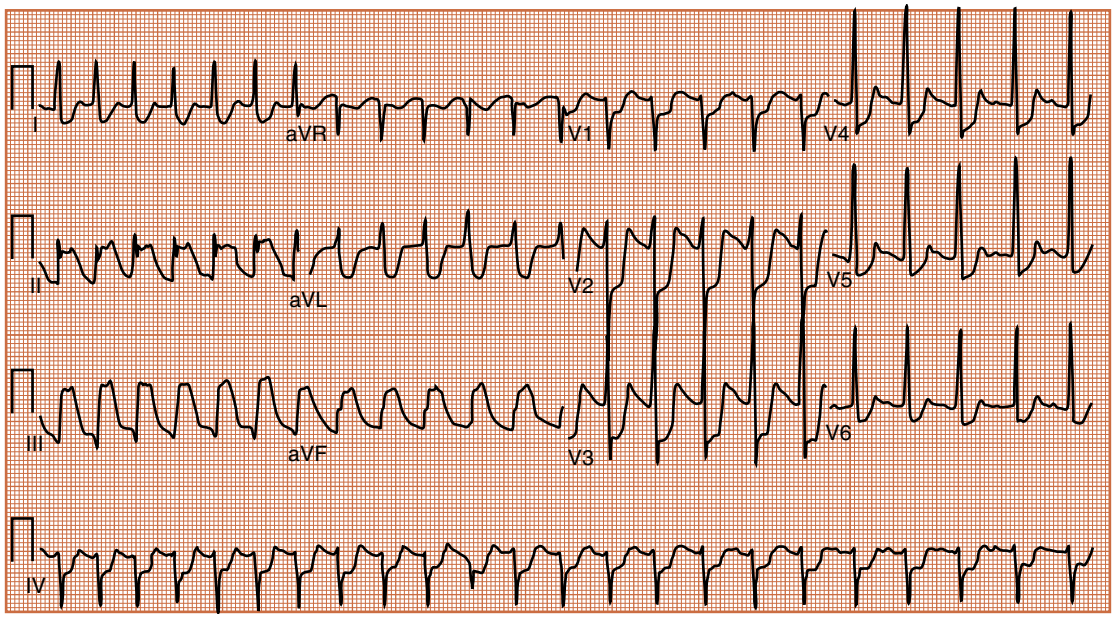

FIGURE 58-2. Electrocardiographic tracing shows an acute inferoposterior myocardial infarction.

waves become fully developed (>0.03-second duration or depth >30% of R wave amplitude or both).

Chronic Phase

Resolution of ST-segment elevation is variable. Resolution is usually complete within 2 weeks of inferior MI, but it can be delayed further after anterior MI. Persistent ST-segment elevation, often seen with a large anterior MI, is indicative of a large area of akinesis, dyskinesis, or ventricular aneurysm. Symmetrical T-wave inversions can resolve during weeks to months or can persist for an indefinite period; hence, the age of an MI in the presence of T-wave inversions is often termed indeterminate. Q waves usually do not resolve after anterior MI but often disappear after inferior wall MI.

Early reperfusion therapy accelerates the time course of ECG changes to minutes or hours instead of days to weeks. ST segments recede rapidly, T-wave inversions and loss of R waves occur earlier, and Q waves may not develop or progress and occasionally may regress. Indeed, failure of ST-segment elevation to resolve by more than 50 to 70% within 1 to 2 hours suggests failure of fibrinolysis and should prompt referral for urgent angiography and consideration of "rescue angioplasty."

True Posterior Myocardial Infarction and Left Circumflex Myocardial Infarction Patterns

True posterior MI presents a mirror-image pattern of ECG injury in leads V_1 to V_2 to V_4 (Fig. 58-2). The location of injury of an isolated true posterior MI by magnetic resonance imaging actually involves portions of the lateral left ventricular wall and is typically caused by occlusion of a nondominant left circumflex artery. In the precordial leads, the acute phase is characterized by ST-segment depression rather than by ST-segment elevation. The evolved and chronic phases show increased R wave amplitude and widening instead of Q waves. Recognition of an isolated true posterior acute MI pattern is challenging but important because the diagnosis should lead to an immediate reperfusion strategy. Extending the ECG to measure left posterior leads V_7 to V_9 increases sensitivity for detection of acute left circumflex–related injury patterns (i.e., ST-segment elevation) with excellent specificity (Chapter 42). Other causes of prominent upright anteroseptal forces include right ventricular hypertrophy, ventricular preexcitation variants (Wolff-Parkinson-White syndrome; Chapter 52), cardiomyopathies, right bundle branch block, and normal variants with early R wave progression. New appearance of these changes or the association with an acute or evolving inferior MI usually allows the diagnosis to be made.

Right Ventricular Infarction

Proximal occlusion of the right coronary artery before the acute marginal branch can cause right ventricular infarction as well as acute inferior MI in about 30% of cases. Because the prognosis and treatment of acute inferior MI differ in the presence of right ventricular infarction, it is important to make this diagnosis. The diagnosis is assisted by obtaining right precordial ECG leads, which are routinely indicated for inferior acute MI (Chapter 42). Acute ST-segment elevation of at least 1 mm (0.1 mV) in one or more leads V_4R to V_6R is both sensitive and specific (>90%) for identifying acute right ventricular injury, and Q or QS waves effectively identify right ventricular infarction.

Diagnosis in the Presence of Bundle Branch Block

The presence of left bundle branch block often obscures ST-segment analysis in patients with suspected acute MI. The presence of a new (or presumed new) left bundle branch block in association with clinical (and laboratory) findings suggesting acute MI is associated with high mortality; patients with new-onset left bundle branch block benefit substantially from reperfusion therapy and should undergo triage and treatment in the same way as patients with ST-elevation MI do. Certain ECG patterns, although relatively insensitive, suggest acute MI if they are present in the setting of left bundle branch block: Q waves in two of leads I, aVL, V_5, and V_6; R wave regression from V_1 to V_4; ST-segment elevation of 1 mm or more in leads with a positive QRS complex; ST-segment depression of 1 mm or more in leads V_1, V_2, or V_3; and ST-segment elevation of 5 mm or more associated with a negative QRS complex. The presence of right bundle branch block usually does not mask typical ST-T wave or Q wave changes except in rare cases of isolated true posterior acute MI, which are characterized by tall right precordial R waves and ST-segment depressions.

TABLE 58-3 NON–MYOCARDIAL INFARCTION CAUSES OF AN ELEVATED TROPONIN LEVEL

OTHER CARDIAC CAUSES
Myocardial injury: cardiac contusion, surgery, ablation, shocks
Myocardial inflammation: myocarditis, pericarditis
Heart failure
Cardiomyopathies: infiltrative, stress, hypertensive, hypertrophic
Aortic dissection
Severe aortic stenosis
Tachycardias
PULMONARY CAUSES
Pulmonary embolism
Pulmonary hypertension
Respiratory failure
NEUROLOGIC CAUSES
Stroke
Intracranial hemorrhage
OTHER
Shock: septic, hypovolemic, cardiogenic
Renal failure

Differential Diagnosis

Although ST-elevation MI is often an easy diagnosis to make on the basis of the presentation and test results (see later), other considerations include acute pericarditis (Chapter 62), acute myocarditis (Chapter 47), stress-induced cardiomyopathy (takotsubo syndrome) (Chapter 47), hyperkalemia, and early repolarization (see Table 58-2). All but early repolarization can be associated with abnormal biomarkers, but none are associated with a coronary occlusion. Early coronary angiography is advised when the cause of ST-segment elevation is unclear (see Table 58-1).

Serum Cardiac Biomarkers of Necrosis

Cardiac-derived troponin-I and troponin-T are proteins specific to sarcomeres. Serial measurement of cardiac troponins is the preferred biomarker approach for differentiating acute MI from unstable angina and non-acute coronary syndromes. In the appropriate clinical setting, acute MI is indicated by a rising and/or falling pattern of troponin, with one or more value(s) above the 99th percentile upper reference limit. High-sensitivity troponin assays can greatly reduce the likelihood of acute MI after a single negative sample and effectively exclude MI in 1 to 2 hours.[8] Such testing has increased the ability to diagnose type 1 MIs (attributable to atherothrombotic events) as well as type 2 MIs (attributable to acute imbalances in myocardial oxygen supply and demand). However, high-sensitivity assays also can lead to an increasing number of false-positive diagnoses of acute MI, because they sometimes can detect increased troponin levels in a number of non-MI settings: myocarditis (Chapter 47); other causes of cardiac injury, such as cardiac, renal, and respiratory failure (Chapter 90); stroke (Chapter 376) and intracranial hemorrhage (Chapter 377); septic shock (Chapter 94); and chronic structural heart diseases (Chapter 56; Table 58-3).[9] As a result, the clinician always must consider the clinical context as well as the finding of a temporal rise and fall of troponin levels.

High-sensitivity troponin assays measure troponin-T, which can be elevated in patients with renal failure (Chapter 117); in this situation, a troponin-I measurement, if available, is preferred. Troponin levels are maximally sensitive at 8 to 12 hours, peak at 10 to 24 hours, and persist for 5 to 14 days. This persistence poses a challenge for the diagnosis of an early recurrent MI, for which the measurement of more rapidly cleared MB isoenzyme of creatine kinase (CK-MB) can be useful.

Other Laboratory Tests

On admission, routine assessment of complete blood count and platelet count, standard blood chemistry studies, a lipid panel, and coagulation tests (prothrombin time, partial thromboplastin time) are useful. Results assist in assessing comorbid conditions and prognosis and in guiding therapy. Hematologic tests provide a useful baseline before initiation of antiplatelet, anticoagulant, and fibrinolytic therapy or coronary angiography or angioplasty. Myocardial injury precipitates polymorphonuclear leukocytosis, thereby commonly resulting in an elevation of the white blood cell count to up to 12,000 to 15,000/μL, which appears within a few hours and peaks at 2 to 4 days. The metabolic panel provides a useful check on electrolytes, glucose, and renal function.

Serum lipid levels may fall in the first 24 to 48 hours after an MI, but a fasting lipid panel is recommended as a baseline for lipid-lowering (statin) therapy (Chapter 190). Unless carbon dioxide retention is suspected, finger oximetry is adequate to diagnose hypoxemia and titrate oxygen therapy. B-type natriuretic peptide, which increases with ventricular wall stress and relative circulatory fluid overload, may provide useful incremental prognostic information in the setting of acute MI.

Imaging

The rapid triage of ST-elevation MI patients to reperfusion therapy, most often for coronary angiography with intent to perform percutaneous intervention (PCI), should not be delayed by routine imaging studies. A chest radiograph is the only imaging test routinely considered in the emergency department for ST-elevation MI, and its usefulness is limited to selected patients with a concern for findings that might affect initial management. Although the chest radiograph is often normal, findings of pulmonary venous congestion, cardiomegaly, or a widened mediastinum can contribute importantly to diagnosis and management decisions. For example, a history of severe, "tearing" chest and back pain in association with a widened mediastinum should raise the question of a dissecting aortic aneurysm (Chapter 63). In such cases, fibrinolytic therapy must be withheld pending more definitive diagnostic imaging of the aorta, and the approach to angiography may be modified. Other noninvasive imaging (e.g., echocardiography [Chapter 43], cardiac nuclear scanning [Chapter 44], and other testing) may be performed later during the course of hospitalization to evaluate specific clinical issues, including suspected complications of acute MI, or for predischarge risk stratification. Coronary angiography (Chapter 59) is performed urgently as part of an interventional strategy for ST-elevation MI or later for risk stratification in higher-risk patients who are initially managed medically.

Echocardiography

Two-dimensional transthoracic echocardiography with color flow Doppler imaging is the most generally useful noninvasive test obtained during the hospital course (Chapter 43). Echocardiography efficiently assesses global and regional cardiac function and enables the clinician to evaluate suspected complications of acute MI. The sensitivity and specificity of echocardiography for regional wall motion assessment are high (>90%), although the age of the abnormality (new vs. old) must be distinguished clinically or by electrocardiography. Echocardiography is helpful in determining the cause of circulatory failure with hypotension (relative hypovolemia, left ventricular failure, right ventricular failure, or mechanical complication of acute MI). Echocardiography also can assist in differentiating pericarditis and perimyocarditis from acute MI. Doppler echocardiography is indicated to evaluate a new murmur and other suspected mechanical complications of acute MI (e.g., papillary muscle dysfunction or rupture, acute ventricular septal defect, and left ventricular free wall rupture with tamponade or pseudoaneurysm). Later in the course of acute MI, echocardiography may be used to assess the degree of recovery of stunned myocardium after reperfusion therapy, the degree of residual cardiac dysfunction and indications for angiotensin-converting enzyme (ACE) inhibitors and other therapies for heart failure, and the presence of left ventricular aneurysm and mural thrombus (requiring oral anticoagulants).

Radionuclide, Magnetic Resonance, and Other Imaging Studies

Radionuclide techniques generally are too time-consuming and cumbersome for routine use in the acute setting of definite or probable acute MI. More commonly, they are used in risk stratification before or after hospital discharge to augment exercise or pharmacologic stress testing (Chapter 44). Thallium Tl 201 or technetium Tc 99 m sestamibi nuclear scans or rubidium Rb 82 positron emission tomography scans can assess myocardial perfusion and viability as well as infarct size. Cardiac magnetic resonance imaging (Chapter 44) with late gadolinium enhancement also can assess infarct size as well as myocardial function during the convalescent phase. Computed tomography and magnetic resonance imaging also can be useful to evaluate patients with a suspected dissecting aortic aneurysm (Chapter 63). When a nonatherosclerotic cause of myocardial necrosis is suspected (e.g., perimyocarditis simulating acute MI), contemporary multislice (e.g., 64-256 slice) coronary computed tomography can assess coronary artery disease qualitatively and semiquantitatively as well as distinguish other causes of chest pain syndromes (Chapters 39 and 44).

TREATMENT

Prehospital Phase

Prehospital cardiac arrest (Chapter 50) and extensive necrosis are major causes of acute MI-associated morbidity and mortality. The first hour after the onset of symptoms represents the best opportunity for myocardial salvage with reperfusion therapy. Thus the primary goals of prehospital care are to recognize symptoms promptly and seek medical attention, deploy an emergency medical system trained in emergency cardiac care, and transport the patient expeditiously to a medical facility capable of advanced coronary care, including reperfusion therapy (primary PCI or fibrinolysis).[10] Guidelines set an average system time goal for first medical contact-to-device of 90 minutes or less. For patients who initially arrive at or are transported to a non–PCI-capable hospital, the system time goal to device is 120 minutes or less. The greatest time lag to reperfusion therapy is the patient's delay in calling for help. Public education efforts aimed at reducing this delay have yielded mixed results, and innovative approaches are needed.

Expert emergency medical system teams perform prehospital ECGs, communicate preliminary diagnoses, and transport patients preferentially to a PCI-capable hospital where an ST-elevation MI team is on alert. This approach results in more rapid primary PCI (average savings of about 15 minutes) and superior clinical outcomes. Direct triage to the catheterization laboratory rather than to the emergency department also may decrease time to reperfusion. However, as many as one third of initial activations of the ST-elevation MI-team may be false positives.

Aspirin (162 to 325 mg, chewed) and sublingual nitroglycerin (0.4 mg every 5 minutes for up to three doses) are administered at first medical contact where appropriate. Administering fibrinolytic therapy in the field by physician-directed systems is feasible when the expected transit time is long (i.e., >120 min), but this practice is rare in the United States. Prehospital antiplatelet therapy of ST-elevation MI patients with ticagrelor does not improve pre-PCI coronary reperfusion.

Emergency Department Phase

The goals of emergency department care are to identify patients with acute myocardial ischemia rapidly, to stratify them into acute ST-elevation MI versus other acute coronary syndromes (Fig. 58-3), to initiate a reperfusion strategy and other appropriate medical care, to assess risk (E-Fig. 58-1), and to triage them rapidly to inpatient care (patients with suspected acute coronary syndrome) or outpatient care (patients without suspected ischemia; see Fig. 57-2).

The evaluation of patients with chest pain and other suspected acute coronary syndromes begins with a 12-lead ECG (with a goal of within 10 minutes of hospital arrival) and continues with a focused history and a targeted physical examination. Continuous ECG monitoring is started, an intravenous line is established, and admission blood tests are drawn (including a troponin level). As rapidly as possible, the patient is stratified into acute ST-elevation MI, likely or definite non–ST-elevation acute coronary syndrome, possible non–ST-elevation acute coronary syndrome (Chapter 57), or noncardiac chest pain categories.

Emergent Therapeutic Measures and Early Inpatient Care

Although troponin assays are the "gold standard" for detecting myocardial necrosis, the decision to proceed with urgent reperfusion (primary angioplasty or fibrinolysis) in ST-elevation MI should be based on the patient's clinical history, and the initial ECG and not be delayed by troponin testing. Coronary reperfusion is accomplished by primary PCI (angioplasty and stenting) or by intravenous fibrinolytic therapy.[11]

Primary PCI

Prompt PCI (with a goal of <90 minutes from first medical contact) is the preferred approach at PCI-capable hospitals for ST-elevation MI patients within 12 hours of the onset of symptoms and is reasonable for ECG and clinical evidence of ongoing ischemia within 12 to 24 hours after the onset of symptoms (Table 58-4). The preferred access site for emergent PCI is the radial artery,[A1] because it results in lower mortality as well as less bleeding compared with a femoral artery approach. Primary PCI also is indicated in patients with cardiogenic shock (Chapter 93) or severe acute heart failure regardless of time delay. Advantages of primary PCI over fibrinolysis include lower rates of early mortality, reinfarction, and intracranial hemorrhage.[A2]

Current guidelines for ST-elevation MI support implantation of advanced-generation drug-eluting stents to provide the best outcomes.[A3] Aspiration thrombectomy does not provide incremental benefit[A4] and is not indicated as a routine strategy.

Risk calculator for 6-month postdischarge mortality after hospitalization for acute coronary syndrome

Record the points for each variable at the bottom left and sum the points to calculate the total risk score. Find the total score on the x-axis of the nomogram plot. The corresponding probability on the y-axis is the estimated probability of all-cause mortality from hospital discharge to 6 months.

All eligible STEMI patients also are treated with dual antiplatelet therapy and an anticoagulant on admission (see text). *Patients with cardiogenic shock or severe heart failure initially seen at a non–PCI-capable hospital should be transferred for cardiac catheterization and revascularization as soon as possible, irrespective of time delay from the onset of the myocardial infarction. †Angiography and revascularization should not be performed within the first 2 to 3 hours after administration of fibrinolytic therapy. CABG = coronary artery bypass grafting; DIDO = door in–door out; PCI = percutaneous coronary intervention. (Modified from O'Gara PT, Kushner FG, Ascheim DD, et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2013;127:e362-e425.)

TABLE 58-4 INDICATIONS FOR PRIMARY ANGIOPLASTY AND COMPARISON WITH FIBRINOLYTIC THERAPY

INDICATIONS
A preferred reperfusion strategy for ST segment elevation or LBBB acute MI within 12 hours of symptom onset (or >12 hours if symptoms persist)
Cardiogenic shock developing within 36 hours of ST-segment elevation/Q wave acute MI or LBBB acute MI in patients <75 years old who can be revascularized within 18 hours of the onset of shock
Recommended at centers performing >400 PCIs/year with backup cardiac surgery and for operators performing >75 PCIs/year
Primary PCI can be performed at centers without on-site cardiac surgery if performed on carefully selected patients by experienced operators and if arrangements are in place for rapid transfer to a surgery-capable center when needed
ADVANTAGES OF PRIMARY PCI
Higher initial reperfusion rates
Reduced risk of intracerebral hemorrhage
Less residual stenosis; less recurrent ischemia or infarction
Usefulness when fibrinolysis is contraindicated
Improvement in outcomes with cardiogenic shock
Evaluation of total burden of coronary artery disease
DISADVANTAGES OF PRIMARY PCI (COMPARED WITH FIBRINOLYTIC THERAPY)
Access, advantages restricted to high-volume centers and operators
Longer average time to treatment
Greater dependence on operators for results
Higher system complexity and costs

LBBB = left bundle branch block; MI = myocardial infarction; PCI = percutaneous coronary intervention (includes balloon angioplasty, stenting).

Randomized trials support that the emergent PCI address not only the infarct-related artery but also significant stenoses in "nonculprit" arteries,[A5] either at the time of the initial procedure or within the next month or so,[A6,A7] except in patients who are in cardiogenic shock.[A8] Such an approach reduces the need for repeat revascularization and also lowers the subsequent risk of recurrent MI and of cardiovascular death.[A9]

Thrombolysis

With the increasing availability of PCI-capable facilities, the use of fibrinolytic therapy (Table 58-5) has decreased. When PCI will be delayed by more than 120 minutes, however, fibrinolytic therapy, in the absence of contraindications, is indicated within 12 hours of the onset of symptoms. It should begin immediately in the emergency department (or ambulance, if available) with a goal of a door-to-needle time of less than 30 minutes. When PCI is not available, fibrinolysis also is reasonable for ECG and clinical evidence of ischemic injury within 12 to 24 hours of the onset of symptoms in patients who are hemodynamically unstable or have a large area of myocardium at risk (Fig. 58-3).

When fibrinolysis is used, an accelerated regimen of a tissue plasminogen activator (plus intravenous heparin) is preferred to streptokinase because the patency rate of the infarct-related artery at 90 minutes is higher and mortality is lower. Longer-acting variants of alteplase, given as single-bolus (tenecteplase) or double-bolus (reteplase) injections, now are more commonly used than alteplase in clinical practice because they are more convenient to administer, but they do not further improve survival.[A10]

The risk-to-benefit ratio should be assessed in each patient when fibrinolysis is considered and specific regimens are selected (Table 58-6). The major risk of fibrinolytic therapy is bleeding. Intracranial hemorrhage is the most serious and frequently fatal complication; its incidence rate is 0.5 to 1% with currently approved regimens. Older age (older than 70 to 75 years), female sex, hypertension, and higher relative doses of plasminogen activators and heparin increase the risk of intracranial hemorrhage. In patients over age 75 years, half-dose tenecteplase is as efficacious as full-dose tenecteplase and associated with less intracranial hemorrhage, thereby making it an attractive alternative.

If fibrinolysis fails to open the infarct-related artery, urgent transfer to a PCI-capable hospital for rescue PCI is more effective than repeated fibrinolysis.

TABLE 58-5 CHARACTERISTICS OF INTRAVENOUS FIBRINOLYTIC AGENTS APPROVED BY THE U.S. FOOD AND DRUG ADMINISTRATION

	STREPTOKINASE (SK)	ALTEPLASE (t-PA)	RETEPLASE (r-PA)	TENECTEPLASE (TNK–t-PA)
Dose	1.5 MU in 30-60 minutes	100 mg in 90 minutes*	10 U + 10 U, 30 minutes apart	30-50 mg† during 5 seconds
Circulating half-life (minutes)	≅20	≅4	≅18	≅20
Antigenic/Allergic reactions	Yes	No	No	No
Systemic fibrinogen depletion	Severe	Mild to moderate	Moderate	Minimal
Intracerebral hemorrhage	≅0.4%	≅0.7%	≅0.8%	≅0.7%
Patency (TIMI 2/3) rate, 90 minutes‡	≅51%	≅73-84%	≅83%	≅77-88%
Lives saved per 100 treated	≅3§	≅4‖	≅4	≅4
Cost per dose (approximate U.S. dollars)	300	1800	2200	2200

*An accelerated alteplase regimen is given as follows: 15-mg bolus, then 0.75 mg/kg during 30 minutes (maximum, 50 mg), then 0.50 mg/kg during 60 minutes (maximum, 35 mg).

†TNK–t-PA is dosed by weight (supplied in 5-mg/mL vials): <60 kg = 6 mL; 61-70 kg = 7 mL; 71-80 kg = 8 mL; 81-90 kg = 9 mL; >90 kg = 10 mL.

§Patients with ST-segment elevation or bundle branch block, treated <6 hours.

‖Based on the finding from the GUSTO trial that t-PA saves one more additional life per 100 treated than does SK. Data from The GUSTO Investigators. An international randomized trial comparing four thrombolytic strategies for acute myocardial infarction. *N Engl J Med.* 1993;329:673-682; and Simes RJ, Topol EJ, Holmes DR Jr, et al. Link between the angiographic substudy and mortality outcomes in a large randomized trial of myocardial reperfusion: importance of early and complete infarct artery reperfusion. GUSTO-I Investigators. *Circulation.* 1995;91:1923-1928.

Even for patients successfully reperfused, rapid transfer to a PCI-capable facility, where angiography and PCI are performed as early as feasible within the window of 3 to 24 hours after fibrinolysis, can reduce the risk for recurrent ischemia, reinfarction, heart failure, cardiogenic shock, or death by about 35%.

Acute Hospital Phase

Ancillary and Other Therapies

General Medical Management

Beyond prompt initiation of reperfusion and other antithrombotic therapy, initial management includes bedrest (i.e., for 12 hours or until ischemia has been relieved and hemodynamic parameters have stabilized) with ECG monitoring. Routine oxygen supplementation does not benefit normoxemic patients.[A11,A12] Oxygen should be used in doses just sufficient to avoid hypoxemia (e.g., initially at 2 to 4 L/minute by nasal cannula; fingertip oximetry may be used to monitor effect) in patients with hypoxemia (oxygen saturation <90%), respiratory distress, or other high-risk features for hypoxemia. Initiation or continuation of high-intensity statin therapy (i.e., atorvastatin 80 mg/day or rosuvastatin 20 or 40 mg/day), beginning on admission, is supported by clinical trials.

Patients with ischemic chest discomfort or pain should be given sublingual nitroglycerin (0.4 mg every 5 minutes for up to three doses). Subsequently, intravenous (IV) nitroglycerin, titrated to symptom relief and blood pressure effects, may be considered to treat ongoing discomfort, uncontrolled hypertension, or heart failure. Bradycardia is a relative contraindication for nitrates, particularly in the setting of acute inferior ST-elevation MI, in which it may slow the heart rate even more. Persistent ischemic pain may be treated with titrated intravenous doses of morphine (i.e., 1 to 4 mg intravenously, repeated in 5 to 30 minutes as needed to relieve pain).

Routine IV β-blocker therapy does not benefit ST-elevation MI patients treated with primary PCI.[A13] However, selected patients (e.g. with hypertension, persistent chest pain, left ventricular dysfunction) may benefit. In such cases, titrated oral β-blockers (e.g., metoprolol tartrate, 12.5 mg orally every 6 hours, increased to 25 to 50 mg every 6 hours as tolerated) can be started, beginning within the first 24 hours if there are no contraindications. For hypertension, intravenous therapy (e.g., metoprolol tartrate, 5 mg every 2 to 5 minutes, up to three doses, transitioning to oral therapy, e.g., 25 to 50 mg every 8 hours) may be used. β-Blockers should be avoided in patients with active heart failure or cardiogenic shock. However, β-blockade, preferably with carvedilol, should be considered in patients with a left ventricular ejection fraction <40% once the heart failure has resolved.

In the absence of contraindications (e.g., hypotension), ACE inhibitors (e.g., initially captopril 6.25 mg every 8 hours or lisinopril 2.5 mg twice daily, titrated upward as tolerated) or angiotensin receptor blockers (e.g., losartan 12.5 to 25 mg once or twice daily, titrated upward as tolerated) should be started within 24 hours in patients with an anterior MI, left ventricular dysfunction, or heart failure. Subsequently (e.g., at 3 to 14 days), patients with an ejection fraction ≤40% and either symptomatic heart failure or diabetes become candidates for the addition of an aldosterone antagonist (i.e., eplerenone; initially, 25 mg once daily) or spironolactone (12.5 to 25 mg twice daily.)

The optimal systolic blood pressure range during acute MI is generally 100 to 140 mm Hg. Excessive hypertension usually responds to titrated nitroglycerin, β-blocker therapy, and morphine. Relative hypotension could require discontinuation of these medications, fluid administration, and/or other measures as appropriate to the hemodynamic subset (Table 58-7). Atropine (0.5 to 1.5 mg intravenously) should be available to treat symptomatic bradycardia and hypotension related to hypervagotonia.

Antiplatelet Therapy

Given the critical role of coronary thrombosis in the precipitation of acute MI, antithrombotic therapy, supplemental to primary PCI or fibrinolysis, plays a key role in management of ST-elevation MI (Fig. 58-4; Table 58-7).

Aspirin (162 to 325 mg, non–enteric-coated) should be given on presentation to all patients unless it is contraindicated (see Fig. 58-4). A daily maintenance aspirin dose of 81 to 325 mg is then given and continued indefinitely. An 81 mg maintenance dose of aspirin is required with ticagrelor and preferred with prasugrel. However, a higher initial dose (325 mg daily for 30 days) of aspirin may be preferred with clopidogrel.

In addition to aspirin, a loading dose of an adenosine diphosphate receptor ($P2Y_{12}$) inhibitor (i.e., clopidogrel 600 mg, prasugrel 60 mg, or ticagrelor 180 mg)

TABLE 58-6 INDICATIONS FOR AND CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY

INDICATIONS
Ischemic-type chest discomfort or equivalent for 30 minutes–12 hours with new or presumed new ST-segment elevation in two contiguous leads of ≥2 mm (≥0.2 mV) in leads V_1, V_2, or V_3 or ≥1 mm in other leads
New or presumed new left bundle branch block with symptoms consistent with myocardial infarction
Absence of contraindications
CONTRAINDICATIONS, ABSOLUTE
Active bleeding or bleeding diathesis (menses excluded)
Prior hemorrhagic stroke, ischemic stroke within 3 months, except acute ischemic stroke within 3-4.5 hours
Intracranial or spinal cord neoplasm or arteriovenous malformation
Suspected or known aortic dissection
Closed head or facial trauma within 3 months
CONTRAINDICATIONS, RELATIVE
Severe, uncontrolled hypertension by history or on presentation (>180/110 mm Hg)
Anticoagulation with therapeutic or elevated international normalized ratio (>2-3)
Old ischemic stroke (>3 months ago); intracerebral disease other than above
Recent (<3 weeks) major trauma/surgery or prolonged (>10 minutes) cardiopulmonary resuscitation or internal bleeding
Active peptic ulcer
Recent noncompressible vascular punctures
Pregnancy
For streptokinase/anistreplase: prior exposure (especially if >5 days ago) or allergic reaction

Modified from Kushner FG, Hand M, Smith SC Jr, et al. 2009 Focused updates: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction and the ACC/AHA/SCAI guidelines on percutaneous coronary intervention. *Circulation.* 2009;120:2271-2306.

TABLE 58-7 IN-HOSPITAL DOSING OF SELECTED ANTITHROMBOTIC DRUGS

DRUG	INITIAL DOSE	MAINTENANCE DOSE
Abciximab	0.25 mg/kg IV bolus	0.125 μg/kg/min (maximum, 10 μg/min) for up to 12 hr
Aspirin	162-325 mg	81 mg*-325 mg/day
Clopidogrel	PCI: 300-600 mg* Fibrinolysis and age >75: 75-150 mg	75 mg/day (optional: 150 mg/day × 1 wk)
Eptifibatide	180 μg/kg IV bolus × 2†	2.0 μg/kg/min for up to 18 hr reduce rate by 50% for CrCl < 50 mL/min
Prasugrel	60 mg	10 mg/day
Ticagrelor	180 mg	90 mg bid (given with aspirin 81 mg/day)
Tirofiban	25 μg/kg IV bolus	0.15 μg/kg/min for up to 12 to 18 hr; reduce rate by 50% for CrCl < 30 mL/min
UFH	PCI‡: 70-100 U/kg IV bolus Fibrinolytic§: 60 U/kg IV bolus (max, 4000 U)	Repeat to achieve, maintain target ACT 12 U/kg/hr (max, 1000 U/hr) initial adjust aPTT to 1.5-2.0 × control (~50-70 sec)
Bivalirudin	PCI‡: 0.75 mg/kg IV bolus Additional 0.3 mg/kg PRN	1.75 mg/kg/hr infusion 1 mg/kg/hr for CrCl < 30 mL/min
Enoxaparin	Fibrinolytic§: 30 mg IV bolus Age >75: no bolus	1 mg/kg SQ at 15 min and q12h (max, 100 mg) 0.75 mg/kg SQ q12h (max, 75 mg) All ages, CrCl <30 mL/min: 1 mg/kg q24h
Fondaparinux	Fibrinolytic§: 2.5 mg IV	2.5 mg SQ daily, starting the next day Contraindicated if CrCl < 30 mL/min

*Generally preferred dose.
†Boluses are separated by 10 minutes.
‡Anticoagulants are generally stopped following uncomplicated PCI.
§Given for the index hospitalization (up to 48 hr [UFH] or up to 8 days [enoxaparin or fondaparinux]) or until revascularization.
ACT = activated clotting time; bid = twice daily; CrCl = creatinine clearance; IV = intravenous; max = maximum; PCI = percutaneous coronary intervention (e.g., stenting); SQ = subcutaneous; UFH = unfractionated heparin.

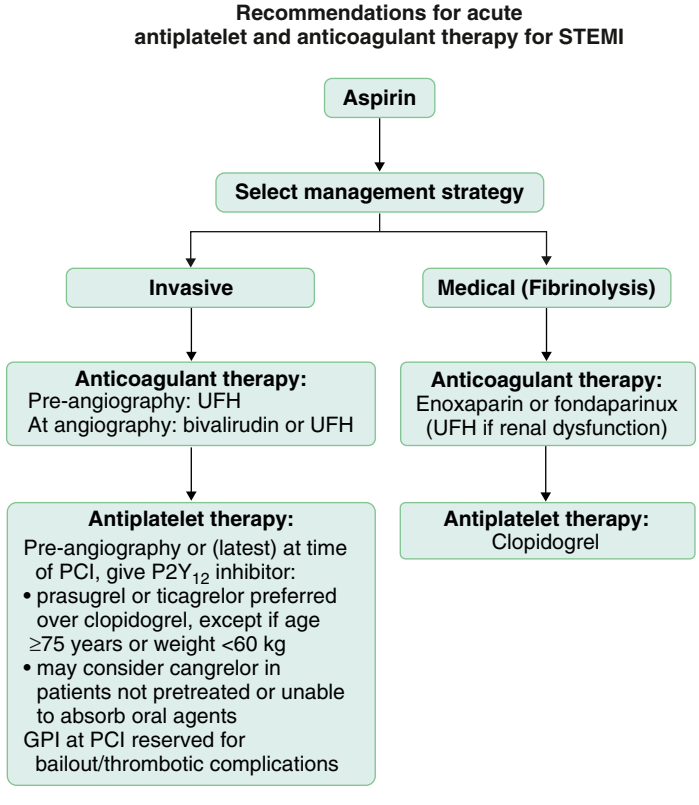

FIGURE 58-4. Recommendations for antiplatelet and anticoagulant therapy for ST-segment elevation myocardial infarction (STEMI). See text for doses. GPI = glycoprotein IIb/IIIa inhibitor; UFH = unfractionated heparin.

should be given as early as possible or at the time of primary PCI to ST-elevation MI patients for whom an invasive approach is planned, followed by a daily maintenance dose for at least 1 year. The more potent prasugrel and ticagrelor are preferred over clopidogrel for ST-elevation MI patients undergoing primary PCI when their bleeding risk is acceptable, with data suggesting that prasugrel is more effective and equally safe.[A14] By comparison, clopidogrel is preferred in patients with a history of a stroke or transient ischemic attack, and it also is recommended for at least 14 days and up to 1 year after fibrinolytic therapy. *Cangrelor*, a short-acting IV $P2Y_{12}$ inhibitor (given as a 30 μg/kg IV bolus followed immediately by a 4 μg/kg/min infusion for at least 2 hours or until the end of the procedure), has a rapid onset/offset of action (3- to 6-minute half-life) and is better than clopidogrel for preventing ischemic events, but at the cost of increased bleeding.

Glycoprotein (GP) IIb/IIIa inhibitors (Table 58-7) can provide a rapid onset of antiplatelet activity in the precatheterization laboratory setting or for the prevention and treatment of periprocedural thrombotic complications. Otherwise, their use is now limited.

Anticoagulant Therapy

Inhibition of thrombin generation is crucial to the management of occluding coronary thrombi in ST-elevation MI. Initiation of a parenteral anticoagulant thrombin inhibitor is recommended at the time of presentation for all ST-elevation MI patients (Fig. 58-4). Intravenous unfractionated heparin and bivalirudin are comparably effective alternatives for the composite end point of death, recurrent MI, and major bleeding in supporting PCI and intensive antiplatelet therapy.[A15] Anticoagulants are generally stopped after an uncomplicated PCI. Recommended options to support fibrinolytic therapy include unfractionated heparin, enoxaparin, and fondaparinux (see Table 58-7).

Combined Oral Anticoagulant and Antiplatelet Therapy

Based on limited evidence, current guidelines recommend dual antiplatelet therapy combined with an oral anticoagulant in post-MI patients with high-risk atrial fibrillation (AF; Chapter 52), a mechanical heart valve (Chapter 60), venous thromboembolism (Chapter 68), or hypercoagulable disorders (Chapter 67) but that the duration of such triple therapy be as short as possible (usually 1 week to 1 month). Warfarin (INR goal 2.0 to 2.5) is indicated as the anticoagulant for patients with a mechanical heart valve or left ventricular thrombus, typically combined with clopidogrel. For patients with AF or a history of venous thromboembolism, a direct-acting oral anticoagulant is preferred: options include low-dose rivaroxaban (15 mg daily) plus a $P2Y_{12}$ inhibitor (primarily clopidogrel), apixaban 2.5 or 5 mg twice daily (depending on renal function) plus a $P2Y_{12}$ inhibitor (primarily clopidogrel),[A16] or very-low-dose rivaroxaban (2.5 mg twice daily) plus dual antiplatelet therapy with aspirin plus a $P2Y_{12}$ inhibitor.[A17]

Coronary Intensive Care

Prompt reperfusion therapy has dramatically lowered the prevalence of MI-related ventricular arrhythmias. After early successful primary PCI, patients who have small infarcts and who are hemodynamically and electrically stable may be transferred to a telemetry step-down unit within 24 hours.

In the contemporary care of patients with an ST-elevation MI, the primary role of coronary intensive care unit admission (Table 58-8) is to manage patients with or at risk for complications of acute MI. The goals of the coronary intensive care unit include continuous electrocardiographic monitoring and therapy for serious arrhythmias (e.g., rapid defibrillation of ventricular fibrillation [VF]; Chapter 53), monitoring the success of the primary PCI, monitoring or continuing fibrinolytic therapy, initiating or continuing other acute medical therapies (as discussed earlier), appropriate hemodynamic assessment and monitoring, and diagnosis and treatment of mechanical and physiologic complications of acute MI.

General care measures in the coronary intensive care unit include attention to activity, diet and bowels, education, reassurance, and sedation. Bedrest is encouraged for the first 12 hours. In the absence of complications, dangling, bed-to-chair, and self-care activities can begin within 24 hours or earlier after successful reperfusion therapy. When stabilization has occurred, usually within 1 to 3 days, patients may be transferred to a step-down unit for progressive ambulation. The risk for emesis and aspiration or the anticipation of angiography or other procedures usually dictates nothing by mouth or clear liquids for the first 4 to 12 hours. Thereafter, a heart-healthy diet in small portions is recommended. In patients at high risk for bleeding gastric stress ulcers, a proton pump inhibitor or an H2-receptor antagonist is recommended. Many patients benefit from an analgesic (see Tables 26-4 and 26-6) to relieve ongoing pain and an anxiolytic or sedative during the acute phase. A benzodiazepine (Table 362-9) is frequently selected, but routine use of anxiolytics is neither necessary nor recommended. Sedatives should not substitute for education and reassurance from concerned caregivers to relieve emotional distress and improve behavior. Constipation often occurs with bedrest and narcotics; stool softeners and a bedside commode are advised.

The ECG should be monitored continuously during the entire hospital course to detect serious arrhythmias and to guide therapy. Measures to limit infarct size (i.e., coronary reperfusion) and to optimize hemodynamics also stabilize the heart electrically. Routine antiarrhythmic prophylaxis (e.g., with lidocaine

TABLE 58-8 SAMPLE ADMISSION ORDERS FOR ST-SEGMENT ELEVATION ACUTE MYOCARDIAL INFARCTION

Diagnosis	Acute ST-segment elevation myocardial infarction
Admit	Coronary care unit with telemetry
Condition	Serious
Vital signs	q½h until stable, then q1-4h and PRN; pulse oximetry × 24 hr; notify if heart rate <50 or >100; respiratory rate <8 or >20; SBP <90 or >150 mm Hg; O_2 saturation <90%
Activity	Bedrest × 12 hr with bedside commode; thereafter, light activity if stable
Diet	NPO except for sips of water until pain free and stable; then 2 g sodium, heart-healthy diet as tolerated, unless on call for catheterization (or other test requiring NPO)
Laboratory tests*	Troponin I or T at 2 hours, then q8h × 3; comprehensive blood chemistry, magnesium, CBC with platelets; PT/INR, aPTT; BNP; lipid profile (fasting in morning); portable CXR
IV therapy	D_5W or NS to keep vein open (increase fluids for relative hypovolemia); second IV if IV medication given
Reperfusion therapy*	Emergency primary coronary angioplasty or fibrinolysis (if appropriate and if not already performed) 1. Primary angioplasty (preferred if available within 90 minutes) 2. Tenecteplase, reteplase or alteplase (preferred); or streptokinase (see Table 58-6 for doses), if primary PCI is unavailable within 90-120 minutes
Medications	1. Nasal O_2 at 2 L/min if with or at risk of hypoxemia, titrated to keep O_2 saturation >90% 2. Aspirin 162-325 mg chewed on admission, then 81-365 mg PO daily 3. IV heparin, 60-U/kg bolus (maximum, 4000 U) and 12 U/kg/hr (maximum, 1000 U/hr), titrate to target aPTT 1.5-2.0 × control (about 50-70 seconds); *or* enoxaparin (preferred with fibrinolytic), 30 mg IV, then 1 mg/kg SQ q12h (maximum SQ doses, 100 mg on day 1; reduce to 0.75 mg/kg for age ≥75 years, increase interval to q24h for CrCl <30 mL/min); *or* bivalirudin (with primary PCI), 0.75-mg/kg IV bolus, then 1.75 mg/kg/hr (delay 30 minutes if heparin given) 4. Metoprolol, 12.5 PO q6h, incremented to 25-50 mg q6h as tolerated (hold for SBP < 100 mm Hg, pulse <50 beats/min, asthma, heart failure); may consider IV metoprolol if immediate effect required (tachyarrhythmia, severe hypertension, unrelieved pain) in the absence of heart failure 5. Consider IV nitroglycerin drip × 24-48 hr (titrated to SBP 100-140 mm Hg) 6. Morphine sulfate, 1-4 mg IV and increment at 5-30 minutes PRN for unrelieved pain 7. Stool softener 8. Anxiolytic or hypnotic if needed 9. ACE inhibitor for hypertension, anterior acute MI, or LV dysfunction, in low oral dose (e.g., captopril, 6.25 mg q8h), begun within 24 hours or when stable (SBP > 100 mm Hg) and adjusted upward 10. Lipid-lowering therapy (i.e., high-intensity statin) regardless of LDL: target LDL reduction of ≥50%; give atorvastatin 80 mg PO or rosuvastatin 20-40 mg PO on admission (pre-cath) and continue daily. 11. Antiplatelet therapy: Ticagrelor, 180 mg PO on admission, then 90 mg bid *or* prasugrel, 60 mg PO on admission, then 10 mg PO daily with a primary PCI strategy (preferred to clopidogrel if acceptable bleeding risk); *or* clopidogrel, 600 mg PO on admission for a primary PCI strategy, or 300 mg PO with fibrinolytic, then 75 mg PO daily. For specific treatments for hemodynamic subgroups, see Table 58-9.

*If not ordered in the emergency department.

ACE = angiotensin-converting enzyme; aPTT = activated partial thromboplastin time; BNP = brain natriuretic peptide; CABG = coronary artery bypass graft surgery; CBC = complete blood count; CrCl = creatinine clearance; CXR = chest radiograph; D_5W = 5% dextrose in water; daily = once daily; INR = international normalized ratio; IV = intravenous; LDL = low-density lipoprotein; LV = left ventricle; MI = myocardial infarction; NPO = nothing by mouth; NS = normal saline; PCI = percutaneous coronary intervention; PO = orally; PRN = as needed; PT = prothrombin time; SBP = systolic blood pressure; SQ = subcutaneous.

or amiodarone) is not indicated, but specific arrhythmias require treatment (see later text).

Hemodynamic evaluation is helpful in assessing prognosis and in guiding therapy (see Table 58-9). Clinical and noninvasive evaluation of vital signs is adequate for normotensive patients without pulmonary congestion. Patients with pulmonary venous congestion are at high risk and must be carefully monitored in terms of fluid status, oxygenation, and urine output (Chapter 46). Invasive hemodynamic monitoring is appropriate only when the cause of circulatory failure is uncertain or when titration of intravenous therapies depends on hemodynamic measurements (e.g., pulmonary capillary wedge pressure and cardiac output). Arterial catheters are appropriate and useful in clinically unstable, hypotensive patients who do not respond to intravenous fluids to replete or to expand intravascular volume (see the later discussion of complications).

Management of Complications

Complications of acute MI have declined with early reperfusion and modern medical therapy, but they remain an important cause of morbidity and mortality.

Recurrent Chest Pain

Recurrent chest pain can be caused by post-infarction ischemia of the border zones of the infarcted territory, acute closure of the treated infarct-related artery, non–infarct-related coronary lesions, mechanical complications (see later), and pericarditis. Characterization of the pain, physical examination, electrocardiography, echocardiography, and cardiac marker determinations assist in the differential diagnosis. Treatment should be specific to the cause.

Postinfarction angina developing spontaneously during hospitalization for acute MI despite medical therapy may indicate infarct extension or reinfarction and usually merits coronary angiography. Infarct expansion implies circumferential slippage with thinning of the infarcted myocardium. Infarct expansion can be associated with chest pain but without recurrent elevation of cardiac markers. Expansive remodeling can lead to a left ventricular aneurysm. The risk for remodeling is reduced by early reperfusion therapy and administration of ACE inhibitors. β-Blockers and nitroglycerin are recommended medical therapies.

Pain with recurrent ST-segment elevation or recurrent elevation of cardiac markers may be due to acute closure (e.g., stent thrombosis) of the treated infarct-related artery. An invasive approach is recommended and preferred to relieve discomfort that occurs hours to days after an acute MI and that is associated with objective signs of reinfarction. Other potential treatment strategies include readministration of thrombolytic therapy or a GP IIb/IIIa inhibitor, along with nitroglycerin, β-blockade, and heparin. Streptokinase, which induces neutralizing antibodies, generally should not be readministered beyond the first few days of an initial administration. Radionuclide perfusion stress testing can be helpful in patients with discomfort that is transient or of uncertain ischemic origin. For lesions with questionable degrees of stenosis at angiography, coronary pressure gradient (fractional flow reserve) or Doppler velocimetry or intracoronary ultrasound can determine whether PCI is warranted.

Acute pericarditis most commonly is manifested on days 2 to 4 when a large, transmural infarction causes pericardial inflammation. On occasion, hemorrhagic effusion with tamponade develops, so excessive anticoagulation should be avoided. Pericarditis developing later (2 to 10 weeks) after acute MI could represent Dressler syndrome, which is believed to be immune mediated. The incidence of this post-MI syndrome has decreased dramatically in the modern reperfusion era. Pericardial pain after ST-elevation MI is usually treated with aspirin, but colchicine, acetaminophen, or narcotic analgesics (Chapter 62) are reasonable if aspirin (even in high doses) is not effective. Glucocorticoids and nonsteroidal anti-inflammatory drugs are potentially harmful after ST-elevation MI and should be avoided.

Rhythm Disturbances

Ventricular Arrhythmias

Acute MI and subsequent reperfusion are associated with a proarrhythmic environment that includes heterogeneous myocardial ischemia, heightened

TABLE 58-9 HEMODYNAMIC SUBSETS OF ACUTE MYOCARDIAL INFARCTION

	BLOOD PRESSURE (RELATIVE)	TYPICAL PHYSICAL FINDINGS	CARDIAC INDEX (L/min/m^2)	PA WEDGE PRESSURE (mm Hg)	SUGGESTED INTERVENTIONS
Normal	Normal	$\pm S_4$	>2.5	≤12	None required
Hyperdynamic	Normal or high	Anxious	>3	<12	Control pain, anxiety; β-blocker; treat SBP to <140 mm Hg
Hypovolemia	Low	Dry	≤2.7	≤9	Add fluids to maintain normal pressure; can develop pulmonary edema if hypotension is caused by unrecognized LV failure
Mild LV failure	Low to high	Rales, $\pm S_3$	2-2.5	>15	Diuresis; nitrates, ACE inhibitor; consider low-dose β-blocker
Severe LV failure	Low to normal	Above $+S_3$, ± ↑ JVP, ± edema	<2	>20	Diuresis; nitrates; low-dose ACE inhibitor; avoid β-blockers; consider inotropes, urgent revascularization
Cardiogenic shock	Very low	Above + cool, clammy; ↓ mental or renal function	≤1.5	>25	Avoid hypotensive agents; place intra-aortic balloon pump or LV assist device; urgent revascularization if possible
RV infarct	Very low	↑ JVP with clear lungs	<2.5	≤12	Give IV fluids; avoid nitrates and hypotensive agents; dobutamine if refractory to fluids

↑ = increased; ↓ = decreased; ACE = angiotensin-converting enzyme; IV = intravenous; JVP = jugular venous pressure; LV = left ventricle; PA = pulmonary artery; RV = right ventricle; SBP = systolic blood pressure.

Modified from Forrester JS, Diamond G, Chatterjee K, et al. Medical therapy of acute myocardial infarction by application of hemodynamic subsets (second of two parts). *N Engl J Med*. 1976;295:1404-1413.

adrenergic tone, intracellular electrolyte disturbance, lipolysis and the production of free fatty acids, and the generation of oxygen free radicals. Micro-reentry likely is the most common electrophysiologic mechanism of early-phase arrhythmias, although enhanced automaticity and triggered activity also are observed in experimental models.

Accelerated idioventricular rhythm (60 to 100 beats per minute) frequently occurs within the first 12 hours and is generally benign (i.e., is not a risk factor for more serious ventricular arrhythmias). Indeed, accelerated idioventricular rhythm frequently heralds successful reperfusion. Antiarrhythmic therapy is not indicated except for sustained, hemodynamically compromising accelerated idioventricular rhythm.

Primary ventricular fibrillation (Chapter 50) is associated with a higher rate of 24-hour in-hospital and short-term mortality, but the longer-term risk of recurrent ventricular tachycardia or ventricular fibrillation and mortality is largely unaffected in survivors. Polymorphic ventricular tachycardia (Chapter 53) and, less commonly, monomorphic ventricular tachycardia are associated life-threatening arrhythmias that can occur in almost 6% of patients in the early phase of acute MI. Clinical features (including warning arrhythmias) are not adequately specific or sensitive to identify patients at risk for sustained ventricular tachyarrhythmias, so all patients should be continuously monitored. Prophylactic lidocaine, which reduces primary ventricular fibrillation but does not decrease (and may increase) mortality, is not recommended.

In comatose ST-elevation MI patients resuscitated from out-of-hospital cardiac arrest due to ventricular fibrillation or pulseless ventricular tachycardia, body temperature management to avoid hyperthermia is beneficial and should be considered as soon as possible after hospital arrival (Chapter 50).

Electrical cardioversion is required for ventricular fibrillation and sustained polymorphic ventricular tachycardia (unsynchronized shock) and for sustained monomorphic ventricular tachycardia (synchronized shock) that causes hemodynamic compromise (Chapters 53 and 54). Brief intravenous sedation is given to conscious, "stable" patients. For slower, stable ventricular tachycardia and nonsustained ventricular tachycardia requiring therapy, intravenous amiodarone or intravenous lidocaine is commonly used. After episodes of ventricular tachycardia or ventricular fibrillation, infusions of antiarrhythmic drugs may be given for 6 to 24 hours; the ongoing risk for arrhythmia then is reassessed. Electrolyte and acid-base imbalance and hypoxia should be corrected. β-Blockade is useful in patients with frequent polymorphic ventricular tachycardia associated with adrenergic activation ("electrical storm"). Additional, aggressive measures should be considered to reduce cardiac ischemia (e.g., emergency PCI or CABG) and to address left ventricular dysfunction (e.g., intra-aortic balloon pump or left ventricular assist device) in patients with recurrent polymorphic ventricular tachycardia despite the use of β-blockers or amiodarone or both.

Late ventricular fibrillation, which develops more than 48 hours after the onset of acute MI, portends a worse prognosis and deserves aggressive therapy (see below). Monomorphic ventricular tachycardia resulting from re-entry in the context of a recent or old MI also can appear late after MI, and patients may require long-term therapy (see below). An implantable cardioverter-defibrillator (ICD; Chapter 54) is indicated in patients with ventricular fibrillation or hemodynamically significant sustained ventricular tachycardia occurring more than 2 days after ST-elevation MI and not due to a transient or reversible cause (e.g., ischemia, reinfarction, metabolic abnormalities; Figure 58-5).

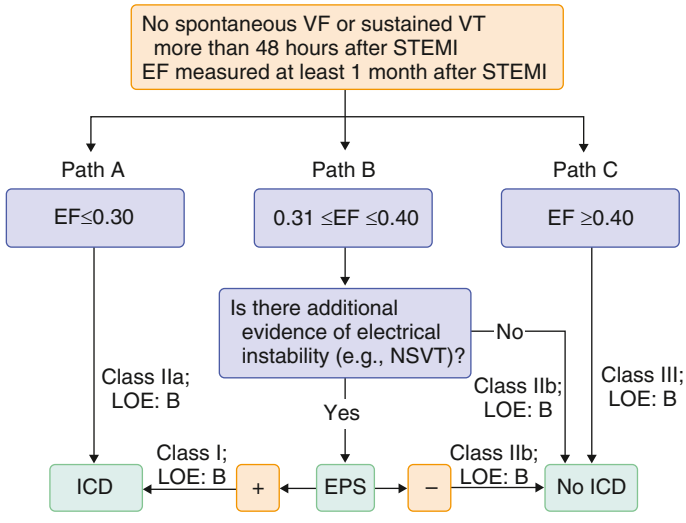

FIGURE 58-5. Algorithm to aid in selection of implantable cardioverter-defibrillator (ICD) in patients with ST-segment elevation myocardial infarction (STEMI) and diminished ejection fraction (EF). The appropriate management path is selected on the basis of left ventricular EF measured at least 1 month after STEMI. All patients, whether an ICD is implanted or not, should receive medical therapy. EPS = electrophysiologic studies; LOE = level of evidence; NSVT = nonsustained ventricular tachycardia; VF = ventricular fibrillation; VT = ventricular tachycardia. (Modified from Antman EM, Anbe DT, Armstrong PW, et al. 2004 Update: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction—executive summary. A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Writing Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. *Circulation*. 2004;110:588-636.)

Atrial Fibrillation and Other Supraventricular Tachyarrhythmias

Atrial fibrillation (AF), which is an important and relatively common acute MI-related arrhythmia, occurs in 5 to 10% of patients with an acute MI, often within the first day (Chapter 52). The incidence of atrial flutter and other supraventricular tachyarrhythmias is much lower. The risk for AF increases with age, larger MIs, heart failure, pericarditis, atrial infarction, hypokalemia, hypomagnesemia, hypoxia, pulmonary disease, and hyperadrenergic states. The incidence of AF is reduced by effective early reperfusion. Hemodynamic compromise with rapid rates and systemic embolism (in about 2% of cases) are adverse consequences of AF. Systemic embolism can occur on the first day, so prompt anticoagulation with heparin is indicated.

Recommendations for management of AF include electrical cardioversion for patients with hemodynamic compromise or ischemia; rate control with an intravenous β-blocker (e.g., metoprolol, 5 mg over 2 minutes to a total of 15 mg over 10 to 15 minutes) in patients without clinical ventricular dysfunction, with intravenous digoxin for patients with ventricular dysfunction (i.e., give 1.0 mg, half initially and half in 4 hours), or with intravenous diltiazem or verapamil in hemodynamically compensated patients with a contraindication to β-blockers; and anticoagulation with heparin (or low-molecular-weight heparin). Amiodarone, which is generally reserved for patients with or at high risk for AF recurrence, may be started and continued for 6 weeks if sinus rhythm is restored and maintained. Long-term chronic anticoagulation may not be necessary thereafter unless other indications exist.

Bradycardias, Conduction Delays, and Heart Block

Bradycardias caused by sinus or atrioventricular (AV) nodal delay, typically owing to increased parasympathetic tone associated with an inferior wall MI, are common and usually benign. Atropine (0.5 to 1.5 mg IV) is useful for symptomatic cases (e.g., heart rates generally <50 beats per minute associated with hypotension, ischemia, or escape ventricular arrhythmias). Temporary pacing is needed rarely. By comparison, atropine can worsen infranodal AV block (usually observed in association with anterior MI and a wide-complex escape rhythm), so it is important to differentiate the two (Chapter 52).

New-onset infranodal AV, intraventricular, and bundle branch blocks predict a four-fold to six-fold increase in in-hospital mortality, but this increase is related more to extensive myocardial damage than to the heart block itself. Temporary pacing usually is indicated, but it only modestly improves survival. Fortunately, the incidence of these arrhythmias has declined markedly in the reperfusion era (from 10 to 20% to ~4%).

Indications for permanent pacing after acute MI depend on the prognosis of the AV block and not solely on symptoms. Indications include even transient second- or third-degree AV block in association with bundle branch block and ongoing symptomatic AV block at any level. However, block at the AV nodal level (Wenckebach) rarely is persistent or symptomatic enough to warrant permanent pacing.

Heart Failure and Other Low-Output States

Of all serious acute MI-related complications, heart failure (Chapters 45 and 46) is the most common and is the leading cause of in-hospital acute MI-related death.[12] Manifestations of circulatory failure can include a weak pulse, low blood pressure, cool extremities, a third heart sound, pulmonary congestion, oliguria, and obtundation. However, pump failure has several distinct mechanisms and causes, which must be distinguished from each other as well as from volume depletion as the cause of a low cardiac output state. Each requires a specific approach to diagnosis, monitoring, and therapy (see Table 58-7).

Left Ventricular Dysfunction

The degree of left ventricular dysfunction correlates well with the extent of acute ischemia and infarction. Hemodynamic compromise becomes evident when impairment involves 20 to 25% of the left ventricle, and cardiogenic shock occurs with impairment of 40% or more (Chapter 93). Pulmonary congestion and S_3 and S_4 gallops are the most common physical findings. Early reperfusion (with fibrinolytic agents, PCI, or CABG) is the most effective therapy to reduce infarct size, ventricular dysfunction, and associated heart failure. Medical treatment of heart failure related to the ventricular dysfunction of acute MI is otherwise generally similar to that of heart failure in other settings (Chapter 46) and includes adequate oxygenation and diuresis (begun early, blood pressure permitting, and continued on a long-term basis if needed). Morphine sulfate (i.e., 1 to 4 mg intravenously, with increments as needed after 5 to 30 minutes or more) is useful for patients with pulmonary congestion. Titrated oral ACE inhibitor therapy (e.g., captopril, incremented from 3.125 to 6.25 mg three times daily to 50 mg twice daily as tolerated, or lisinopril, 1.25 to 2.5 mg once or twice daily, titrated as tolerated up to 10 to 20 mg twice daily) also is indicated for heart failure and pulmonary edema unless excessive hypotension (systolic blood pressure <100 mm Hg) is present. Nitroglycerin reduces preload as well as afterload and effectively relieves congestive symptoms; treatment can be begun sublingually (0.4 mg every 5 minutes times three), and then transition can be made to intravenous therapy (initially 5 to 10 μg/minute, incrementing by 5 to 20 μg/minute until symptoms are relieved or until mean arterial pressure falls by 10% in normotensive patients or 30% in hypertensive patients but not <90 mm Hg or >30 mm Hg lower than baseline).

Volume Depletion

Relative or absolute hypovolemia is a frequent cause of hypotension and circulatory failure and is easily corrected if it is recognized and treated promptly. Poor hydration, vomiting, diuresis, and disease- or drug-induced peripheral vasodilation can contribute to this condition. Occult gastrointestinal and/or access site bleeding should also be considered. Hypovolemia should be identified and corrected with intravenous fluids before more aggressive therapies are considered. An empirical fluid challenge may be tried in the appropriate clinical setting (e.g., for hypotension in the absence of congestion, for inferior or right ventricular infarction, and for hypervagotonia). If filling pressures are measured, cautious fluid administration to a pulmonary capillary wedge pressure 15 to 20 mm Hg may optimize cardiac output and blood pressure without impairing oxygenation.

Right Ventricular Infarction

Right ventricular ischemia and infarction occur with proximal occlusion of the right coronary artery (before the take-off of the right ventricular branches). Ten percent to 15% of inferior acute ST-elevation MIs show classic hemodynamic features, and these patients form the highest-risk inferior MI subgroup for morbidity and mortality (25 to 30% vs. <6% hospital mortality). Improvement in right ventricular function commonly occurs over time if short-term management is successful.

Hypotension in patients with clear lung fields and elevated jugular venous pressure in the setting of inferior or inferoposterior acute MI should raise the suspicion of right ventricular infarction. The Kussmaul sign (distention of the jugular veins on inspiration) is relatively specific and sensitive in this setting. ST-segment elevation in lead V_1 and in right precordial lead V_4R (Chapter 42), particularly in the first 24 hours, is the most sensitive electrocardiographic marker of right ventricular infarction. Echocardiography is helpful in confirming the diagnosis. (Right ventricular dilation and dysfunction are observed.) When right-sided heart pressures are measured, a right atrial pressure of 10 mm Hg or greater and 80% or more of the pulmonary capillary wedge pressure are relatively sensitive and specific for right ventricular ischemic dysfunction.

Management of right ventricular infarction consists of early maintenance of preload with intravenous fluids, reduction of right ventricular afterload (i.e., treatment of pulmonary congestion), early reperfusion, short-term inotropic support if needed, and avoidance of venodilators (e.g., nitrates) and diuretics used for left ventricular failure (they may cause marked hypotension). Volume loading with normal saline solution alone is often effective. If the cardiac output fails to improve after 0.5 to 1 L of fluid, inotropic support with intravenous dobutamine (starting at 2 μg/kg/minute and titrating to hemodynamic effect or tolerance, up to 20 μg/kg/minute) is recommended. High-grade AV block is common, and restoration of AV synchrony with temporary AV sequential pacing can lead to substantial improvement in cardiac output. Because the onset of AF (in up to one third of right ventricular infarcts) can cause severe hemodynamic compromise, it requires prompt cardioversion. In rare circumstances, a right ventricular assist device may be required if shock from right ventricular failure persists despite optimized hemodynamic parameters and rhythm control. Early coronary reperfusion with PCI or fibrinolysis markedly improves outcomes.

Cardiogenic Shock

Cardiogenic shock (Chapter 93) is a form of severe left ventricular failure characterized by marked hypotension (systolic pressures <90 mm Hg) and reductions in cardiac index (to <1.8 L/minute/m^2) despite high left ventricular filling pressure (pulmonary capillary wedge pressure >18 mm Hg). The cause is loss of a critical functional mass (>40%) of the left ventricle. Risk factors include age, large (usually anterior) acute MI, previous MI, and diabetes. The treatment and prognosis of cardiogenic shock are discussed in Chapter 46.

Mechanical Complications

Mechanical complications of acute MI may occur throughout the hospital course and include acute mitral valve regurgitation (often caused by papillary muscle dysfunction or rupture), ventricular septal defect, and left ventricular free wall rupture.[13,14] These mechanical complications are much less common after early reperfusion therapy: in ST-elevation MI patients treated with primary PCI, current risks are about 0.5% for free wall rupture, 0.2% for ventricular septal defect, and 0.3% for papillary muscle rupture, for a total mechanical complication rate of 1% or less. Prompt diagnosis and early surgery, although still associated with a high mortality rate, lead to better outcomes than delayed diagnosis and medical therapy alone

A left ventricular aneurysm can develop after a large, most commonly anterior, acute MI and create mechanical and electrical complications. If refractory heart failure, ventricular tachycardia, or systemic embolization occurs despite medical therapy and PCI, aneurysmectomy with CABG is indicated.

Thromboembolic Complications

Arterial thromboembolism, typically arising from the left ventricle or left atrium, is very unusual in ST-elevation MI patients who are treated with early reperfusion and aggressive antithrombotic therapies. Arterial embolism can cause dramatic clinical events, such as hemiparesis (Chapter 376), loss of a pulse, ischemic bowel (Chapter 129), or sudden changes in blood pressure, depending on the regional circulation involved.

Left ventricular mural thrombosis occurs typically in the setting of a large (especially anterior) acute ST-elevation MI and heart failure. The risk for embolism is particularly high when a mural thrombus is detected by echocardiography. Thus, in patients with anterior acute ST-elevation MI and in other high-risk patients, echocardiography should be performed during hospitalization; if results are positive, oral anticoagulation (e.g., apixiban 5 mg twice daily) should be started and continued for 3 to 6 months.[15,16]

Pulmonary emboli, which commonly arise from thrombi in leg veins, are highly unusual unless patients are immobilized for several days. Deep venous thrombosis can be prevented by lower extremity compression therapy, by

limiting the duration of bedrest, and by the use of subcutaneous heparin (in patients at risk and not receiving intravenous heparin) until patients are fully ambulatory (Chapter 68).

As noted in more detail previously (see Combined Oral Anticoagulant and Antiplatelet Therapy), adding a direct-acting oral anticoagulant to aspirin and a $P2Y_{12}$ inhibitor for the prevention of venous thromboembolic disease (Chapters 67 and 68) or the prevention of systemic embolization in patients with AF (Chapter 52) is indicated for up to about 1 month in an ST-elevation MI patient with AF and a high risk of systemic emboli, recent venous thromboembolism, or a hypercoagulable disorder. For patients with a mechanical heart valve or left ventricular mural thrombus (Chapter 70), warfarin, usually to an international normalized ratio of 2.0 to 2.5, should be added to dual antiplatelet therapy for 3 months. To minimize bleeding, careful attention must be paid to the appropriate selection and doses of antithrombotic regimens based on age, weight, renal function, and other comorbid conditions.

Late Hospital Phase

Transfer from coronary intensive care to a step-down unit usually occurs within 1 to 3 days, when the cardiac rhythm and hemodynamics are stable. The duration of this late phase of hospital care is usually an additional 1 to 3 days in uncomplicated cases. Activity levels should be increased progressively under continuous electrocardiographic monitoring. Medical therapy should progress from parenteral and short-acting agents to oral medications appropriate and convenient for long-term outpatient use. Risk stratification and functional evaluations are critical to assess prognosis and to guide therapy as the time for discharge, which may be as early as 2 to 3 days in uncomplicated, successfully reperfused patients. Functional evaluation also can be extended to the early period after hospital discharge. Education must be provided about diet, activity, smoking, and other risk factors (e.g., lipids, hypertension, and diabetes—see later).

Risk Stratification after Myocardial Infarction

Risk stratification is a continuous process that begins on admission and continues through hospital discharge. The goals of risk stratification before and early after discharge for acute MI are to assess ventricular and clinical function, latent ischemia, and arrhythmic risk; to use this information for patient education and prognostic assessment; and to guide therapeutic strategies (E-Fig. 58-1).

Cardiac Functional Assessment

An echocardiogram should be obtained to assess resting left ventricular function before discharge in all patients. Patients who initially have a reduced left ventricular ejection fraction and who are possible candidates for ICD therapy should have the ejection fraction re-evaluated 40 days or more after discharge.

Risk stratification during hospitalization or around the time of discharge should include an assessment of exertional capacity. This assessment can be formally addressed with submaximal exercise stress testing at 4 to 6 days after the infarction or limited stress testing at 2 to 6 weeks after discharge (to peak heart rate of 120 to 130 beats per minute or 70% of the predicted maximum) unless patients have unstable post-MI angina, uncompensated heart failure, or serious cardiac arrhythmias. Alternatively, patients may undergo symptom-limited stress testing at 2 to 6 weeks before they return to work or resume other increased physical activities. Abnormal test results include not only ECG ST-segment depression but also low functional capacity, exertional hypotension, and serious arrhythmias. Patients with positive test results should be considered for coronary angiography if coronary anatomy had not been previously defined. Imaging-enhanced stress testing with radionuclide perfusion tests (Chapter 44), echocardiography (Chapter 43), or cardiac magnetic resonance (Chapter 44) can increase the sensitivity for detecting latent ischemia compared with stress ECG tests, can provide information about ejection fraction and infarct size, and should be used for patients with ECG changes that preclude accurate ECG interpretation during stress. For patients unable to exercise, pharmacologic stress testing can be performed with adenosine, a long-acting bolus analogue of adenosine (e.g., regadenoson), or by dipyridamole scintigraphy.

Discharge and Post-Hospital Phase

Secondary Prevention

Advances in secondary prevention have resulted in increasingly effective measures to reduce recurrent MI and cardiovascular death. Secondary prevention should be conscientiously applied after acute MI (Table 58-10).

Lipid Reduction

A fasting lipid profile is recommended within 24 hours of admission, and high-intensity lipid-lowering therapy with a statin should start in the hospital, preferably on admission, and be continued as outpatient therapy in all patients with ST-elevation MI and no contraindication to its use (e.g., atorvastatin, 80 mg daily or rosuvastatin 20 to 40 mg daily; Chapter 190). Ezetimibe (10 mg daily) or a PCSK9 inhibitor can be considered in patients who have not achieved an LDL-cholesterol goal of 70 mg/dL or lower.

Continued smoking doubles the subsequent mortality risk after acute MI, and smoking cessation reduces the risk for reinfarction and death within 1 year (Chapter 363). An individualized smoking cessation plan should be formulated, including pharmacologic aids (nicotine gum and patches, bupropion, or varenicline).

Antiplatelet and Anticoagulation Therapies

Antiplatelet therapy (Chapter 70) is indicated in all patients, and some patients require concomitant anticoagulant therapy. After PCI for ST-elevation MI, at

TABLE 58-10 DISCHARGE MEDICATION CHECKLIST AFTER MYOCARDIAL INFARCTION*

MEDICATION	DOSES	REASONS NOT TO USE	COMMENTS
Aspirin	81 (preferred) to 325 mg daily	High bleeding risk	Reduces mortality, reinfarction, and stroke
Clopidogrel *Or*	75 mg daily	High bleeding risk; suboptimal antiplatelet response	Indicated after PCI for at least 1 year (shorter time for BMS if high bleeding risk); also reduces vascular events when added to aspirin in non–ST-segment elevation acute MI (also useful on the basis of clinical trials after ST-segment elevation acute MI) Genetic variants (CYP2C19) may reduce response Controversial interaction with proton pump inhibitors (e.g., omeprazole)
Prasugrel *Or*	10 mg daily	High bleeding risk	Avoid with history of prior stroke or TIA
Ticagrelor	90 mg bid		Consider 5 mg prasugrel daily in patients >75 years or <60 kg Avoid if history of intracranial bleed Limit daily aspirin dose to 81 mg
β-Blocker (e.g., metoprolol, carvedilol)	Metoprolol: 25-200 mg daily Carvedilol: 6.25-25 mg bid	Asthma, bradycardia, heart failure	Reduces mortality, reinfarction, sudden death, arrhythmia, hypertension, angina, atherosclerosis progression
ACE inhibitor (e.g., ramipril, lisinopril) or ARB (e.g., valsartan, losartan)	Ramipril: 2.5-10 mg daily Lisinopril: 5-10 mg daily Valsartan: 80-160 mg daily-bid Losartan: 50-100 mg daily	Hypotension, allergy, hyperkalemia	Reduces mortality, reinfarction, stroke, heart failure, diabetes, atherosclerosis progression
Lipid-lowering agent (i.e., a high-intensity statin; e.g., atorvastatin, rosuvastatin)	Atorvastatin: 80 mg daily Rosuvastatin: 20-40 mg daily	Myopathy, rhabdomyolysis, hepatitis	Goal = LDL ≥50% reduction (statins also can benefit patients with lower LDL†)
Nitroglycerin sublingual	0.4 mg SL PRN for angina	Aortic stenosis; sildenafil (Viagra) use	Instruct on PRN use and appropriate need for medical attention

*Medications given at hospital discharge improve long-term compliance. All are oral except for nitroglycerin.

†Heart Protection Study (*Lancet.* 2002;360:7); and PROVE-IT study (*N Engl J Med.* 2004;350:1495).

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; bid = twice daily; BMS = bare metal stent; daily = once daily; LDL = low-density lipoprotein; MI = myocardial infarction; PCI = percutaneous coronary intervention; PRN = as needed; SL = sublingual; TIA = transient ischemic attack.

least 1 year of dual antiplatelet therapy generally has been indicated (usually aspirin [81 mg/day] plus a $P2Y_{12}$ inhibitor) to reduce ischemic events and stent thrombosis, with treatment beyond 1 year providing additional anti-ischemic benefit but at the expense of more bleeding.[A18] However, accumulating evidence with second-generation polymer-free, drug-eluting stents (Chapter 59) suggests safety with just 1 month of dual antiplatelet therapy, because stent thrombosis now is less common,[A19,A20] and that the duration and strength of antiplatelet therapy should be individualized (Chapter 59) based on bleeding and thrombotic risks. For patients who are not at a high risk of bleeding, prasugrel (10 mg/day) or ticagrelor (90 mg twice daily) is the preferred $P2Y_{12}$ inhibitor rather than clopidogrel (75 mg daily) because of greater efficacy, and prasugrel appears to be superior to ticagrelor. A genotype-guided approach to the selection of prasugrel versus clopidogrel at discharge is of uncertain benefit.[A21]

For patients with AF (Chapter 52), recent trials support a shortened period of triple antithrombotic therapy (i.e., ≤1 month) followed by dual antithrombotic therapy consisting of a direct-acting oral anticoagulant and a $P2Y_{12}$ inhibitor (e.g., dabigatran [110 or 150 mg twice daily] plus clopidogrel or ticagrelor or apixaban plus clopidogrel),[A22,A23] with clopidogrel usually preferred over ticagrelor because of its lower bleeding risk. Patients with venous thromboembolic disease (Chapter 68) can be treated similarly. For other hypercoagulable states (Chapter 67), data are sparse, but generally the antiplatelet therapy would be added to the background anticoagulant therapy. By comparison, patients with a left ventricular thrombus require a direct-acting oral anticoagulant (e.g., apixaban 5 mg twice daily), and patients with a mechanical heart valve require careful chronic warfarin anticoagulation in addition to antiplatelet therapy.

Prevention and Treatment of Heart Failure

ACE inhibitor therapy can prevent adverse myocardial remodeling after acute MI and can reduce heart failure and death; it is strongly indicated for long-term use in patients with anterior acute MI or an left ventricular ejection fraction less than 40%. ACE inhibitors also reduce recurrent MI in patients with an ejection fraction greater than 40%, except in patients who have stable coronary disease and are at low risk for a recurrent coronary event (i.e., without heart failure, hypertension, or glucose intolerance). Recommended ACE inhibitors include ramipril (2.5 mg titrated to 10 mg/day) or lisinopril (2.5 to 5 mg titrated to 10 mg/day). An angiotensin-receptor blocker (e.g., valsartan, 80 to 160 mg twice daily, or losartan, 50 to 100 mg/day) should be substituted in patients who cannot tolerate an ACE inhibitor (Chapter 46). Overt heart failure requires careful treatment (Chapter 46) titrated to symptoms and tolerance. Sacubitril plus valsartan is no better than ramipril alone in this setting.[A24]

Anti-Ischemic Therapies

Long-term β-blocker therapy does not benefit patients who have a preserved ejection fraction when added to standard modern therapy during the first year after acute MI, but it is recommended for MI survivors who have a reduced ejection fraction without other contraindications. Options include metoprolol (20 to 200 mg/day) or carvedilol (6.25 to 25 mg twice daily). However, chronic β-blocker therapy in patients at low subsequent cardiovascular risk (normal ventricular function, successful reperfusion, absence of arrhythmias) currently is viewed as reasonable but not mandatory.

Nitroglycerin (0.4 mg) is commonly prescribed for sublingual or buccal administration for acute anginal attacks (Chapter 56), although this long-standing practice has never been fully evaluated. Longer-acting oral therapy (isosorbide mononitrate, 30 to 60 mg orally every morning, or dinitrate, 10 to 40 mg orally two or three times daily) or topical nitroglycerin (e.g., start with 0.5 inch; can be titrated up to 2 inches every 6 hours for 2 days) may be added to treatment regimens for angina or heart failure (in combination with hydralazine) in selected patients.

Calcium-channel blockers are negatively inotropic and are not routinely given on a long-term basis. However, they may be used in selected patients who do not have left ventricular dysfunction (ejection fraction >0.40), who are intolerant of β-blockers, and who require these drugs for antianginal therapy (e.g., amlodipine, 5 to 10 mg/day orally, or diltiazem, 120 to 480 mg/day orally as sustained-release preparations or in divided doses; see Chapter 56) or for control of heart rate in AF (e.g., diltiazem, 120 to 480 mg/day orally, or verapamil, 180 to 480 mg/day orally, as sustained-release preparations or in divided doses). Short-acting nifedipine should be avoided.

If these medical approaches do not control post-infarction angina and complete revascularization was not performed during an acute PCI, coronary angiography should be considered in patients whose symptoms would warrant it (Chapter 56).[17]

Anti-Inflammatory Therapy

In patients who have survived an MI and have a high-sensitivity C-reactive protein level of 2 mg/L or greater, the use of canakinumab, a monoclonal antibody against interleukin-1β (150 mg subcutaneously every 3 months) reduced the risk of subsequent nonfatal MI, nonfatal stroke, or cardiovascular death.[A25] Colchicine (0.5 mg daily) also can reduce the risk of subsequent cardiovascular events in patients who have survived a myocardial infarction,[A26] especially if begun within 3 days of the MI.[A27] Whether these therapies will become a part of routine post-MI medical care is yet to be determined.

Antiarrhythmic Therapy

In patients who do not require an acute ICD (see Ventricular Rhythms, earlier), an ICD is recommended for those with severe left ventricular dysfunction (ejection fraction ≤0.30) at least 40 days after ST-elevation MI and 3 months after CABG, even without spontaneous or induced ventricular tachycardia or ventricular fibrillation.[A28] Antiarrhythmic drugs are not generally recommended after acute MI, and class I antiarrhythmic agents can increase the risk for sudden death. Class III drugs (amiodarone, sotalol, dofetilide) may be used as part of the management strategy for specific arrhythmias (e.g., AF, ventricular tachycardia) (Chapters 52 and 53).

Other Medical Therapies

Hypertension (Chapter 64) and diabetes mellitus (Chapter 210) must be assessed and tightly controlled in patients after an acute MI. ACE inhibitors or β-blockers as described earlier are usually the first-choice therapies for hypertension, with ARBs indicated when ACE inhibitors are not tolerated. ACE inhibitors and ARBs also can reduce the long-term complications of diabetes. Such drugs should be titrated to a goal blood pressure of less than 130/80 mm Hg, which is equivalent to an office goal of 120/80 mm Hg (Chapter 64).

Hormone replacement therapy (Chapter 222) with estrogen with or without progestin is not begun after an acute MI because it increases thromboembolic risk and does not prevent reinfarction. For women already receiving hormone replacement, therapy should be discontinued unless it is being given for a compelling indication.

Antioxidant supplementation (e.g., vitamin E, vitamin C) does not benefit patients after acute MI and is not recommended. The role of fish oil and related supplements is unclear, but purified agents such as eicosapentoic ethyl appear to decrease cardiovascular events in chronic coronary heart disease.

Patient Education and Rehabilitation

The hospital stay provides an important opportunity to educate patients about their MI and its treatment, coronary risk factors, and behavioral modification. Education should begin on admission and continue to and beyond discharge. At hospital discharge, a detailed, evidence-based plan of care should emphasize the importance of a healthy lifestyle, including diet (Chapter 13), exercise (Chapter 14), smoking cessation (Chapter 363), and compliance with medications. Timely outpatient health care follow-up also should be scheduled and a rehabilitation program referral provided. Exercise-based cardiac rehabilitation may reduce reinfarction by about 50% and overall mortality by about 25%, with home-based programs being as safe and effective as center-based programs.[A29] Many hospitals use case managers and prevention specialists to augment physicians and nurses, to provide educational materials, to review important concepts, to assist in formulating and actualizing individual risk reduction plans, and to ensure proper and timely outpatient follow-up. This follow-up should include early return appointments with the patient's physician (within 2 to a few weeks), which may be facilitated with virtual platforms. Instructions on activities also should be given before discharge.

PROGNOSIS

With the broad application of reperfusion and other contemporary therapies, the prognosis often myocardial infarction continues to improve.[18] The 30-day mortality after ST-elevation MI is now less than 6%, and the 1-year mortality rate is 7 to 8%. Since reductions in mortality can be directly related to the number of evidence-based therapies given, patients treated at high-performing hospitals live about 1 year longer than do patients treated at low-performing hospitals. Of note is that the long-term survival is similar in patients who do and do not have evidence of obstructive coronary disease on acute coronary arteriography.[19]

INTERVENTIONAL DIAGNOSIS AND TREATMENT OF CORONARY ARTERY DISEASE

PAUL S. TEIRSTEIN AND AJAY J. KIRTANE

Percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) surgery represent alternative and sometimes complementary approaches to coronary revascularization. Each has its relative indications, advantages, disadvantages, and contraindications.

CORONARY ARTERIOGRAPHY TO ASSESS CORONARY STENOSIS

For coronary angiography, catheters are inserted into the epicardial arteries of the heart to obtain radiographic images of the coronary vasculature and to define the site and severity of any lesions or anomalies, as well as any visible collateral blood vessels beyond arterial stenoses or occlusions. Coronary arteriography often is part of a more comprehensive catheterization to assess valvular (Chapter 60), congenital (Chapter 55), or myocardial diseases (Chapter 47) or to perform a variety of catheter-based interventions (E-Table 59-1).

THE PROCEDURE

Vascular access under local anesthetic is preferably via the radial artery,[1] which is associated with less bleeding and equivalent or better outcomes compared with femoral access.[A1] A specially shaped catheter is inserted over a guidewire to facilitate atraumatic passage to a coronary artery ostium (origin at the aorta) to inject radiographic contrast media for coronary arteriography. This process is performed twice, once for the left coronary ostium and once for the right, although each may be accompanied by more than one injection as needed. Hemodynamic data may be acquired to assist in the evaluation of cardiac function at rest or sometimes after stationary exercise.

After a radial procedure, the patient can ambulate immediately and may be discharged 2 to 4 hours later. After a femoral procedure, however, the patient must remain stationary in bed for 1 to 2 hours using a vascular closure device (or otherwise for 4 hours) and can be discharged after 4 to 6 hours of recovery.

ASSESSMENT OF CORONARY STENOSES

The patient's coronary arteriographic images are compared with normal anatomy (Fig. 59-1). The degree of stenosis in any vessel is based on a visual estimate of the percentage reduction in luminal diameter at the most severely narrowed coronary segment compared with the closest angiographically unobstructed vessel segment (Fig. 59-2). The degree of coronary collateralization, which is assessed qualitatively, correlates with longer chronicity of stenoses or complete occlusion and is associated with a more favorable prognosis.

Because these estimates of the severity of stenoses may vary, even among experienced angiographers, the importance of an intermediately severe lesion (i.e., a 40 to 90% stenosis) can be determined by passing a pressure sensor guidewire to measure the pressure gradient across the stenosis after injecting adenosine to maximize flow. The ratio of post-lesion pressure to aortic pressure during maximal flow (the fractional flow reserve) indicates the percentage of normal flow across the stenosis.[2] Stenoses with fractional flow reserve (a ratio of distal hyperemic pressure to aortic pressure) above 0.80 are considered nonischemic and typically do not require revascularization, whereas a lower fractional flow reserve typically warrants percutaneous coronary intervention (PCI).

COMPLICATIONS OF CARDIAC CATHETERIZATION

Diagnostic cardiac catheterization has few contraindications and a low but not trivial risk of serious complications (Table 59-1). In the United States, for example, the overall risk is less than 0.2% for death, less than 0.5% for myocardial infarction, less than 0.07% for stroke, less than 0.5% for serious arrhythmia, and less than 1% for major vascular complications (including thrombosis or cholesterol embolization [Chapter 110]), bleeding requiring transfusion, or pseudoaneurysm.[3,4] Vascular complications are less common with the radial artery approach.

For a diagnostic catheterization, patients are not routinely anticoagulated except for the radial approach, in which preexisting anticoagulation is typically maintained or heparin is given to reduce the occurrence of radial artery occlusion. For the femoral approach, anticoagulation may be uninterrupted or held for 2 to 3 days before the procedure. For a patient who is taking warfarin after a mechanical valve replacement, warfarin is withheld for 3 days before the procedure, with consideration of bridging heparin in high-risk cases.

Most medications should be continued up to and including the morning of the procedure. For diabetic patients, 50% of the usual morning dose of insulin is usually given; metformin should be withheld.

Contrast-induced acute kidney injury, which usually is not clinically evident until 2 to 3 days after the procedure,[5] is clinically significant in about 1.2% of patients,[6] but the risk is 3 to 5 times higher in patients who have diabetes or renal insufficiency or who are dehydrated. In such patients, preprocedural hydration with sodium chloride is usually indicated to increase urine output.[A2] An oral statin (e.g., rosuvastatin, either 40 mg on admission followed by 20 mg per day for patients with an acute coronary syndrome or 10 mg for two days before and three days afterward for patients with diabetes and

INTERVENTIONAL DIAGNOSIS AND TREATMENT OF CORONARY ARTERY DISEASE

PAUL S. TEIRSTEIN AND AJAY J. KIRTANE

Percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) surgery represent alternative and sometimes complementary approaches to coronary revascularization. Each has its relative indications, advantages, disadvantages, and contraindications.

CORONARY ARTERIOGRAPHY TO ASSESS CORONARY STENOSIS

For coronary angiography, catheters are inserted into the epicardial arteries of the heart to obtain radiographic images of the coronary vasculature and to define the site and severity of any lesions or anomalies, as well as any visible collateral blood vessels beyond arterial stenoses or occlusions. Coronary arteriography often is part of a more comprehensive catheterization to assess valvular (Chapter 60), congenital (Chapter 55), or myocardial diseases (Chapter 47) or to perform a variety of catheter-based interventions (E-Table 59-1).

THE PROCEDURE

Vascular access under local anesthetic is preferably via the radial artery,[1] which is associated with less bleeding and equivalent or better outcomes compared with femoral access.[A1] A specially shaped catheter is inserted over a guidewire to facilitate atraumatic passage to a coronary artery ostium (origin at the aorta) to inject radiographic contrast media for coronary arteriography. This process is performed twice, once for the left coronary ostium and once for the right, although each may be accompanied by more than one injection as needed. Hemodynamic data may be acquired to assist in the evaluation of cardiac function at rest or sometimes after stationary exercise.

After a radial procedure, the patient can ambulate immediately and may be discharged 2 to 4 hours later. After a femoral procedure, however, the patient must remain stationary in bed for 1 to 2 hours using a vascular closure device (or otherwise for 4 hours) and can be discharged after 4 to 6 hours of recovery.

ASSESSMENT OF CORONARY STENOSES

The patient's coronary arteriographic images are compared with normal anatomy (Fig. 59-1). The degree of stenosis in any vessel is based on a visual estimate of the percentage reduction in luminal diameter at the most severely narrowed coronary segment compared with the closest angiographically unobstructed vessel segment (Fig. 59-2). The degree of coronary collateralization, which is assessed qualitatively, correlates with longer chronicity of stenoses or complete occlusion and is associated with a more favorable prognosis.

Because these estimates of the severity of stenoses may vary, even among experienced angiographers, the importance of an intermediately severe lesion (i.e., a 40 to 90% stenosis) can be determined by passing a pressure sensor guidewire to measure the pressure gradient across the stenosis after injecting adenosine to maximize flow. The ratio of post-lesion pressure to aortic pressure during maximal flow (the fractional flow reserve) indicates the percentage of normal flow across the stenosis.[2] Stenoses with fractional flow reserve (a ratio of distal hyperemic pressure to aortic pressure) above 0.80 are considered nonischemic and typically do not require revascularization, whereas a lower fractional flow reserve typically warrants percutaneous coronary intervention (PCI).

COMPLICATIONS OF CARDIAC CATHETERIZATION

Diagnostic cardiac catheterization has few contraindications and a low but not trivial risk of serious complications (Table 59-1). In the United States, for example, the overall risk is less than 0.2% for death, less than 0.5% for myocardial infarction, less than 0.07% for stroke, less than 0.5% for serious arrhythmia, and less than 1% for major vascular complications (including thrombosis or cholesterol embolization [Chapter 110]), bleeding requiring transfusion, or pseudoaneurysm.[3,4] Vascular complications are less common with the radial artery approach.

For a diagnostic catheterization, patients are not routinely anticoagulated except for the radial approach, in which preexisting anticoagulation is typically maintained or heparin is given to reduce the occurrence of radial artery occlusion. For the femoral approach, anticoagulation may be uninterrupted or held for 2 to 3 days before the procedure. For a patient who is taking warfarin after a mechanical valve replacement, warfarin is withheld for 3 days before the procedure, with consideration of bridging heparin in high-risk cases.

Most medications should be continued up to and including the morning of the procedure. For diabetic patients, 50% of the usual morning dose of insulin is usually given; metformin should be withheld.

Contrast-induced acute kidney injury, which usually is not clinically evident until 2 to 3 days after the procedure,[5] is clinically significant in about 1.2% of patients,[6] but the risk is 3 to 5 times higher in patients who have diabetes or renal insufficiency or who are dehydrated. In such patients, preprocedural hydration with sodium chloride is usually indicated to increase urine output.[A2] An oral statin (e.g., rosuvastatin, either 40 mg on admission followed by 20 mg per day for patients with an acute coronary syndrome or 10 mg for two days before and three days afterward for patients with diabetes and

ABSTRACT

Percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) surgery are two commonly performed procedures used to increase blood flow to cardiac muscle receiving inadequate blood supply due to coronary artery stenoses. PCI and CABG can be competitive or, at times, complementary techniques. PCI, which is one of the most widely used medical procedures based on its simplicity, usually requires entry of only a small-diameter catheter into the radial (wrist) or femoral artery under local anesthesia. In an awake patient, a thin guidewire is passed through catheter, across the arterial stenosis. A metallic stent is then passed over the wire and expanded by balloon inflation to push the plaque aside and scaffold the artery open. The balloon is then removed, thereby leaving the stent in place and creating a normal-diameter lumen. Patients are often discharged the same day. The advantages of PCI include its high effectiveness, low morbidity, very short period of observation/hospitalization, and complete recovery within hours. Its main disadvantages are restenosis, which occurs in 5 to 20% of patients, and the need for antiplatelet therapy for 3 to 12 months following the procedure.

CABG is performed using the internal thoracic artery or a reverse saphenous vein from the leg. One end of the bypass is attached to the aorta and the other to the obstructed coronary artery beyond the obstruction. Open chest surgery with general anesthesia and typically cardiopulmonary bypass is required. The advantages of CABG include its high effectiveness and the durability of the result. Its main disadvantage is the need for open chest surgery, which results in increased procedural morbidity, requires a 4- to 7-day hospital stay, and several weeks for full recovery. The decision between PCI and CABG is largely determined by clinical status and anatomic features, but in some patients the decision regarding which procedure is favored may be dictated by the patient's own preferences.

E-TABLE 59-1 PROCEDURES PERFORMED IN CARDIAC CATHETERIZATION LABORATORIES

Diagnostic cardiac catheterization (right and/or left heart catheterization, including drug studies)
Coronary angiography
Coronary intervention including stents
Coronary intravascular imaging and translesional hemodynamic assessment
Coronary atherectomy (rotational, orbital, laser)
Endomyocardial biopsy
Insertion of an intra-aortic balloon pump
Insertion of percutaneous ventricular assist devices
Pericardiocentesis
Alcohol septal ablation
Transseptal puncture
Balloon valvuloplasty
Percutaneous valve repair/replacement (tricuspid, pulmonic, mitral, aortic)
Percutaneous treatment of large-bore access complications (balloon occlusion, covered stenting of iliofemoral vessels)
Closure of a patient foramen ovale
Treatment of congenital heart defects (atrial septal defect, patent ductus arteriosus, coarctation, post-congenital surgery procedures)
Implantation of intra-atrial shunt devices
Closure of a left atrial appendage
Implantation of pulmonary artery pressure sensor (for remote hemodynamic monitoring)
Peripheral angiography/peripheral intervention (subclavian, lower extremity: iliac, femoral, popliteal, tibial)
Cerebral angiography and intervention
Carotid angiography and interventions (stenting)
Venous thrombectomy/intravascular thrombolysis/vena cava filter
Renal angiography and intervention
Repair of an abdominal or thoracic aortic aneurysm

TABLE 59-1 CARDIAC CATHETERIZATION: CONTRAINDICATIONS AND COMPLICATIONS

ABSOLUTE CONTRAINDICATIONS
Inadequate facilities
Patient refusal
RELATIVE CONTRAINDICATIONS
Severe uncontrolled hypertension
Ventricular arrhythmias
Recent acute stroke
Severe anemia
Active gastrointestinal bleeding
Allergy to radiographic contrast agents
Acute renal failure
Uncompensated heart failure (patient cannot lie flat)
Unexplained febrile illness or untreated active infection
Electrolyte abnormalities (e.g., hypokalemia)
Severe coagulopathy
Pregnancy
Uncontrolled arrhythmias, hypertension
Uncooperative patient or patient refusal
MAJOR COMPLICATIONS
Death
Cerebrovascular accident
Myocardial infarction, shock
Ventricular tachycardia or fibrillation
RARE BUT SERIOUS COMPLICATIONS
Aortic dissection
Cardiac perforation
Tamponade
Heart failure
Reaction to contrast agents, anaphylaxis
Nephrotoxicity

chronic kidney disease) can reduce the risk of acute kidney injury by about 50%.[A3] Treatment with sodium bicarbonate or *N*-acetylcysteine (Mucomyst) is not of incremental value and is not routinely recommended.[A4,A5] In patients who have advanced chronic kidney disease and in whom radiocontrast is contraindicated, angiography can be avoided, with PCI guided by intravascular ultrasound and physiologic measurements.

Adverse reactions to contrast media are potentially serious but rare, with an overall incidence of 5% or less. However, adverse reactions occur in about 15% of patients with a previously reported allergic contrast reaction. Patients who have had a previous allergic reaction to contrast media should be premedicated with prednisone (60 mg orally the evening before and morning of the procedure) and diphenhydramine (25 to 50 mg orally the morning of the procedure).

Vasovagal hypotension, which is relatively common, is treated with intravenous fluids and atropine (0.5 to 1.0 mg intravenously). Hypotension that is accompanied by back pain is rare but suggests retroperitoneal bleeding and hematoma and requires emergency intervention. Hypotension also can be caused when perforation of a coronary artery leads to cardiac tamponade (Chapter 62); this emergency requires urgent pericardiocentesis and treatment of any coronary perforation. Pulmonary congestion, which may develop in patients with compromised left ventricular function or valvular heart disease, is treated with oxygen and diuretics (Chapter 46) or more intensive interventions if it progresses to cardiogenic shock (Chapter 93).

Chest pain is unusual during coronary angiography, but may be associated with myocardial ischemia and ST segment changes during PCI. Treatment (e.g., nitroglycerin, heparin, and antiplatelet medications) usually controls myocardial ischemia before revascularization (Chapter 57). Atrial or ventricular premature contractions or even brief episodes of supraventricular tachycardia

are common and usually resolve spontaneously. Ventricular tachycardia and ventricular fibrillation are rare but require prompt defibrillation (Chapter 50).

PERCUTANEOUS CORONARY INTERVENTION

Percutaneous coronary intervention is applicable to most forms of coronary artery disease, including single- and double-vessel disease, but also can be performed for multivessel disease, total occlusions, saphenous vein graft disease, unstable angina (Chapter 57), and acute myocardial infarction (MI) (Chapter 58). An estimated 2 million PCIs are performed worldwide each year, making it one of the most widely used medical procedures. Its popularity is based largely on its simplicity, the need for only local anesthesia, a short (≈1 day or even outpatient) hospitalization, and negligible postprocedure recovery time. In the United States, PCI is a cornerstone of the treatment of acute coronary syndromes (Chapters 57 and 58), but the number of nonacute PCIs has declined by over one third since 2010.

MECHANISMS AND TECHNICAL CONSIDERATIONS

Under local anesthesia, a hollow-bore needle is inserted percutaneously into a peripheral artery (usually the radial or femoral artery). A guidewire is placed through this needle and advanced into the aorta. The needle is removed, leaving the guidewire, over which a small-caliber (≈3 mm), specially shaped catheter (called a guiding catheter) is advanced under fluoroscopic guidance into the ostium of the obstructed coronary artery. By use of radiographic contrast injections that provide fluoroscopic visualization of the coronary artery lumen, a thin (≈0.014 inch), highly steerable guidewire is directed down the coronary artery and across the stenotic lesion. This guidewire becomes a "rail" over which therapeutic tools such as inflatable balloons, stents, and atherectomy catheters are passed to the diseased segment (Fig. 59-3).

Balloon catheters (Fig. 59-4) typically have two lumens, one to allow passage over the guidewire and another to carry a mixture of saline and radiographic contrast material to inflate a balloon at the distal catheter tip. Under fluoroscopy, the balloon is centered across the lesion and inflated to typically 4 to 30 atmospheres of pressure. Balloon inflation widens the narrowed lumen by stretching the vessel and, in most cases, causing a tear (a therapeutic dissection) at the edges of the plaque, where the atheroma meets the nondiseased media. Atherectomy catheters, which also are passed over a guidewire to the diseased segment, remove plaque by a shaving, grinding, slicing, or suction mechanism. Coronary stents are metallic or polymeric scaffolding devices that are crimped onto a deflated balloon catheter before insertion into the diseased vessel (Videos 59-1, 59-2, and 59-3). During balloon inflation, the collapsed stent expands to support the vessel lumen (see E-Fig. 59-1 and Video 59-4). Although balloons and atherectomy devices create an adequate, albeit rough channel through diseased arteries, the supporting structure of the stent can widen the lumen to near its predisease dimensions. With a stent, tissue flaps are "pinned" against the wall, and recoil is limited (Video 59-5). Most stents are designed so that the metallic struts comprise only about 20% of the surface area, thereby allowing for endothelialization, which reduces the risk of thrombosis.[7] In some cases (e.g., PCI of saphenous vein grafts), filters deployed within a coronary vessel beyond the target lesion can limit distal embolization of plaque, platelet aggregates, and other "debris" can further reduce ischemic complications in vessels with a friable endothelium.

During the PCI procedure, the interventional cardiologist is able to assess the target vessel fluoroscopically by injections of contrast material through the guiding catheter (Fig. 59-5). A more detailed assessment of the target vessel is often obtained using intravascular imaging technologies, with catheters that use sound waves or light to produce an image of the lumen (channel for blood flow) and vessel walls (E-Fig. 59-2). When the coronary artery has been opened successfully, all catheters are withdrawn and the arterial access site is sealed by mechanical pressure, an absorbable plug, or an external suturing device. Patients without comorbidity ambulate in 2 to 6 hours. Discharge from the hospital usually occurs 2 to 6 hours later or the morning after the procedure, when stability of the arterial access site, cardiac biomarkers, and the electrocardiogram are confirmed.

SELECTION OF PATIENTS FOR PERCUTANEOUS CORONARY INTERVENTION

Any decision to perform PCI must include a comprehensive and detailed review of the coronary angiogram by an experienced interventional cardiologist to assess the lesion's technical suitability for the procedure. Coronary flow is not significantly obstructed until a stenosis narrows the coronary artery lumen by at least 60%. A pressure drop of more than 20% (which corresponds to a fractional flow reserve <0.80) predicts a clinical benefit from PCI[A6,A7] in stable chronic ischemic heart disease but not clearly for stenting a nonculprit lesion in a patient with a non–ST elevation acute myocardial infarction.[A8]

For each patient, the benefits of PCI must be weighed against the procedural risk. Patients whose lesions are characterized by longer length, tortuous vessels, calcification, or the presence of thrombus can be treated with PCI but are at increased risk. Other patient characteristics conveying increased risk include advanced age (i.e., >75 years), diabetes, smaller vessels that are often found in women, prior MI, significant impairment of left ventricular function, and renal insufficiency.

PROCEDURAL SUCCESS AND COMPLICATIONS

With use of modern techniques in appropriately selected patients, most PCI procedures have a greater than 95% success rate. The single exception is a chronic total coronary occlusion (100% obstruction of the lumen), in which the interventional cardiologist's ability to negotiate a guidewire through the blockage is only about 60% to 90% and varies substantially with the operator's expertise. With the increased use of coronary stents and adjunctive antiplatelet agents, acute coronary artery closure is rarely encountered. When PCI is performed by an experienced interventional cardiologist in appropriately selected patients, the risk of in-hospital death is less than 0.5%, but the risk of a type 4 MI (usually a small, non–ST segment elevation MI; Chapter 57) is not negligible, especially when assessed by sensitive biomarker assays.[8] The

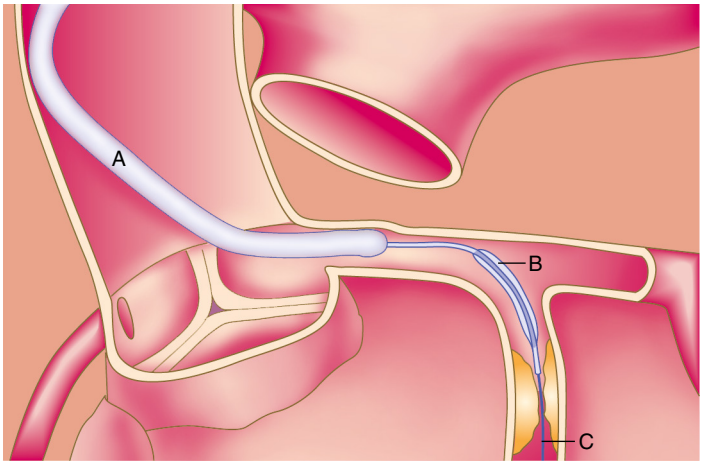

FIGURE 59-3. Schematic view of coronary angioplasty technique. A guide catheter (A) is inserted into the orifice of the coronary artery (in this figure, the left main artery), and a balloon catheter (B) is advanced over a thin guidewire (C) into the lesion. Balloon inflation dilates the stenotic region. (Modified from Baim DS. Percutaneous balloon angioplasty and general coronary intervention. In: Baim DS, ed. *Grossman's Cardiac Catheterization, Angiography, and Intervention*. 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2005.)

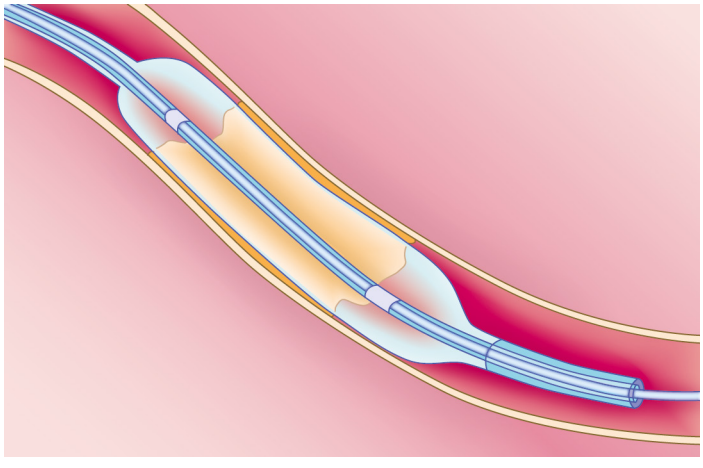

FIGURE 59-4. Balloon angioplasty catheter. The catheter consists of two lumens, an inflation lumen and a guidewire lumen. Two radiopaque markers, indicating the lateral balloon margins, aid in positioning of the balloon before inflation.

E-FIGURE 59-1. Balloon-expandable coronary stent. The stainless steel stent is crimped onto a balloon catheter to allow low-profile passage through the coronary artery. When it is positioned across the lesion, the balloon is inflated, expanding the stent (**A**). After balloon deflation and removal, the stent remains, providing a scaffold that supports the vessel lumen and conforms to the vessel's geometry (**B**).

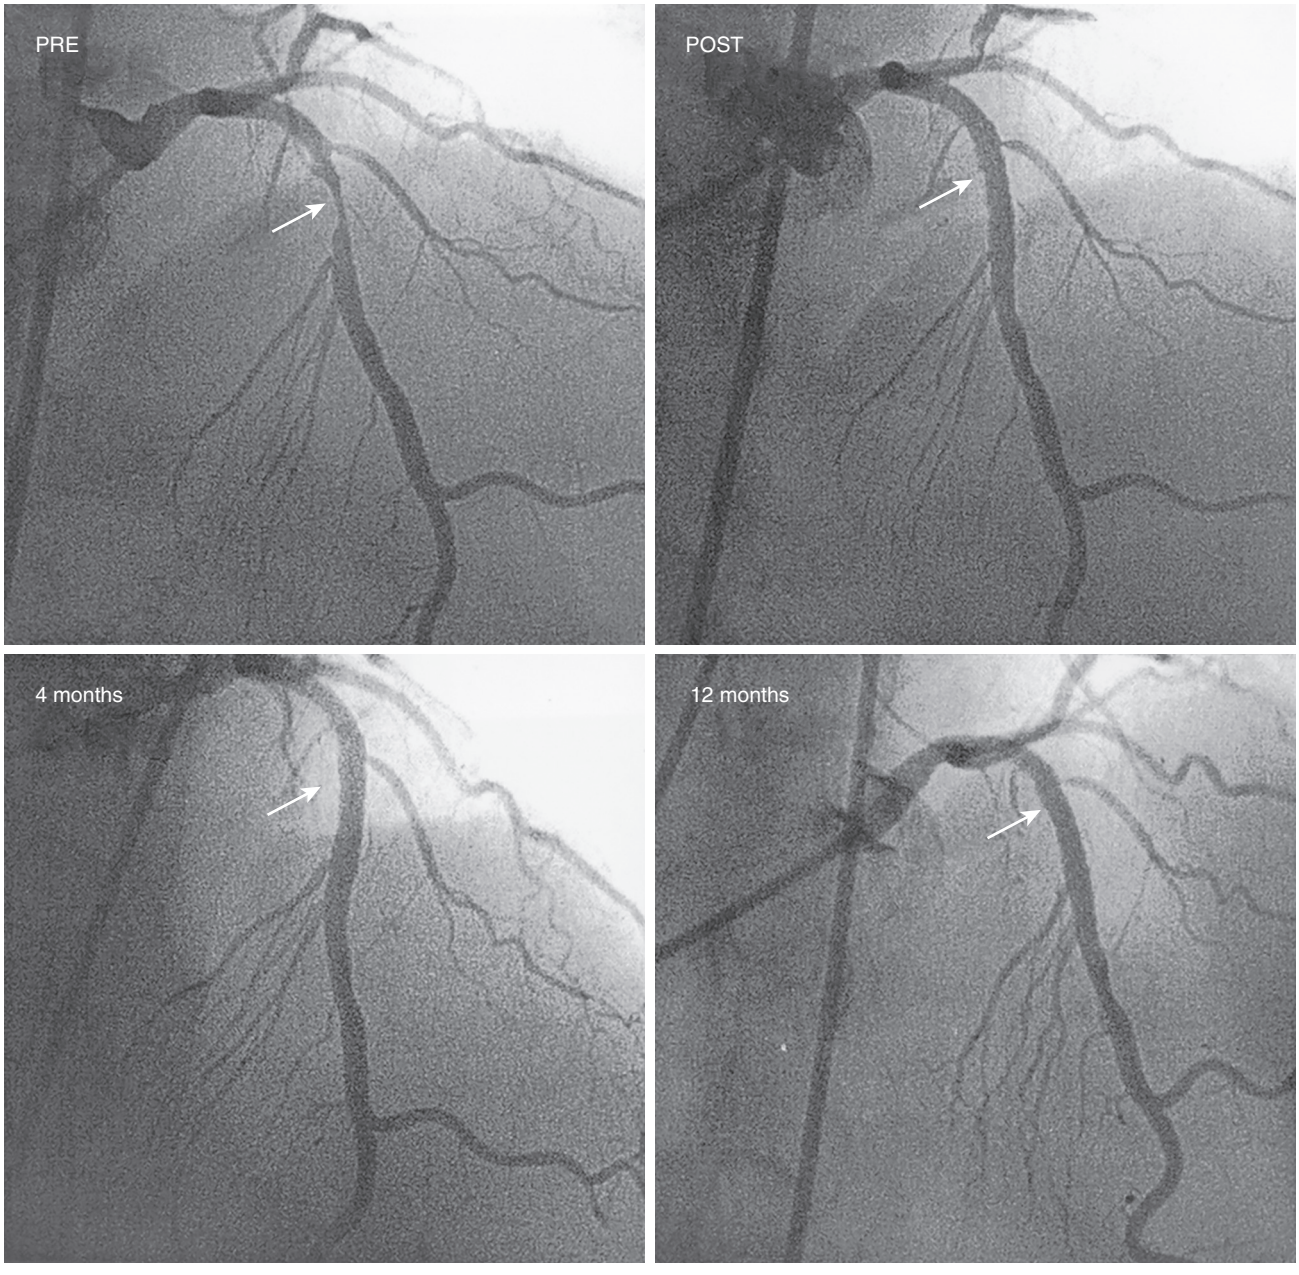

FIGURE 59-5. Angiographic images before, after, and at late follow-up after placement of a drug-eluting stent. The left anterior descending artery contains a tight stenosis *(arrow, upper left panel)*. After stent implantation *(upper right panel)*, the stenosis is abolished *(arrow)*. Follow-up at 4 and 12 months *(bottom panels)* reveals a completely open lumen with no evidence of restenosis *(arrows)*.

rate of clinically apparent MI characterized by chest discomfort, electrocardiographic changes, or a new wall motion abnormality is typically less than 2%. The need for urgent or emergent CABG surgery, stroke, and coronary perforation are less than 1%, and morbidity at the arterial access site (i.e., hematoma, pseudoaneurysm, or arteriovenous fistula) occurs in fewer than 5% of patients. As a result of these low complication rates, PCI without the availability of on-site surgery has not been demonstrably associated with higher mortality or rate of emergency CABG surgery.

Restenosis and Thrombosis

Restenosis[9] is a renarrowing of an artery after a PCI procedure, usually resulting from one of two mechanisms. The first mechanism, unfavorable remodeling and elastic recoil, is a mechanical renarrowing caused by adventitial constriction and shrinkage of the vessel lumen. The second mechanism, neointimal hyperplasia, is caused by the proliferation of smooth muscle cells and matrix in response to the injury caused by balloons, stents, or atherectomy devices. After balloon angioplasty alone without stenting, restenosis occurs in 10% to 50% of patients, usually within the first 6 months after the procedure, because of remodeling and recoil. Bare metal coronary stents, which provide a semi-rigid scaffolding within the lumen, eliminate the mechanical component of restenosis, but the proliferative component is enhanced; restenosis is reduced by about one third compared with balloon angioplasty alone. Drug-eluting stents, which contain and release antiproliferative drugs (e.g., sirolimus, everolimus, zotarolimus, and paclitaxel) reduce the need for early repeat PCI to less than 5%.[A9] Even with drug-eluting stents, however, about 10% of all PCI procedures in the United States are performed for restenosis.[10]

CHOICES RELATED TO STENTING

Balloon angioplasty is essentially always followed immediately by the insertion of a drug-eluting coronary stent.[A10] Biodegradable drug-eluting scaffolds, which completely dissolve over 2 to 3 years, were posited as a promising new technology but appear to be associated with a higher risk of in-stent thrombosis and myocardial infarction compared with metallic drug-eluting stents at 3-year follow-up.[A11]

The treatment of highly calcified vessels often requires rotational atherectomy or lithotripsy. Atherectomy (using a spinning catheter containing abrasive particles or laser energy) pulverizes plaque into microparticles that pass through the coronary microcirculation and is particularly helpful for the treatment of

heavily calcified lesions. Intravascular lithotripsy catheters deliver localized pulsatile sonic pressure waves that disrupt calcified plaque by creating microfractures. After the calcium has been cracked by lithotripsy or pulverized by atherectomy, the artery can be more easily expanded, and a drug-eluting stent is usually implanted.

DISCHARGE ISSUES

Discharge planning after PCI represents an important opportunity to emphasize evidence-based medical treatment of atherothrombotic disease and coronary risk factor modification (Chapter 40). Prolonged use of lipid-lowering agents, angiotensin-converting enzyme inhibitors, and in some cases β-blockers should be considered on the basis of randomized trials showing improved long-term outcome, particularly in patients who present with unstable coronary syndromes (Chapters 57 and 58). Smoking cessation (Chapter 363), blood pressure control (Chapter 64), stress management, exercise, weight loss, changes in dietary habits, and strict blood glucose control for patients with diabetes (Chapter 210) also are important elements of the discharge plan.

All patients should receive aspirin (81 mg/day) indefinitely. For patients receiving bare metal stents, a minimum 2-week course of a $P2Y_{12}$ receptor inhibitor (e.g., clopidogrel 75 mg/day, prasugrel 10 mg/day, or ticagrelor 90 mg/day) is mandatory. If a drug-eluting stent is deployed, aspirin plus a $P2Y_{12}$ inhibitor historically was required for a minimum of 3 to 6 months if the stent was implanted in a stable patient and 6 to 12 months if stenting was performed due to an acute coronary syndrome (unstable angina or myocardial infarction),[A12] However, switching to $P2Y_{12}$ monotherapy can be safe and effective in selected high-risk patients after 1 to 3 months of dual antiplatelet therapy.[A13] In fact, with second-generation polymer-free drug-eluting stents,[11] 1 month of dual anti-platelet therapy followed by 11 months of clopidogrel alone is a potential option to limit bleeding in patients with higher risks of bleeding. [A14,A15] Extending dual antiplatelet therapy to 30 or 36 months reduces ischemic cardiovascular events but increases bleeding. In patients with atrial fibrillation (Chapter 52), dual therapy with a direct-acting oral anticoagulant (e.g., dabigatran 110 mg or 150 mg twice daily) plus a $P2Y_{12}$ receptor inhibitor carries similar ischemic protection with a lower risk of bleeding compared with triple therapy with aspirin, warfarin, and either clopidogrel or ticagrelor.[A16]

Activity restrictions after PCI are modest. If the femoral artery was instrumented, heavy lifting is discouraged for several days. Intense aerobic exercise is usually discouraged for 2 to 4 weeks (especially after stent implantation) because exercise can activate platelets and lead to formation of thrombus at the angioplasty site. Patients may return to work 1 or 2 days after the procedure if their occupation does not include heavy lifting or excessive physical exercise. There is usually no restriction on driving an automobile. Routine postoperative functional testing has not been shown to be beneficial.[A17]

CORONARY ANGIOPLASTY VERSUS MEDICAL THERAPY

Percutaneous coronary intervention reduces angina and commonly leads to better treadmill exercise performance and improved quality-of-life measurements. However, in patients with stable angina, PCI has not been shown to reduce the risks of death, MI, or other major cardiovascular events compared with modern optimal medical therapy (Chapter 56).[A18-A22] In truly asymptomatic patients, significant ischemia first should be documented by functional testing, or a large quantity of myocardium should be supplied by the stenotic coronary artery. Patients experiencing acute MI such as ST segment elevation MI (Chapter 58) represent an important subgroup in whom PCI has proved beneficial compared with medical therapy (Fig. 59-6). In ST segment elevation MI, randomized trials have consistently shown a reduction in mortality, stroke, subsequent MI, and recurrent ischemia with immediate PCI compared with thrombolytic therapy or with initial thrombolytic therapy followed by rescue PCI as needed even if immediate PCI requires transfer to another hospital. For non–ST segment elevation MI and many patients with unstable angina, an early aggressive approach that includes either PCI or CABG in angiographically suitable patients is generally preferable to a conservative strategy except in lower risk patients (Chapter 57).[12]

CORONARY ARTERY SURGERY

Coronary artery bypass graft surgery is based on the premise that the morbidity and mortality associated with coronary atherosclerosis are largely related to atherosclerotic coronary stenoses that can be demonstrated by coronary angiography and that if grafts are constructed to route blood flow around these stenoses, myocardial blood supply can be improved or preserved, cardiac symptoms relieved, cardiac events diminished, and survival prolonged.

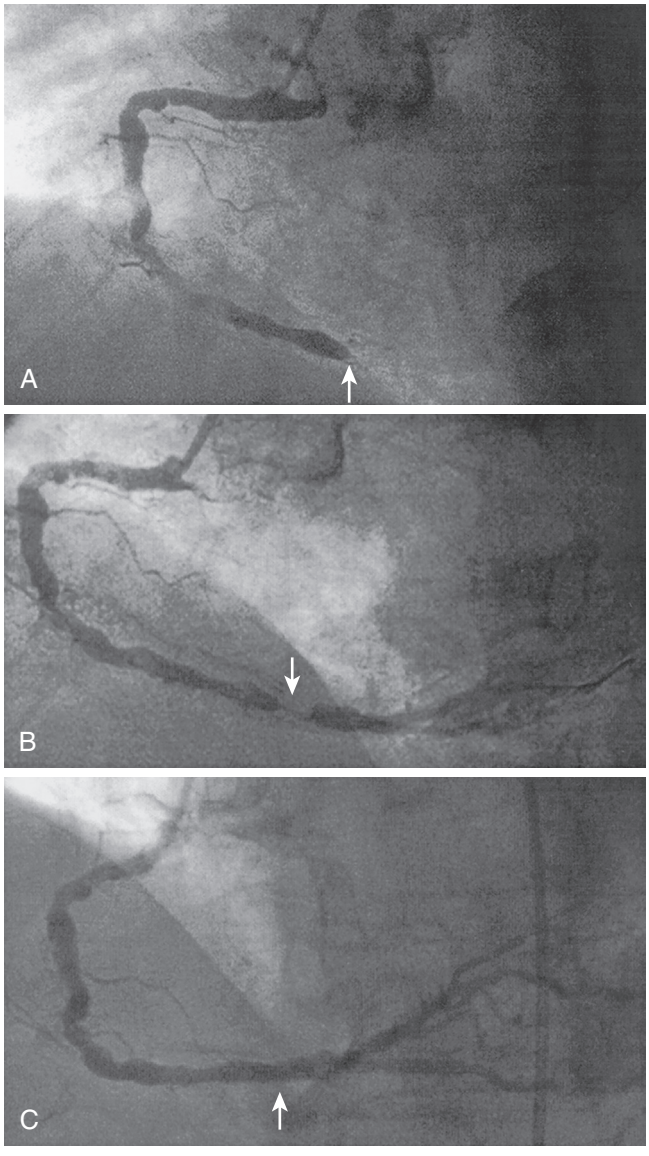

FIGURE 59-6. Primary coronary angioplasty for acute myocardial infarction. This 50-year-old man presented at midnight with 70 minutes of crushing substernal chest pressure accompanied by inferior ST segment elevation. Emergency angiography performed 45 minutes after arrival found 100% occlusion of the right coronary artery (**A**, *arrow*). Within 10 minutes, a guidewire was negotiated through the obstruction (presumably caused by fresh thrombus), allowing perfusion into the distal vessel and uncovering a high-grade stenotic lesion (**B**, *arrow*). After deployment of a coronary stent (**C**, *arrow*), the stenosis was abolished and significant myocardial damage aborted.

The most common types of grafts for coronary artery bypass have been reversed segments of saphenous vein and the internal thoracic arteries. Saphenous vein grafts are anastomosed to the aorta (proximal anastomosis) and to the coronary artery distal to the major obstruction (Fig. 59-7). Saphenous vein grafts have the advantages of availability, larger size than most coronary arteries, and favorable handling characteristics. With time, however, saphenous vein grafts may develop intrinsic pathologic changes, intimal fibroplasia, and vein graft atherosclerosis, each of which may lead to narrowing or occlusions. Modern treatment with platelet inhibitors and statins (Chapter 190) decreases the risk of vein graft failure but cannot eliminate it. Internal thoracic artery grafts, on the other hand, are resistant to the development of late atherosclerosis. When used as an in situ (subclavian origin intact) graft to the left anterior descending (LAD) coronary artery, the left internal thoracic artery graft has a more than 90% patency rate up to 20 years after operation. As a result, patients who receive a left internal thoracic artery to LAD graft, with or without saphenous vein grafts, have a better long-term survival rate, fewer reoperations, and fewer cardiac events compared with

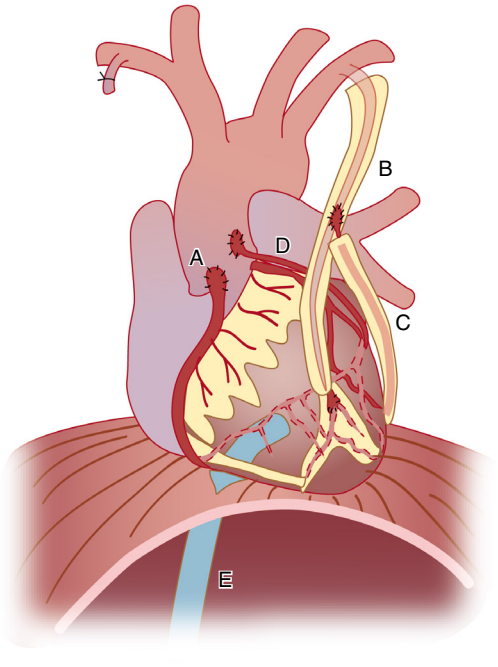

FIGURE 59-7. Types of bypass grafts. Bypass grafts include reversed saphenous vein graft from the aorta to the right coronary artery (**A**), in situ left internal mammary artery graft to the anterior descending coronary artery (**B**), Y graft of the right internal mammary artery from the left internal mammary artery to the circumflex coronary artery (**C**), radial artery graft from the aorta to the circumflex coronary artery (**D**), and in situ gastroepiploic graft to the posterior descending branch of the right coronary artery (**E**).

patients receiving only saphenous vein grafts. The right internal thoracic artery also may be used for revascularization as an in situ graft, as an aorta to coronary artery graft, or as a composite arterial graft from the left internal thoracic artery to a coronary artery. Despite its theoretical appeal, use of both internal thoracic arteries as grafts has not been proven to provide benefit over a single internal thoracic artery graft strategy and is associated with a higher rate of sternal infections and complications.[A23,A24] For the second graft, using the radial artery as another arterial conduit is preferred over a saphenous vein graft.[A25]

Most CABG operations are performed with a full median sternotomy incision, historically with the aid of cardiopulmonary bypass, aortic cross-clamping, and cardioplegic solution—techniques that allow exposure and arrest of the heart such that detailed microsurgical anastomoses can be constructed while myocardial function is effectively protected. By comparison, operations performed through smaller incisions (minimally invasive surgery) can be more challenging to perform without specialized training and have had limited application for coronary revascularizations. In randomized trials, beating heart ("off-pump") surgery without cardiopulmonary bypass has not consistently reduced morbidity, often has been associated with a lower rate of long-term graft patency, and does not provide better outcomes;[A26] as a result, it is usually reserved for carefully selected patients.

PERIOPERATIVE RISKS

The risk of mortality associated with CABG correlates with the extent of ischemia at the time of operation, left ventricular function, extent of coronary stenoses, noncardiac atherosclerosis, and comorbid conditions, as well as with the experience, skill, and judgment of the surgeon. Effective myocardial protection has diminished much of the incremental risk based on the severity of cardiac disease. For patients younger than 70 years without serious comorbid conditions, the mortality risk of primary CABG surgery is less than 1% in experienced hands. Nevertheless, CABG surgery in the presence of ongoing myocardial ischemia caused by acute MI, unstable angina, or acute vessel closure after PCI is still associated with increased risk. Noncardiac comorbid conditions (aortic atherosclerosis, renal function, chronic obstructive pulmonary disease, and coagulation system disorders) increase perioperative risk when these conditions are severe.

Aside from mortality, the most serious postoperative morbidity after CABG is stroke, often related to aortic or cerebrovascular atherosclerosis and atherosclerotic embolization. Heightened awareness of the importance of aortic and carotid atherosclerosis and improved management strategies appear to have decreased the risk of focal stroke in patients previously at high risk. Serious wound complications of median sternotomy are uncommon (1 to 2%).

INDICATIONS FOR BYPASS SURGERY

The goals of CABG are to relieve symptoms and to prolong life expectancy. On the basis of randomized trials and the emergence of alternative medical treatments and PCI, the surgical population has evolved toward patients who benefit most from CABG relative to other treatments: patients with complex conditions, often involving left main or triple-vessel disease, diffuse coronary stenoses, totally obstructed vessels, abnormal left ventricular function, and diabetes. Surgically treated patients with single-vessel disease usually have LAD stenoses or have failed alternative treatments, such as developing recurrent restenosis after PCI.

Relief of Symptoms

If patients who experience angina have severe stenoses in graftable coronary arteries that supply areas of myocardium ischemia at rest or with stress, CABG will reliably relieve angina. Randomized trials have shown that the relief of angina after CABG is more consistent than that achieved with alternative treatments. When intermittent heart failure symptoms represent an "anginal equivalent" that is also caused by ischemia, such symptoms also respond well to relief of that ischemia by CABG. For patients with symptoms of heart failure at rest, dobutamine echocardiography (Chapter 43), positron emission tomography (Chapter 44), and cardiac magnetic resonance imaging (Chapter 44) can identify segments of viable but hibernating myocardium (ischemic at rest) that may improve with bypass grafting, thus reducing symptoms of heart failure.

Survival

Chronic Stable Angina

In randomized trials of patients with mild to moderate chronic stable angina, an improved survival rate has been documented for patients treated with initial CABG compared with those treated with initial medical treatment in the presence of a left main stenosis of more than 50% of the diameter, triple-vessel disease, double-vessel disease with a proximal LAD lesion, abnormal left ventricular function, or a strongly abnormal exercise test result (Chapter 56). Meta-analysis of these randomized trials also suggests a survival benefit of CABG for any patient with a proximal LAD lesion and myocardial ischemia. These are subgroups of patients for whom bypass surgery should be strongly considered even in the absence of severe symptoms. During these trials, patients with severe angina were not randomized but were included in observational studies that noted improved survival rates with CABG for patients with double- and triple-vessel disease and normal or abnormal left ventricular function. Medical, interventional, and surgical treatments have all advanced substantially since these trials were completed.

Acute Coronary Syndrome and Ischemic Cardiomyopathy

Current data suggest an aggressive strategy, including CABG when indicated, in patients who have an acute coronary syndrome (unstable angina or non–ST segment elevation acute MI; Chapter 57). Patients who have coronary artery disease, heart failure, and severe left ventricular systolic dysfunction often can be controlled symptomatically with medications (Chapter 46). However, CABG added to guideline-directed medical therapy significantly reduces all-cause death, death from cardiovascular causes, and death from any cause or hospitalization for cardiovascular causes at 10 years,[A27] irrespective of whether it improves left ventricular function.[A28]

Other Ischemic Syndromes

ST Segment Elevation Acute Myocardial Infarction

For patients with ST segment elevation acute MI, CABG may be indicated in the acute setting when thrombolytic therapy or PCI has not been effective, ischemia is ongoing, and large areas of myocardium remain jeopardized. CABG after a completed MI may be indicated in patients in whom persistent ischemia in noninfarcted areas of myocardium produces post-infarction angina or hemodynamic instability. Mechanical complications of myocardial necrosis, including papillary muscle rupture, ventricular septal rupture, and myocardial free wall rupture, are acute life-threatening situations that usually require urgent operation for repair of the defect, often combined with CABG (Chapter 58).

Failed Percutaneous Coronary Intervention

Drug-eluting stents have decreased the need for emergency CABG to treat acute failure of PCIs. Current indications for emergency CABG include closure or threatened closure of a vessel supplying a significant amount of myocardium or recurrent restenosis despite several PCIs.

Coronary Bypass Reoperations

Patients in whom new stenoses develop in native arteries or in bypass grafts may have recurrent ischemic syndromes. Severe vein graft atherosclerosis is an unstable lesion that often leads to serious cardiac events, particularly if the LAD or multiple vessels are jeopardized; reoperation appears to improve the survival rate of these patients. Conversely, if the LAD coronary artery is supplied by a patent internal thoracic artery graft, reoperation does not appear to improve survival, although it may improve symptoms. Reoperations are more difficult and dangerous than primary procedures, but the risk now approaches that for primary procedures in institutions performing a large number of reoperations. PCI is often less-invasive and potentially a lower-risk alternative for the treatment of vein graft disease.

Late Outcomes

The late outcomes after CABG are related to age, severity of cardiac disease before operation, noncardiac comorbid conditions, progression of atherosclerosis, and the operation itself. For patients with severe coronary artery disease, CABG prolongs life expectancy. The achievement of complete revascularization (bypass grafts to all stenotic coronary vessels) and the use of internal thoracic artery grafts improve long-term survival rates and symptomatic status.

More than 80% of patients are alive more than 10 years after operation. Over the long term, control of the progression of atherosclerosis by lifestyle modifications, pharmacologic treatment of hypertension (Chapter 64) and lipids (Chapter 190), and platelet inhibitors (Chapter 70) appear to extend the benefits of CABG.[13]

COEXISTING CARDIAC DISEASE

During cardiac operations performed for valvular (Chapter 60) or aortic (Chapter 63) disease, the standard treatment is to perform bypass grafts to major coronary arteries with angiographic stenoses of more than 50% of the luminal diameter. No randomized trials have addressed this issue, and these indications, although logical given the natural history of atherosclerosis, remain practice patterns based on consensus but not on definitive data.

PERCUTANEOUS CORONARY INTERVENTION VERSUS CORONARY ARTERY BYPASS GRAFTING

The decision between PCI and CABG surgery is largely determined by clinical status and anatomic features, but some areas remain controversial. For patients with acute coronary syndromes, PCI is the preferred initial approach and has been shown to improve the survival rate of patients with ST segment elevation MI.[14] CABG is reserved for patients with failed acute PCI or residual myocardial ischemia. For patients who have chronic coronary syndromes, no data confirm that PCI prolongs life regardless of anatomy.

By comparison, randomized trials, albeit older trials, demonstrate that CABG prolongs the life expectancy of patients with severe coronary artery disease, particularly patients with left ventricular dysfunction or severe ischemia. Patients with more complex, multivessel coronary artery disease benefit most from CABG, including a clear improvement in survival rate, but patients with more limited coronary disease have equivalent survival outcomes with drug-eluting PCI.[A29] For patients with left main coronary artery disease[15] without extensive additional disease, PCI appears to be similar to CABG in terms of subsequent death, superior with respect to stroke, but inferior with respect to the need for repeat revascularization and out-of hospital myocardial infarction, and perhaps all-cause mortality.[A30-A33] Randomized trials also show that diabetic patients with multivessel coronary artery disease have better survival rates with CABG compared with PCI.[A34]

60 VALVULAR HEART DISEASE

BLASE A. CARABELLO AND SUSHEEL KODALI

APPROACH TO THE PATIENT WITH VALVULAR HEART DISEASE

The cardiac valves permit unobstructed forward blood flow through the heart when they are open while preventing backward flow when they are closed. Most valvular heart diseases cause either valvular stenosis with obstruction to forward flow or valvular regurgitation with backward flow. Valvular stenosis imparts a pressure overload on the left or right ventricle because these chambers must generate higher than normal pressure to overcome the obstruction to pump blood forward. Valvular regurgitation imparts a volume overload on the heart, which now must pump additional volume to compensate for what is regurgitated. When valve disease is severe, these hemodynamic burdens can lead to ventricular dysfunction, heart failure, and sudden death (Table 60-1). In almost every instance, definitive therapy for severe valvular heart disease is mechanical restoration of valve function.

A careful history and physical examination are key to the evaluation of a patient with suspected or known valvular heart disease. Because the presence or absence of symptoms dramatically affects prognosis and hence the proper therapy in most valvular diseases, an intense effort must focus on the patient's symptomatic status. The physical examination should include not only careful auscultation but also a detailed assessment for evidence of heart failure (Chapter 45). Transthoracic echocardiography (Chapter 43), which is the mainstay of diagnosis, provides both anatomic and physiologic information regarding the lesion's type, cause, and severity. In cases in which transthoracic echocardiography fails to provide adequate information, transesophageal echocardiography, cardiac magnetic resonance imaging (MRI; Chapter 44), and cardiac computed tomography (CT) usually provide the additional needed information, but invasive hemodynamic measurements are still occasionally required.[1,2]

AORTIC STENOSIS

EPIDEMIOLOGY

Bicuspid and Other Congenitally Abnormal Aortic Valves

Approximately 0.8% of the population is born with a bicuspid aortic valve,[3] with a male preponderance (Chapter 55). Although this abnormality does not usually cause a hemodynamic disturbance at birth, bicuspid aortic valves tend to deteriorate with age. Approximately one third of these valves become stenotic, another third become regurgitant, and the remainder cause only minor hemodynamic abnormalities. A murmur is typically noted in childhood or adolescence, and congenital aortic stenosis from a bicuspid tricuspid valve can cause symptoms during childhood and require correction by adolescence (Chapter 55). However, bicuspid valves more commonly become symptomatic when patients are in their 40s, 50s, and 60s. Aortic aneurysms develop in nearly one-third of patients with bicuspid aortic valves, so careful screening is warranted, even in asymptomatic patients.

Tricuspid Aortic Valve Stenosis

The most common form of aortic stenosis is a calcific process that results from the deposition of calcium and the thickening of valve leaflets in patients with apparently normal tricuspid aortic valves. This disease process typically develops in the seventh to eighth decade of life. This type of aortic stenosis is not a degenerative process but rather arises from an active inflammatory process similar to that of coronary heart disease (Chapter 41), with hypertension and hyperlipidemia as risk factors.

Rheumatic Valvular Heart Disease

Rheumatic valve disease is now a rare cause of aortic stenosis in developed countries, but rheumatic fever and its sequelae remain an important issue in many developing countries (Chapter 269). In virtually every case, the mitral valve is also involved in the disease process.

PATHOBIOLOGY

The normal aortic valve area is 3 to 4 cm^2, and little hemodynamic disturbance occurs until the orifice is reduced to about half of normal, at which point a systolic gradient develops between the left ventricle and aorta. Typically left ventricular and aortic pressures are nearly equal during systole (E-Fig. 60-1A). In aortic stenosis, however, intracavitary left ventricular pressure must increase above aortic pressure to produce forward flow across the stenotic valve and to achieve acceptable downstream pressure (E-Fig. 60-1B). Each of the processes that cause aortic stenosis has a typical pathoanatomic configuration (Fig. 60-1). There is a geometric progression in the magnitude of the gradient as the valve area narrows. Given a normal cardiac output, the gradient rises rapidly from 10 to 15 mm Hg at valve areas of 1.5 to 1.3 cm^2 to about 25 mm Hg at 1.0 cm^2, 50 mm Hg at 0.8 cm^2, 70 mm Hg at 0.6 cm^2, and 100 mm Hg at 0.5 cm^2. The rate of progression of aortic stenosis varies widely from patient to patient; it may remain stable for many years or increase by more than 15 mm Hg per year.

A major compensatory response to the increased left ventricular pressure associated with aortic stenosis is the development of concentric left ventricular hypertrophy. The Laplace equation—Stress (s) = Pressure (p) × Radius (r)/2 Thickness (th)—indicates that the stress on the left ventricle (afterload) varies directly with intracavitary pressure and radius but inversely with wall thickness. As left ventricular pressure increases with increasing severity of aortic stenosis, it can be offset by increased left ventricular wall thickness (concentric hypertrophy). The determinants of the left ventricular ejection fraction are contractility, preload, and afterload. By normalizing afterload, the development of concentric hypertrophy helps preserve ejection fraction and cardiac output despite the pressure overload. Although hypertrophy may serve as a compensatory function, it also has a pathologic role and is in part responsible for the classic symptoms and the poor outcome of untreated symptomatic aortic stenosis.

Angina

In general, angina (Chapter 56) results from ischemia when myocardial oxygen (and other nutrient) demand exceeds supply, which is predicated on coronary blood flow. In normal subjects, coronary blood flow can increase five- to eight-fold under maximum metabolic demand, but in patients with aortic stenosis, this reserve is limited. Reduced coronary blood flow reserve may be caused by a relative diminution in capillary ingrowth to serve the needs of the hypertrophied left ventricle or by a reduced transcoronary gradient for coronary blood flow because of the elevated left ventricular end-diastolic pressure. Restricted coronary blood flow reserve is in part responsible for angina in many patients who have aortic stenosis despite normal epicardial coronary arteries, but angina also may be caused by increased oxygen demand when inadequate hypertrophy allows wall stress, a key determinant of myocardial oxygen consumption, to increase.

Syncope

Syncope (Chapters 39 and 49) generally occurs because of inadequate cerebral perfusion. In aortic stenosis, syncope is often related to exertion. It may result when exertion causes a fall in total peripheral resistance that cannot be offset by increased cardiac output because output is limited by the obstruction to outflow across the stenotic valve. Furthermore, patients with small left ventricular cavity size are more prone to syncope because of lower stroke volume. In addition, high left ventricular pressure during exercise may trigger a systemic vasodepressor response that lowers blood pressure and produces syncope. Any sudden drop in preload may precipitate syncope because the left ventricle is unable to maintain cardiac output. Finally, cardiac arrhythmias, often related to a dilated left atrium, can also result in hypotension and syncope.

Heart Failure

In aortic stenosis, contractile dysfunction (systolic failure) and failure of normal relaxation (diastolic failure) result in symptoms of heart failure (Chapter 45). The extent of ventricular contraction is governed by contractility and afterload. In aortic stenosis, contractility (the ability to generate force) is often reduced. The mechanisms of contractile dysfunction may include abnormal calcium handling, microtubular hyperpolymerization causing an internal viscous load on the myocyte, and myocardial ischemia (Chapter 41). In some cases, contractile function is normal, but the hypertrophy is inadequate to normalize wall stress and excessive afterload results. Excessive afterload inhibits ejection, reduces forward output, and leads to heart failure.

The increased wall thickness that helps normalize stress increases diastolic stiffness. Even if muscle properties remain normal, higher filling pressure is required to distend a thicker ventricle. As aortic stenosis advances, collagen deposition also stiffens the myocardium and adds to the diastolic dysfunction. These processes eventually result in elevated left atrial and pulmonary artery pressures.

ABSTRACT

The heart valves are mechanical structures that control one-way circulation through the heart. Valve malfunction is manifest either by stenosis, which creates obstruction to flow, or by regurgitation, which allows backward flow. When severe, valve disease is almost universally fatal, but when treated properly, the outcome is excellent. In most cases, mechanical problems created by valve disease require mechanical solutions for proper management. The advent of transcatheter valve repair and replacement has broadened applicability of these solutions to a wide range of previously untreatable patients. Increased therapeutic options also increase the need for an understanding of their place in the valve disease armamentarium. This chapter describes the etiology and diagnosis of valvular heart disease, with a special emphasis on the proper timing and appropriate use of the therapeutic options.

TABLE 60-1 SUMMARY OF SEVERE VALVULAR HEART DISEASE

	AORTIC STENOSIS	MITRAL STENOSIS	MITRAL REGURGITATION	AORTIC REGURGITATION
Etiology	Idiopathic calcification of a bicuspid or tricuspid valve Congenital Rheumatic	Rheumatic fever Annular and leaflet calcification	Mitral valve prolapse Ruptured chordae Endocarditis Ischemic papillary muscle dysfunction or rupture Collagen vascular diseases and syndromes Secondary to LV myocardial diseases	Annuloaortic ectasia Hypertension Endocarditis Marfan syndrome Ankylosing spondylitis Aortic dissection Syphilis Collagen vascular disease
Pathophysiology	Pressure overload on the LV with compensation by LVH. As disease advances, reduced coronary flow reserve predisposes to angina. Hypertrophy and afterload excess lead to systolic and diastolic LV dysfunction.	Obstruction to LV inflow increases LA pressure and limits cardiac output, thus mimicking LV failure. Mitral valve obstruction increases the pressure work of the RV. Right ventricular pressure overload is augmented further when pulmonary hypertension develops.	Places volume overload on the LV. Ventricle responds with eccentric hypertrophy and dilation, which allow increased ventricular stroke volume. Eventually, however, LV dysfunction develops if volume overload is uncorrected.	*Chronic:* Total stroke volume causes hyperdynamic circulation, induces systolic hypertension, and causes pressure and volume overload. Compensation is by concentric and eccentric hypertrophy. *Acute:* Because cardiac dilation has not developed, hyperdynamic findings are absent. High diastolic LV pressure causes mitral valve preclosure and potentiates LV ischemia and failure.
Symptoms	Angina Syncope Dyspnea Heart failure	Dyspnea Orthopnea PND Hemoptysis Hoarseness Edema Ascites	Dyspnea Orthopnea PND	Dyspnea Orthopnea PND Angina
Signs	Systolic ejection murmur radiating to the neck Delayed carotid upstroke S_4, soft or paradoxical S_2	Diastolic rumble after an opening snap Loud S_1 RV lift Loud P_2	Holosystolic apical murmur radiating to the axilla, S_3 Displaced PMI	*Chronic:* Diastolic blowing murmur Hyperdynamic circulation Displaced PMI Quincke pulse de Musset sign Austin Flint murmur *Acute:* Short diastolic blowing murmur Soft S_1
Electrocardiogram	LAA LVH	LAA RVH	LAA LVH	LAA LVH
Chest radiograph	Boot-shaped heart Aortic valve calcification on lateral view	Straightening of left heart border Double density at right heart border Kerley B lines Enlarged pulmonary arteries	Cardiac enlargement	*Chronic:* Cardiac enlargement Uncoiling of the aorta *Acute:* Pulmonary congestion with normal heart size
Echocardiographic findings	Concentric LVH Reduced aortic valve cusp separation Doppler shows mean gradient ≥40 mm Hg in most severe cases	Restricted mitral leaflet motion Valve area ≤1.5 cm^2 LA enlargement Tricuspid Doppler may reveal pulmonary hypertension	LA enlargement LV enlargement and LV dysfunction in severe cases Doppler: large regurgitant jet	*Chronic:* LV enlargement Large Doppler jet with PHT <400 msec *Acute:* Small LV Mitral valve preclosure
Catheterization findings	Increased LVEDP Transaortic gradient 40 mm Hg AVA ≤0.8 in most severe cases	Elevated pulmonary capillary wedge pressure Transmitral gradient usually >5 mm Hg in severe cases MVA <1.5 cm^2	Elevated pulmonary capillary wedge pressure with prominent V waves Ventriculography shows regurgitation of dye into LA	Wide pulse pressure Aortography shows regurgitation of dye into LV
Medical therapy	Avoid vasodilators Avoid a decline in venous return (preload) Diuretics for symptom control in inoperable cases	Diuretics for mild symptoms Anticoagulation in atrial fibrillation Digitalis, β-blockers, verapamil, or diltiazem for rate control	Afterload reduction in acute MR—primarily with ACE inhibitors Blood pressure control	*Chronic:* Vasodilators in chronic asymptomatic disease with hypertension even if LV function is normal *Acute:* Vasodilators
Indications for surgery	Appearance of symptoms in patients with severe disease (see text) or asymptomatic LV dysfunction	Appearance of more than mild symptoms Development of pulmonary hypertension Appearance of persistent atrial fibrillation	Appearance of symptoms EF <0.60 ESD ≥40 mm	*Chronic:* Appearance of symptoms EF <0.50 ESD ≥50 mm *Acute:* Even mild heart failure Mitral valve preclosure

ACE = angiotensin-converting enzyme; AVA = aortic valve area; EF = ejection fraction; ESD = end-systolic diameter; LA = left atrial; LAA = left atrial abnormality; LV = left ventricle or left ventricular; LVEDP = left ventricular end-diastolic pressure; LVH = left ventricular hypertrophy; MR = mitral regurgitation; MVA = mitral valve area; PHT = pressure half-time; PMI = point of maximal impulse; PND = paroxysmal nocturnal dyspnea; RV = right ventricle or right ventricular; RVH = right ventricular hypertrophy.

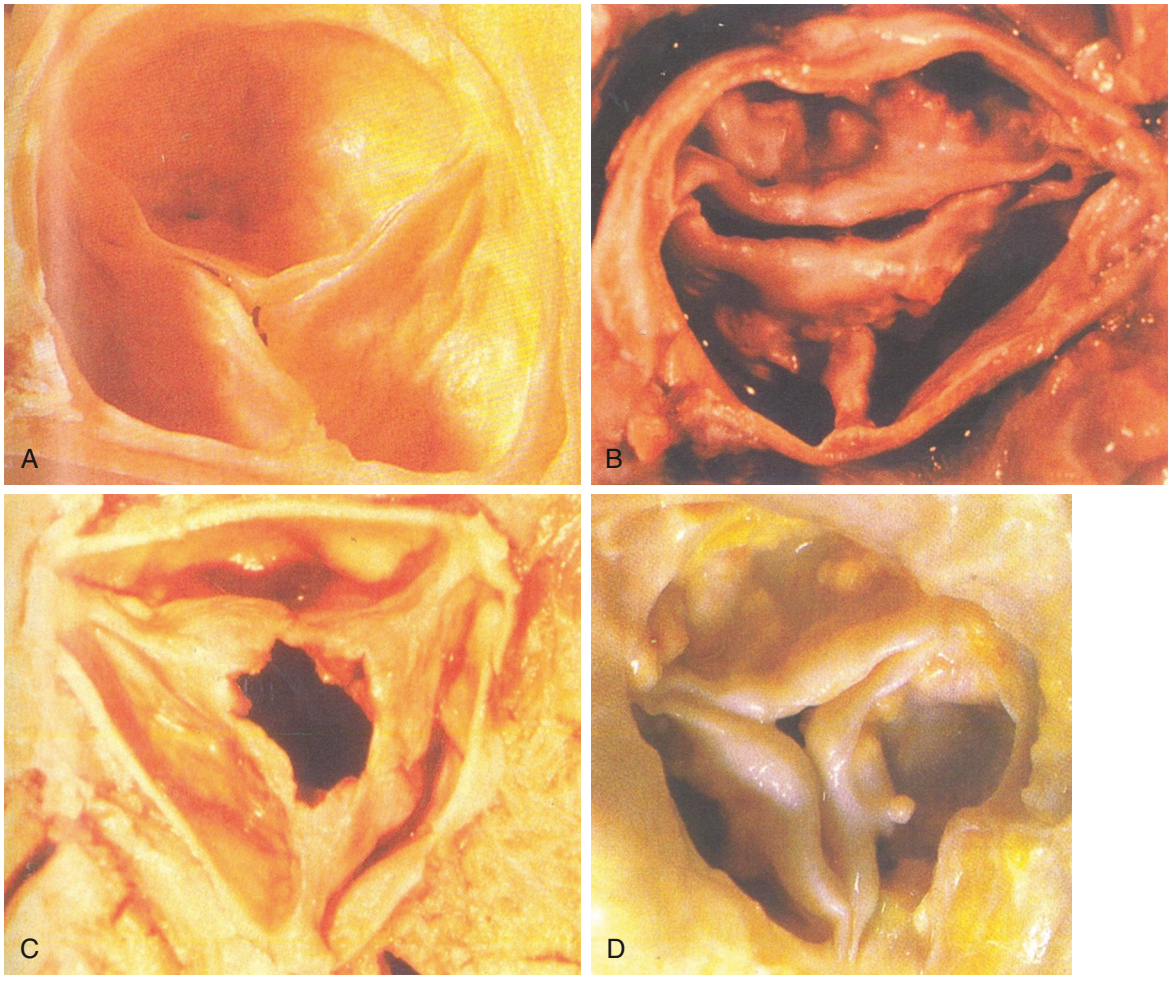

FIGURE 60-1. Pathology of aortic stenosis. A, A normal aortic valve. **B,** A stenotic congenital bicuspid valve. **C,** Rheumatic aortic stenosis. **D,** A stenotic calcified tricuspid aortic valve. (From Bonow RO, Braunwald E. Valvular heart disease. In: Zipes DP, Libby P, Bonow RO, Braunwald E, eds. *Heart Disease: A Textbook of Cardiovascular Medicine*. 7th ed. Philadelphia: WB Saunders; 2005:1583.)

CLINICAL MANIFESTATIONS

The diagnosis of aortic stenosis is usually first suspected when the classic systolic ejection murmur is heard during physical examination (Chapter 39) in an often asymptomatic individual. The murmur is loudest in the aortic area and radiates to the neck. In some cases, the murmur may disappear over the sternum and reappear over the left ventricular apex, thereby giving the false impression that a murmur of mitral regurgitation is also present (Gallavardin phenomenon). The intensity of the murmur increases with cycle length because longer cycles are associated with greater aortic flow. In mild disease, the murmur peaks in intensity in early systole or mid systole. As the severity of stenosis worsens, the murmur peaks progressively later in systole. Perhaps the most helpful clue to the severity of aortic stenosis by physical examination is the characteristic delay in the carotid pulse with a diminution in its volume (see Fig. 39-4 in Chapter 39); in elderly patients, however, increasing carotid stiffness may pseudonormalize the carotid upstrokes. The left ventricular apical impulse in aortic stenosis is not displaced but is enlarged and forceful. The simultaneous palpation of a forceful left ventricular apex beat and a delayed and weakened carotid pulse is a persuasive clue that severe aortic stenosis is present. S_1 in aortic stenosis is generally normal. In congenital aortic stenosis when the valve is not calcified, S_1 may be followed by a systolic ejection click. In calcific disease, S_2 may be single and soft when the aortic component is lost because the valve neither opens nor closes well. In some cases, delayed left ventricular emptying may create paradoxical splitting of S_2. An S_4 gallop is common. In advanced disease, pulmonary hypertension and signs of right-sided failure are common.

Because of the dire consequences of missing the diagnosis of aortic stenosis, the physician must have a low threshold for obtaining an echocardiogram whenever aortic stenosis cannot be excluded by physical examination, especially in patients with a history of angina, syncope, or heart failure. In asymptomatic patients with suspicious murmurs, early diagnosis allows the patient and physician to be more vigilant regarding possible early signs and symptoms.

Although exercise testing is contraindicated in symptomatic patients with aortic stenosis because of the high risk for complications, cautious exercise testing is reasonable in asymptomatic patients to detect latent symptoms or hemodynamic instability that is otherwise unrecognized. Exercise-induced hypotension (>10 mm Hg drop in systolic blood pressure from baseline) or symptoms are indications for aortic valve replacement in patients who have severe aortic stenosis; in patients who have only mild to moderate aortic stenosis, another source of exercise limitation should be sought.

DIAGNOSIS

Echocardiography (Chapter 43) performed in multiple views by an experienced sonographer is the primary modality for confirming the diagnosis of aortic stenosis (Fig. 60-2). Although the visual appearance of the valve leaflets is useful, the assessment of the severity of aortic stenosis relies on Doppler interrogation of the aortic valve. As blood flows from the body of the left ventricle across the stenotic valve, the flow rate must accelerate for the volume to remain constant. Doppler interrogation of the valve can be performed to detect this increase in velocity. If the peak aortic flow velocity is 3.0 m/second or less, symptoms are unlikely to develop in the next 5 years; by comparison, in patients with a flow velocity of 4.0 m/second or greater, symptoms usually develop within 2 years, and when the velocity exceeds 5 m/second, symptoms are likely to develop within 1 year. The modified Bernoulli equation (gradient = $4 \times \text{velocity}^2$) can calculate the peak gradient across the valve and estimate the aortic valve area (Chapter 43). In patients in whom there is discrepancy between the visual appearance of the aortic valve and the calculated valve area, transesophageal echocardiography can measure the valve area directly by tracing its opening, although the measured orifice area should not replace other ways to assess the severity of aortic stenosis.

When echocardiography shows severe aortic stenosis and the patient has one or more of the classic symptoms of the disease, cardiac catheterization to document the severity of the stenosis is not recommended. However, when the

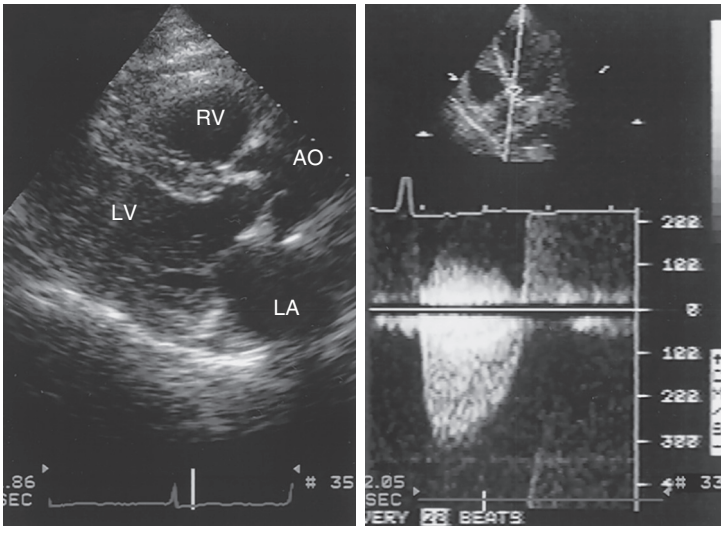

FIGURE 60-2. Doppler echocardiogram from a patient with aortic stenosis. The *left panel* shows thickened aortic valve leaflets that dome into the aorta with restricted opening in systole. The *top right panel* shows a miniaturized apical four-chamber view at the top with a Doppler cursor through the aorta, and the *bottom right panel* shows a continuous-wave spectral Doppler signal with a peak velocity of 3 m/second. The peak valve gradient can be calculated as 4×3^2, or 36 mm Hg. AO = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle. (Courtesy of Dr. Anthony DeMaria.)

hemodynamic diagnosis is unclear, right- and left-sided heart catheterization should be performed to determine the transaortic valvular pressure gradient and cardiac output, which are used to calculate the aortic valve area by the Gorlin formula:

$$A = \frac{CO/SEP \times HR}{44.3\sqrt{h}}$$

where *CO* is the cardiac output (mL/minute), *SEP* is the systolic ejection period (seconds), *HR* is the heart rate, and *h* is the mean gradient. Coronary arteriography is commonly recommended before aortic valve surgery because most patients with aortic stenosis are of the age at which coronary disease is common.

The extent of valve calcification correlates with the severity of aortic stenosis, so quantification of valve calcification by CT scanning can occasionally be helpful. A calcium score greater than 1300 in women or greater than 2000 in men is consistent with severe aortic stenosis.

Brain natriuretic peptide levels may be higher in patients who will become symptomatic in a short time span and also have prognostic importance. Levels exceeding three to four times the normal value portend a poor prognosis and may be a criterion for referral for valve replacement.

The electrocardiogram (ECG) in patients with aortic stenosis usually shows left ventricular hypertrophy (Chapter 48). In some cases of even severe aortic stenosis, however, left ventricular hypertrophy is absent on the ECG, possibly because of the lack of left ventricular dilation. Left atrial abnormality is common because the stiff left ventricle increases left atrial afterload and causes the left atrium to dilate.

The chest radiograph in aortic stenosis is generally nondiagnostic. The cardiac silhouette is not usually enlarged but may assume a boot-shaped configuration. In advanced cases, there may be signs of cardiomegaly and pulmonary congestion; severe aortic valve calcification may be seen in the lateral view.

Low Flow, Low Gradient Aortic Stenosis

Two types of pathophysiology can reduce cardiac output and reduce the aortic gradient, thereby misleading the clinician into underestimating the severity and clinical gravity of aortic stenosis. The first type occurs in patients who have developed systolic dysfunction, typically from valvular heart disease or coronary artery disease. In such patients, the ejection fraction and stroke volume are reduced, as is the transvalvular gradient. Although these patients have a poorer prognosis than do patients with preserved left ventricular function, many still benefit from aortic valve replacement. The second type is patients who have severe left ventricular hypertrophy, which reduces left ventricular volume. Although the ejection fraction is normal, stroke volume and the valve gradient are reduced. Such patients also usually benefit from valve replacement.

In general, the diagnosis of severe aortic stenosis should not rely on a single diagnostic value or test, and current guidelines deemphasize valve area as the single gold standard of severity. Rather, the findings of the physical examination, jet velocity, transvalvular gradient, valve area, biomarkers, and valve calcium should be viewed in their totality.

Mixed Moderate Aortic Stenosis and Regurgitation

Some patients have combined moderate aortic stenosis and regurgitation, with neither condition by itself mandating therapy. However, symptomatic patients with combined moderate stenosis and moderate regurgitation have a prognosis similar to that of patients with pure severe aortic stenosis if their peak aortic jet velocity is 4.0 m/sec or greater. As a result, they should undergo aortic valve replacement.[4]

TREATMENT

Asymptomatic Patients

In asymptomatic patients, no medical treatment has been shown to delay the progression of stenosis, but careful blood pressure control (Chapter 64) is recommended to minimize pressure overload on the left ventricle. Close follow-up is very important to detect early symptoms, especially in elderly patients who may have other reasons to limit their exercise. In patients with severe asymptomatic aortic stenosis, the prognosis is poor, and data suggest that early aortic valve replacement improves outcomes.[A1,A2] For example, valve replacement may be considered in asymptomatic patients who have left ventricular dysfunction with very high jet velocities (>5 m/second), brain natriuretic peptide values three to four times normal, or positive exercise tolerance test results.

Symptomatic Patients

No accepted effective medical therapy is available for symptomatic aortic stenosis, and valve replacement should be performed as expeditiously as possible.[5] In patients who are awaiting surgery, diuretics can be used cautiously to relieve pulmonary congestion and nitrates may be used very cautiously to treat angina pectoris. However, vasodilation reduces pressure distal to the obstruction, often without increasing cardiac output, and may cause syncope. In rare situations in which surgery is impossible, diuretics can improve symptoms but will not improve life expectancy.

Aortic Valve Procedures

Balloon Aortic Valvuloplasty

Percutaneous balloon aortic valvuloplasty, by which a balloon is inserted via the femoral artery and inflated across the aortic valve to increase its mobility, can provide a temporary reduction in the aortic valve gradient for perhaps 6 to 12 months. This palliation may be useful in inoperable patients and is sometimes used in very advanced patients who have low flow and a low left ventricular ejection fraction to determine whether aortic valve replacement may be of benefit.

Valve Replacement Surgery

Surgical aortic valve replacement, which nearly always requires either a mechanical or bioprosthetic valve, is a proven effective therapy for symptomatic aortic stenosis and for selected asymptomatic patients (see earlier). The one exception is young patients with bicuspid valves, in whom the Ross procedure (an autograft by which the patient's own pulmonic valve is transplanted to the aortic portion and a prosthetic pulmonic valve is implanted) is the preferred operation.[6] Even octogenarians benefit from valve replacement unless other comorbid factors preclude surgery, so aortic valve replacement should not be denied simply on the basis of age. Class I indications for aortic valve replacement include the presence of symptoms or severe disease in patients who are undergoing another cardiac operation. Valve replacement also should not be denied because the ejection fraction is reduced, because the excess afterload imposed by the stenotic valve is relieved with valve replacement, and a depressed ejection fraction usually improves dramatically after surgery. The exception to this rule is a patient who has a severely reduced ejection fraction (<20%) and a low aortic valve gradient (<20 mm Hg); in this case, the severity of the aortic stenosis may be overestimated because the failing left ventricle has difficulty opening a mildly to moderately stenotic valve. In such patients, left ventricular dysfunction either has another cause or is often so severe that it does not recover after valve replacement. Even in this situation, however, patients who demonstrate increased cardiac output during dobutamine infusion may benefit from aortic valve replacement.

Transcatheter Aortic Valve Replacement

Percutaneous transcatheter aortic valve implantation[7] reduces the 1-year mortality rate by 45% (from 51 to 31%) in patients who have severe aortic stenosis and are too ill to undergo open surgery. In addition, outcomes, including mortality at up to 5 years, are as good as or better than standard surgical valve replacement in high-risk, intermediate-risk, and low-risk adults,[A3–A7] using either a balloon-expandable or self-expanding prosthesis. In intermediate-risk patients with noncomplex coronary artery disease, a percutaneous valve replacement with coronary stenting is as good as open valve replacement and coronary artery bypass surgery.[A8]

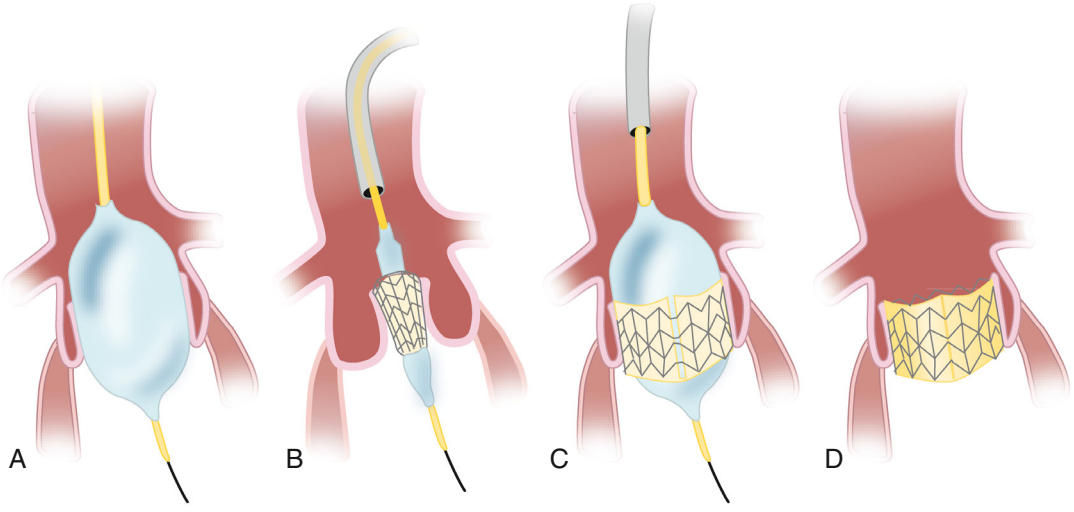

FIGURE 60-3. Steps for transcatheter aortic valve replacement. A, Dilation of the native stenotic valve. **B,** A crimped stented valve has been inserted over a guidewire into the aortic annulus. **C,** Inflation of the balloon deploys the valve. **D,** The balloon is deflated and removed with the aortic valve replaced. (Modified from Cleveland Clinic. Heart valve disease—percutaneous interventions. http://my.clevelandclinic.org/heart/percutaneous/percutaneousValve.aspx.)

It is important to note that major randomized trials of transcatheter aortic valve replacement have been limited to patients who have degenerated tricuspid aortic valves. Emerging data on current devices suggest equivalent outcomes in patients with bicuspid valves or rheumatic aortic disease,[8] but data are limited.

Two types of valves are available throughout much of the world, including the United States. One is a balloon-expandable, a bioprosthetic, stented valve that is crimped onto a balloon catheter, which is advanced across the aortic annulus (Fig. 60-3). The balloon is then inflated to expand the prosthesis and secure it in the native annulus while excluding the diseased valve. In the second type, the tissue valve is sewn into a self-expanding frame and crimped within a delivery catheter, which is advanced across the aortic valve and slowly withdrawn, thereby allowing the prothesis to expand and exclude the diseased valve.

The success of transcatheter aortic valve replacement has resulted in an estimated 100,000 such procedures being performed annually in the United States and exceeding the volume of surgical aortic valve replacement. Rates of stroke are lower with transcatheter aortic valve replacement than with surgical valve replacement; paravalvular regurgitation now occurs rarely. Finally, the rate of structural deterioration of newer transcatheter valves appears to be similar to that of surgical tissue valves, at least in the mid-term. After implantation, 3 months of aspirin alone is preferred over 3 months of dual-antiplatelet therapy in patients who do not have an indication for ongoing anticoagulation.[A9]

PROGNOSIS

In asymptomatic patients with normally functioning or minimally dysfunctional aortic valves, the survival rate is reasonably similar to age-matched control participants, and sudden death is rare, occurring in fewer than 1% of asymptomatic patients. However, mortality is increased with a valve gradient above 20 mm Hg, and about 25% of patients require surgery by 20 years after diagnosis. In adults with asymptomatic but hemodynamically significant aortic stenosis, symptoms typically develop within 5 years. A higher peak aortic jet velocity, heavy valve calcification, a positive exercise test result, severe left ventricular dysfunction, and high brain natriuretic peptide levels predict a worse prognosis and may warrant consideration of valve replacement in asymptomatic patients with severe disease.

The progression of mild to moderate aortic stenosis to severe disease is the key to the natural history of the disease and is quite variable. Aortic stenosis may remain mild for a decade or more in some patients, but it may progress to severe disease in as little as 5 years in other patients.

When symptoms develop, survival declines precipitously. Approximately 35% of patients with aortic stenosis are initially evaluated for angina. Of these, 50% are dead in 5 years unless aortic valve replacement is performed. Approximately 15% have syncope; of these, 50% are dead in only 3 years unless the aortic valve is replaced. Of the 50% with symptoms of heart failure, 50% are dead in 2 years without aortic valve replacement. In all, only 25% of patients with symptomatic aortic stenosis survive 3 years in the absence of valve replacement, and the annual risk for sudden death ranges from 10% in patients with angina to 15% with syncope to 25% with heart failure. After valve replacement surgery, prognosis improves to near normal, especially for patients older than 65 years at the time of valve implantation, presumably because older patients have fewer years at risk for valve-related complications.

MITRAL STENOSIS

EPIDEMIOLOGY

Traditionally the cause of acquired mitral stenosis has been rheumatic heart disease. Although it has become rare in developed countries because of the waning incidence of rheumatic fever, rheumatic mitral stenosis is still prevalent in developing nations, where rheumatic fever is common (Chapter 269). Rheumatic disease is three times more common in women and usually develops in their 40s and 50s. Although the vast majority of mitral stenosis worldwide still results from rheumatic disease, severe age-associated calcification of the mitral annulus and leaflet bases is an increasingly common cause of mitral stenosis in the absence of rheumatic involvement.[9]

PATHOBIOLOGY

At the beginning of diastole, a transient gradient between the left atrium and left ventricle normally initiates left ventricular filling. After early filling, left atrial and left ventricular pressures equilibrate. In mitral stenosis, obstruction to left ventricular filling increases left atrial pressure and produces a persistent gradient between the two chambers (E-Fig. 60-2). The combination of elevated left atrial pressure (and pulmonary venous pressure) and restriction of inflow into the left ventricle limits cardiac output. Although myocardial involvement from the rheumatic process occasionally affects left ventricular muscle function, the muscle itself is normal in most patients with mitral stenosis. However, in approximately one third of patients with mitral stenosis, left ventricular ejection performance is reduced despite normal muscle function because of reduced preload (from inflow obstruction) and increased afterload as a result of reflex vasoconstriction caused by reduced cardiac output.

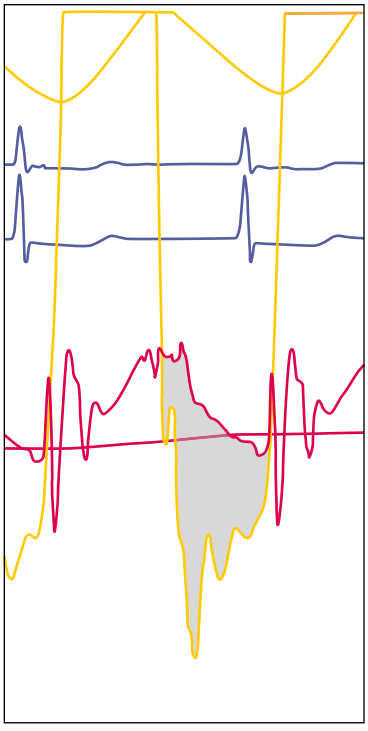
Because the right ventricle generates most of the force that propels flow across the mitral valve, the right ventricle incurs the pressure overload of the transmitral gradient. In addition, secondary but reversible pulmonary vasoconstriction develops, thus further increasing pulmonary artery pressure and the burden on the right ventricle. As mitral stenosis worsens, right ventricular failure develops.

CLINICAL MANIFESTATIONS

Patients with mitral stenosis usually remain asymptomatic until the valve area is reduced to about one third its normal size of 4 to 5 cm^2. Then the symptoms typical of left-sided failure—dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea—develop. As the disease progresses and right ventricular failure occurs, ascites and edema are common. Hemoptysis, which is common in mitral stenosis but uncommon in other causes of left atrial hypertension, develops when high left atrial pressure ruptures the anastomoses of small bronchial veins. In some cases, a large left atrium may impinge on the left recurrent laryngeal nerve and cause hoarseness (Ortner syndrome) or may impinge on the esophagus and cause dysphagia.

Physical Examination

Although mitral stenosis produces typical and diagnostic findings on physical examination, the diagnosis is missed frequently because the auscultatory



E-FIGURE 60-2. **The gradient (gray area) between left atrial pressure *(red tracing)* and left ventricular pressure *(yellow tracing)* in a patient with severe mitral stenosis.**

findings may be subtle. Palpation of the precordium finds a quiet apical impulse. If pulmonary hypertension and right ventricular hypertrophy have developed, the examiner notes a parasternal lift. S_1 is typically loud and may be the most prominent physical finding of the disease. A loud S_1 is present because the transmitral gradient holds the mitral valve open throughout diastole until ventricular systole closes the fully opened valve with a loud closing sound. In far-advanced disease, the mitral valve may be so damaged, however, that it neither opens nor closes well, so S_1 may become soft. S_2 is normally split; the pulmonic component is increased in intensity if pulmonary hypertension has developed. Left-sided S_3 and S_4 gallop sounds, which represent the ventricular and atrial components of rapid left ventricular filling, are exceedingly rare in mitral stenosis because obstruction at the mitral valve prevents rapid filling. S_2 is usually followed by an opening snap. The distance between S_2 and the opening snap provides a reasonable estimation of left atrial pressure and the severity of the mitral stenosis. The higher the left atrial pressure, the sooner the left atrial pressure and the falling left ventricular pressure of early ventricular relaxation equilibrate. At this equilibration point, the mitral valve opens, and the opening snap occurs. When left atrial pressure is high, the opening snap closely (0.06 second) follows S_2. Conversely, when left atrial pressure is relatively normal, the snap occurs later (0.12 second) and may mimic the cadence of an S_3 gallop. The opening snap is followed by the classic low-pitched early diastolic mitral stenosis rumble, which increases in length as the mitral stenosis worsens. This murmur may be inaudible if the patient has a relatively low resting cardiac output. Modest exercise, such as isometric handgrip, may accentuate the murmur's intensity. If the patient is in sinus rhythm, atrial systole may produce a presystolic accentuation of the murmur. If pulmonary hypertension has developed, the pulmonic component of S_2 increases in intensity to become as loud as or louder than the aortic component. With pulmonary hypertension, a diastolic blowing murmur of pulmonary insufficiency (Graham Steell murmur) is often heard, although in many cases, a coexistent murmur of mild aortic insufficiency is mistaken for this murmur. Neck vein elevation, ascites, and edema are present if right ventricular failure has developed.

DIAGNOSIS

Similar to other valvular lesions, an echocardiogram is the most important diagnostic tool in confirming the diagnosis (Fig. 60-4). Transthoracic echocardiography or, if necessary, transesophageal echocardiography makes the diagnosis in nearly 100% of cases and accurately assesses severity. Mitral stenosis, similar to aortic stenosis, can be quantified by assessing the transvalvular gradient with the modified Bernoulli principle. The stenosis is considered severe when the area is smaller than 1.5 cm^2 and very severe when the valve area is smaller than 1.0 cm^2. It is important to keep in mind that gradients are rate dependent. In patients with poorly controlled atrial fibrillation, gradients will be increased owing to decreased diastolic filling time. Therefore, it is important to assess multiple heart beats or obtain better rate control to assess mitral stenosis properly.

During echocardiography, the suitability of the valve for percutaneous balloon mitral valvotomy also can be assessed. Patients with pliable valves, minimal valvular calcification, limited involvement of the subvalvular apparatus, and less than moderate mitral regurgitation are ideal candidates.

In addition to evaluating the mitral valve, echocardiography can be used to evaluate pulmonary artery pressures by measuring the systolic gradient across the tricuspid valve. The elevation of pulmonary pressures is a poor prognostic sign in mitral stenosis and may drive treatment decisions.

Atrial fibrillation is common, especially in patients older than 50 years of age, but left atrial abnormality is generally present on the ECG if the patient is in sinus rhythm. If pulmonary hypertension has developed, there is often evidence of right ventricular hypertrophy.

On the chest radiograph, left atrial enlargement produces straightening of the left heart border and a double density at the right heart border as a result of the combined silhouettes of the right and left atria. Pulmonary venous hypertension produces increased vascularity. Kerley B lines, which represent thickening of the pulmonary septa secondary to chronic venous engorgement, also may be seen.

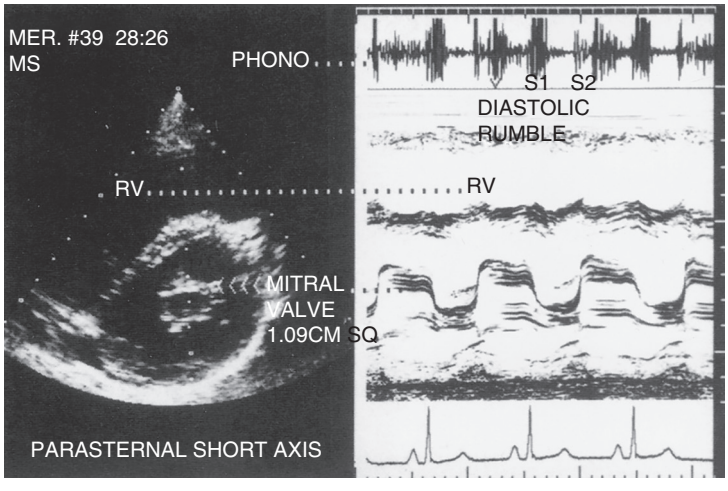


FIGURE 60-4. Mitral stenosis. An *en face* view of a stenotic mitral valve in the short-axis view of the left ventricle is shown on the *left*. Planimetry for the mitral valve orifice yielded an area of 1.09 cm^2. The M-mode echocardiogram on the *right* has been aligned with the appropriate structures on the *left*. It shows the restricted opening of the mitral valve in diastole associated with the classic diastolic rumbling murmur. RV = right ventricle. (From Assey ME, Usher BW, Carabello BA. The patient with valvular heart disease. In: Pepine CJ, Hill JA, Lambert CR, eds. *Diagnostic and Therapeutic Cardiac Catheterization*. 3rd ed. Baltimore: Williams & Wilkins; 1998:709.)

Invasive Evaluation

Cardiac Catheterization

Cardiac catheterization is usually unnecessary to assess the severity of mitral stenosis. Because many patients with mitral stenosis are of an age when coronary disease might be present, however, coronary arteriography is generally performed if cardiac surgery is anticipated or if the patient has coexistent angina. In these cases, it is common to perform left- and right-sided heart catheterization to confirm the transmitral gradient and to calculate the valve area from the Gorlin formula (see earlier).

PREVENTION, TREATMENT, AND PROGNOSIS

Mitral stenosis can be prevented by appropriate antibiotic treatment of β-hemolytic streptococcal infections (Chapter 269).

Medical Therapy

Asymptomatic patients with mitral stenosis and sinus rhythm require no therapy. Symptoms of mild dyspnea and orthopnea can be treated with diuretics alone. When symptoms worsen to more than mild or if pulmonary hypertension develops (resting pulmonary artery systolic pressure > 50 mm Hg), mechanical correction of the stenosis is preferable to medical therapy because it improves longevity in severely symptomatic patients. In patients in whom symptoms are not consistent with resting hemodynamics, exercise testing with either echocardiography or invasive hemodynamic monitoring is reasonable to assess exercise tolerance as well as the expected increases in gradients and pulmonary pressures with exercise.

Patients with mitral stenosis in whom atrial fibrillation develops usually decompensate because the rapid heart rate reduces diastolic filling time, increases left atrial pressure, and decreases cardiac output. The heart rate must be controlled promptly, preferably with an infusion of diltiazem, amiodarone, or esmolol for acute atrial fibrillation or with a β-blocker, a calcium-channel blocker, or oral digoxin in chronic atrial fibrillation (Chapter 52).

Conversion to sinus rhythm is routinely recommended either pharmacologically or with direct-current countershock (Chapter 52) after anticoagulation is therapeutic. It should be noted that patients with rheumatic atrial fibrillation have been excluded from trials of echocardiogram-guided cardioversion without anticoagulation and from trials of rate control versus rhythm control for the chronic management of atrial fibrillation. If sinus rhythm cannot be maintained, mechanical therapy for the mitral stenosis is generally recommended in the hope that sinus rhythm can be restored after the obstruction to atrial outflow is corrected. However, the cause of atrial fibrillation in patients with mitral stenosis probably includes atrial rheumatic inflammation, so restoration of sinus rhythm is unpredictable even after mechanical intervention.

Because patients with concomitant mitral stenosis and atrial fibrillation have an extraordinarily high risk for systemic embolism, they should undergo chronic anticoagulation with warfarin at an international normalized ratio (INR) target of 2.5 to 3.5 unless there is a serious contraindication to its use. It should be noted that atrial fibrillation with rheumatic mitral stenosis or a mechanical heart valve requires vitamin K antagonist anticoagulation instead of direct-acting oral anticoagulants (Chapter 70).

Mechanical Therapy

When symptoms occur with ordinary activity or if pulmonary hypertension develops, prognosis is worse unless the mitral stenosis is relieved. In contrast to aortic stenosis, the valve leaflets are fused at the commissures in mitral stenosis.

As a result, percutaneous balloon dilation produces a commissurotomy, thereby substantially increasing the valve area, and provides improvement comparable to that of open surgical commissurotomy for at least a decade in suitable patients. Even at 20 years, 30% of patients have durable functional benefit. In patients whose anatomy is not suitable for balloon dilation, usually because of significant mitral regurgitation, open surgery with placement of a bioprosthetic or mechanical valve is preferred.

Nonrheumatic mitral stenosis caused by mitral annular calcification does not respond to balloon valvotomy. The only effective mechanical therapy for this condition is surgical debridement of the mitral annulus followed by mitral valve replacement. Because this procedure carries up to a 30% risk, it should be reserved for highly symptomatic patients with an otherwise good life expectancy and performed only by surgeons with experience performing this operation. Clinical trials are ongoing to evaluate the role of transcatheter valve replacement as an option to open surgical therapy in this population.[10]

PRIMARY (ORGANIC) MITRAL REGURGITATION

EPIDEMIOLOGY

The mitral valve is composed of the mitral annulus, the leaflets, the chordae tendineae, and the papillary muscles. Abnormalities in any of these structures may lead to mitral regurgitation. In primary mitral regurgitation, valvular abnormalities cause the valve to leak; the resulting hemodynamic overload, if prolonged and severe, causes left ventricular damage, heart failure, and eventual death if untreated. This condition must be distinguished from secondary or functional mitral regurgitation, wherein disease of the left ventricle causes the valve to leak; this secondary mitral regurgitation is discussed later in this chapter.

The most common cause of primary mitral regurgitation in the United States is mitral valve prolapse, which is responsible for approximately 90% of all cases and comprises many diseases, including myxomatous degeneration of the valve (E-Fig. 60-3). Annular calcification, endocarditis, papillary muscle dysfunction or infarction, collagen vascular disease, and rheumatic heart disease are less common causes. Dopamine receptor agonists such as pergolide, cabergoline and ergot derivatives and serotonin receptor agonists such as fenfluramine when used in high doses and for prolonged periods of time may lead to mitral regurgitation.

Primary mitral regurgitation can be subdivided on the basis of chronicity. Common causes of severe acute mitral regurgitation include ruptured chordae tendineae and infective endocarditis. Chronic severe mitral regurgitation is more likely to be caused by myxomatous degeneration of the valve, rheumatic heart disease, or annular calcification.[11]

PATHOBIOLOGY

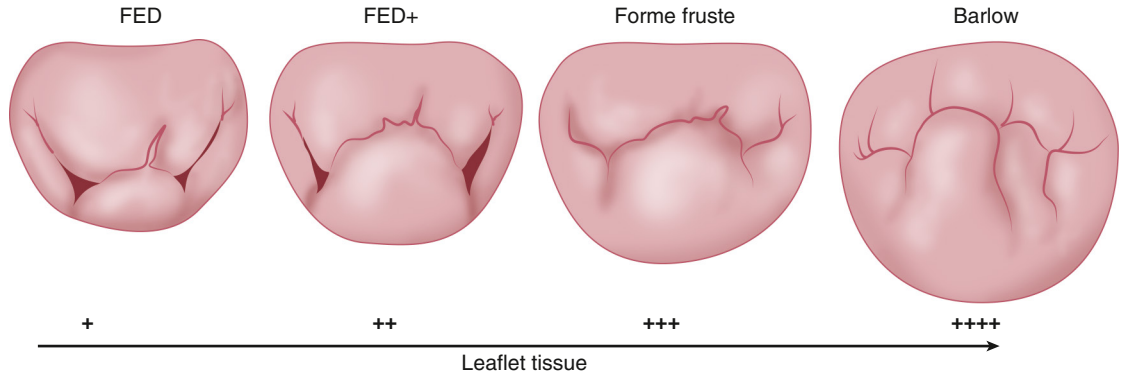
The pathophysiology of mitral regurgitation can be divided into three phases (Fig. 60-5). In acute mitral regurgitation of any cause, the sudden option for ejection of blood into the left atrium "wastes" a portion of the left ventricular stroke volume as backward rather than forward flow. The combined regurgitant and forward flow causes volume overload of the left ventricle and stretches the existing sarcomeres toward their maximum length. Use of the Frank-Starling mechanism is maximized, and end-diastolic volume increases concomitantly. The regurgitant pathway unloads the left ventricle in systole because it allows ejection into the relatively low-impedance left atrium and thereby reduces end-systolic volume. Although increased end-diastolic volume and decreased end-systolic volume act in concert to increase total stroke volume, forward stroke volume is subnormal because a large portion of the total stroke volume is regurgitated into the left atrium. This regurgitant volume increases left atrial pressure, so the patient experiences heart failure with low cardiac output and pulmonary congestion despite normal left ventricular contractile function.

In many cases, severe acute mitral regurgitation necessitates emergency surgical correction. By comparison, patients who can be managed through the acute phase or in whom the valve abnormalities develop more slowly may enter the phase of hemodynamic compensation. In this phase, eccentric left ventricular hypertrophy and increased end-diastolic volume, combined with normal contractile function, allow ejection of a sufficient total stroke volume to permit forward flow to return toward normal. At the same time, left atrial enlargement allows accommodation of the regurgitant volume while maintaining a lower left atrial pressure. In this phase, the patient may be relatively asymptomatic even during strenuous exercise. Although mitral regurgitation is often thought to reduce left ventricular afterload, reduced afterload occurs only in acute, severe, primary mitral regurgitation. In the chronic phase, the increased left ventricular radius returns afterload (wall stress) to normal, and impedance is decreased only in the most severe cases.

	Preload SL (μ)	Afterload ESS (kdyne/cm^2)	CF	EF	RF	FSV (mL)
N	2.07	90	N	.67	.0	100
AMR	2.25	60	N	.82	.50	70
CCMR	2.19	90	N	.79	.5	95
CDMR	2.19	120	↓	.58	.57	65

FIGURE 60-5. Mitral regurgitation (MR). Normal physiology (N) **(A)** is compared with the physiology of acute mitral regurgitation (AMR) **(B)**. Acutely, the volume overload increases preload (sarcomere length [SL]), and end-diastolic volume (EDV) increases from 150 to 170 mL. Unloading of the left ventricle (LV) by the presence of the regurgitant pathway decreases afterload (end-systolic stress [ESS]), and end-systolic volume (ESV) falls from 50 to 30 mL. These changes result in an increase in the ejection fraction (EF). Because 50% of the total LV stroke volume (regurgitant fraction [RF]) is ejected into the left atrium (LA), however, forward stroke volume (FSV) falls from 100 to 70 mL. At this stage, contractile function (CF) is normal. **C,** Chronic compensated mitral regurgitation (CCMR). In CCMR, eccentric cardiac hypertrophy has developed, and EDV has increased substantially. Increased EDV, combined with normal contractile function, permits ejection of a larger total stroke volume and a larger forward stroke volume than in the acute phase. Left atrial enlargement permits lower left atrial pressure. Because the radius term in the Laplace equation has increased with increasing LV volume, afterload and ESV return to normal. **D,** Chronic decompensated mitral regurgitation (CDMR). In this stage, contractile dysfunction causes a large increase in ESV with a fall in total and forward stroke volume. Additional LV enlargement leads to worsening mitral regurgitation. The relatively favorable loading conditions in this phase still permit a normal EF, however, despite contractile dysfunction. (From Carabello BA. Mitral regurgitation: basic pathophysiologic principles. *Mod Concepts Cardiovasc Dis*. 1988;57:53-57.)

Although severe mitral regurgitation may be tolerated for many years, the lesion often causes left ventricular dysfunction, atrial fibrillation, or heart failure within 5 years of the detection of severe mitral regurgitation. The now damaged ventricle has impaired ejection performance, and end-systolic volume increases. Greater left ventricular residual volume at end systole increases end-diastolic volume and end-diastolic pressure, and the symptoms of pulmonary congestion may reappear. Additionally, left ventricular dilation may worsen the amount of regurgitation by causing further enlargement of the mitral annulus and displacement of the papillary muscles, thereby leading to malcoaptation of the mitral leaflets. Although there is substantial contractile dysfunction, the increased preload and the presence of the regurgitant pathway, which mitigates the increased afterload expected from ventricular enlargement, augment the ejection fraction and may maintain it in a relatively normal range.



E-FIGURE 60-3. **Pathology specimens of myxomatous degeneration of the mitral valve showing the progression of disease from its simplest form (fibroelastic deficiency [FED]) to more extensive FED (FED+) to the early stages of a Barlow-type valve (forme fruste) to the highly redundant Barlow type valve.** (From Adams DH, Rosenhek R, Falk V. Degenerative mitral valve regurgitation: best practice revolution. *Eur Heart J*. 2010;31:1958-1966.)

The causes of left ventricular contractile dysfunction in patients with mitral regurgitation may relate to loss of contractile proteins and abnormalities in calcium handling. In at least some cases, contractile dysfunction is reversible by timely mitral valve surgery.

CLINICAL MANIFESTATIONS

In the medical history, the standard symptoms of left-sided heart failure should be sought (Chapter 45). An attempt to discover potential causes should be made by questioning for a history of a heart murmur or abnormal findings on cardiac examination (Chapter 39), rheumatic heart disease, endocarditis (Chapter 61), or the use of anorexigenic drugs.

Volume overload of the left ventricle displaces the apical impulse downward and to the left. S_1 may be reduced in intensity, whereas S_2 is usually physiologically split. In severe mitral regurgitation, S_2 is followed by S_3, which may not indicate heart failure but reflects rapid filling of the left ventricle by the large volume of blood stored in the left atrium during systole. The typical murmur of mitral regurgitation is a holosystolic apical murmur that often radiates toward the axilla (Chapter 39). There is a rough correlation between the intensity of the murmur and the severity of the disease, but this correlation is too weak to use in clinical decision making because the murmur may be soft when cardiac output is low. In contrast to aortic stenosis, murmur intensity does not usually vary with the RR interval. In acute mitral regurgitation, the presence of a large v wave may produce rapid equilibration of left atrial and left ventricular pressure, thereby reducing the driving gradient and shortening the murmur. Pulmonary hypertension may develop and produce right-sided signs, including an right ventricular lift, an increased P_2, and, if right ventricular dysfunction has developed, signs of right-sided heart failure.

DIAGNOSIS

The ECG usually shows left ventricular hypertrophy and left atrial abnormality. The chest radiograph typically shows cardiomegaly; the absence of cardiomegaly indicates either that the mitral regurgitation is mild or that it has not been chronic enough to allow cardiac dilation to occur.

Echocardiography shows the extent of left atrial and left ventricular enlargement (Chapter 43). Ultrasonic imaging of the mitral valve is excellent and offers clues to the mitral valve abnormalities responsible for the regurgitation. In some patients, three-dimensional echocardiography can add pathoanatomic information of potential use in aiding surgical repair of the valve. Color-flow Doppler interrogation of the valve (Fig. 60-6) helps assess the severity of regurgitation, but because this technique images flow velocity rather than actual flow, it is subject to errors in interpretation. The Doppler technique is excellent for excluding the presence of mitral regurgitation and for distinguishing between mild and severe degrees. Newer techniques may quantify regurgitation more precisely but are not applicable in every patient,

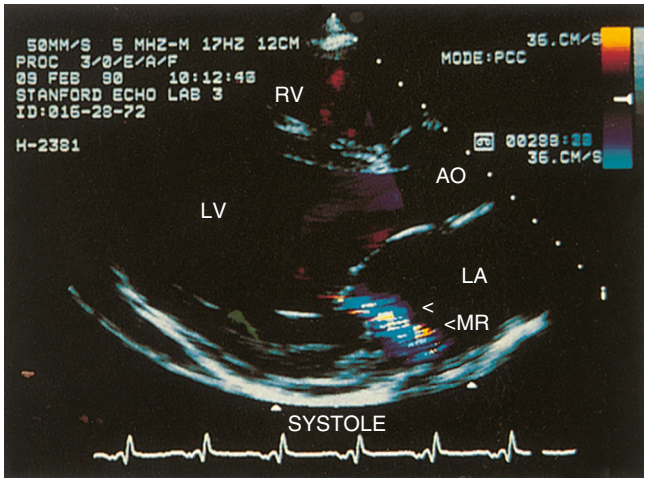


FIGURE 60-6. Two-dimensional echocardiogram of mitral regurgitation with Doppler flow mapping superimposed on a portion of the image. The color information is represented in the sector of the imaging plane extending from the apex of the triangular plane to the two small *arrowheads* at the *bottom* of the image plane. Mitral regurgitation (MR) is indicated *(open arrows)* and extends from the mitral valve leaflets toward the posterior aspect of the left atrium (LA) during systole. The mosaic of colors representing the mitral regurgitant signal is typical of high-velocity turbulent flow. The low-intensity *orange-brown* signal represents flow directed away from the transducer on the chest wall, and the *blue* shades represent blood in the left ventricular outflow tract moving toward the transducer. AO = aorta; LV = left ventricle; RV = right ventricle.

and standard color-flow Doppler examination may not be sufficient for exact quantification of mitral regurgitation or to determine whether the severity of the lesion is sufficient to cause eventual left ventricular dysfunction. Cardiac MRI (Chapter 44), when available, can more precisely quantify the severity of the regurgitation. When the severity of mitral regurgitation is in doubt or if mitral valve surgery is being contemplated, cardiac catheterization (Chapter 59) can be helpful in resolving the severity of the lesion; coronary arteriography should be included in patients older than 40 years or with symptoms suggesting coronary disease (Chapter 56).

TREATMENT AND PROGNOSIS

Medical Therapy

Severe Acute Mitral Regurgitation

In severe acute mitral regurgitation, the patient is usually symptomatic with heart failure or even shock. The goal of medical therapy is to increase forward cardiac output while concomitantly reducing regurgitant volume (Chapter 46). Arterial vasodilators reduce systemic resistance to flow and preferentially increase aortic outflow and simultaneously decrease the amount of mitral regurgitation and left atrial hypertension. If hypotension already exists, vasodilators such as nitroprusside lower blood pressure further and cannot be used. In these cases, intra-aortic balloon counterpulsation (Chapter 93) is preferred if the aortic valve is competent. Counterpulsation increases forward cardiac output by lowering ventricular afterload while augmenting systemic diastolic pressure.

Chronic Symptomatic Mitral Regurgitation

In patients with *symptomatic* mitral regurgitation, angiotensin-converting enzyme (ACE) inhibitors (e.g., lisinopril, 20 mg/day) reduce left ventricular volume and improve symptoms but do not alter outcome and are reserved for inoperable patients. Observational evidence suggests that such patients may benefit from administration of β-blockers. Mitral valve surgery rather than medical therapy is indicated in most symptomatic patients with mitral regurgitation. When atrial fibrillation is present, anticoagulation is indicated.

Chronic Asymptomatic Mitral Regurgitation

Vasodilators have had little effect in reducing left ventricular volume or improving normal exercise tolerance in patients with mitral regurgitation, perhaps because afterload is not usually increased in chronic asymptomatic mitral regurgitation, so there is no definitive indication to begin afterload reduction before symptoms appear. However, hypertension, if present, should be treated with standard guideline-directed therapy (Chapter 64).

Surgical Therapy

The timing of mitral valve surgery must weigh the risks of the operation and placement of a prosthesis, if one is inserted, against the risk for irreversible LV dysfunction if surgery is delayed unwisely. In patients with mitral regurgitation, the native valve often can be repaired, and this option may influence the patient and physician towards earlier surgery.

Types of Mitral Valve Surgery

Mitral Valve Repair

When feasible, mitral valve repair (Fig. 60-7) is the preferred operation.[12] Repair restores valve competence, maintains the functional aspects of the apparatus, and avoids the insertion of a prosthesis. Repair is most applicable in cases of posterior chordal rupture; anterior involvement and rheumatic involvement make repair more difficult. Currently, the percentage of mitral valve surgeries that are valve repair average about 70% across the United States overall, with outcomes that are highly dependent on the skill and experience of the operating physician.

Percutaneous mitral valve repair, with implantation of a clip device via the femoral vein and a transseptal puncture, is less invasive than conventional mitral valve repair but is also less effective than open surgery for eliminating mitral regurgitation.[A10] Percutaneous repair, which is approved in the United States for primary mitral regurgitation in symptomatic patients who are at high risk for surgery, usually leaves the patient with mild to moderate residual regurgitation that does not usually worsen over time.[13]

Mitral Valve Replacement with Preservation of the Mitral Apparatus

In this procedure, a prosthetic valve is inserted, but continuity between the native leaflets and the papillary muscles is maintained. This procedure has the advantage of ensuring mitral valve competence while preserving the functional aspects of the mitral apparatus in the left ventricle. Even if only the posterior leaflets and chordae are preserved, the patient benefits from improved postoperative ventricular function and possibly better survival. Although the patient benefits from restored mitral valve competence and maintenance of left ventricular function, insertion of a prosthesis still carries all prosthesis-associated risks. Operative mortality with all mitral valve replacement operations is at least twice as high as with mitral valve repair.

Mitral Valve Replacement without Preservation of the Mitral Apparatus

When the native valve cannot be repaired or the chordae preserved, such as in severe rheumatic deformity, the mitral valve leaflets and its apparatus are

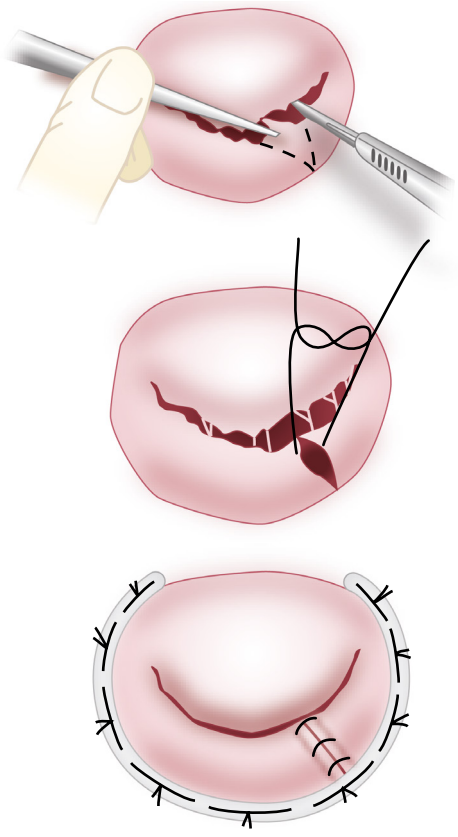

FIGURE 60-7. The stages of mitral valve repair. (Modified from Cleveland Clinic. Mitral valve repair. http://my.clevelandclinic.org/heart/disorders/valve/mvrepair.aspx.)

removed and a prosthetic valve is inserted. Although this operation almost guarantees mitral valve competence, the mitral valve apparatus is responsible for coordinating left ventricular contraction and for helping maintain the efficient prolate ellipsoid shape of the left ventricle. Destruction of the apparatus leads to a sudden fall in left ventricular function and a decline in postoperative ejection fraction that is often permanent.

Transcatheter Mitral Valve Replacement

Transcatheter mitral valve replacement has been used especially in patients who are unsuitable for repair, such as patients who have severe mitral annular calcification and have an extremely high operative risk.[14] Although the technical success rate has been promising, the procedure is still experimental.

Timing of Surgery

Symptomatic Patients

Most patients with symptoms of dyspnea, orthopnea, or fatigue should undergo surgery regardless of which operation is performed because they already have lifestyle limitations from their disease. The mere presence of symptoms worsens the prognosis despite relatively well-preserved left ventricular function. The onset or worsening of symptoms is a summary of the patient's pathophysiology and may give a broader view of cardiovascular integrity than possible with any single measurement of pressure or function. For patients with acute mitral regurgitation owing to flail mitral valve leaflets, earlier surgery appears to be better than prolonged medical management, but randomized trials have not been performed.

Asymptomatic Patients with Normal Left Ventricular Function

Surgery has increasingly been considered in asymptomatic patients who have normal left ventricular function but echocardiographic findings indicating that valve repair is likely to be successful. Although these patients are at low risk with continued medical therapy, early surgery reduces the risks of subsequent left ventricular dysfunction or atrial fibrillation and should be considered if the risk associated with valve repair is less than 1% because lifespan can be normal if successful repair is performed before left ventricular dysfunction has developed. This approach is sensible, however, only if it is certain that valve repair can be performed, because insertion of a prosthesis carries unacceptable risk in this low-risk group.

Asymptomatic Patients with Left Ventricular Dysfunction

The onset of left ventricular dysfunction in patients with mitral regurgitation may occur without causing symptoms. Early surgery is warranted to prevent the muscle dysfunction from becoming severe or irreversible. Regardless of whether valve repair or replacement is eventually performed, survival is prolonged if surgery is performed before the ejection fraction declines to less than 60% or the left ventricular end-systolic dimension increases beyond 40 mm. Elevated brain natriuretic peptide levels and deterioration of global longitudinal strain also may be considered as adjuncts to the decision for surgery. Patients with severe mitral regurgitation should be monitored yearly with a history, physical examination, and echocardiographic evaluation of left ventricular function. When the patient reports symptoms or echocardiography shows the onset of left ventricular dysfunction, surgery should be undertaken. However, it is not necessary to wait until these thresholds are reached to recommend surgery. If it is clear that valve repair is highly likely and the patient is approaching these indications for intervention, surgery should be considered at that time.

Asymptomatic Elderly Patients

Among Medicare recipients, the operative mortality rate is 4% for patients undergoing mitral valve repair and 9% for patients undergoing replacement. Even in patients who have no comorbid conditions, the mortality rates are 2% for repair and 4% for replacement. Patients older than 75 years of age may have poorer surgical results than younger patients, especially if coronary disease is present or if mitral valve replacement rather than repair must be performed. As a result, there is little compelling reason to commit elderly asymptomatic patients to a mitral valve operation.

MITRAL VALVE PROLAPSE

DEFINITION

Mitral valve prolapse occurs when one or both of the mitral valve leaflets prolapse during systole beyond the mitral valve annular plane and into the left atrium. The importance of mitral valve prolapse varies from patient to patient. In some cases, prolapse is simply a consequence of normal left ventricular physiology without significant medical impact, such as in situations that produce a small left ventricle (e.g., the Valsalva maneuver or an atrial septal defect), in which reduction of ventricular volume causes relative lengthening of the chordae tendineae and subsequent mitral valve prolapse. At the other end of the spectrum, severe redundancy and deformity of the valve, which occur in myxomatous valve degeneration, increase the risk for stroke, arrhythmia, endocarditis, and progression to severe mitral regurgitation.[15]

DIAGNOSIS

History

Most patients with mitral valve prolapse are asymptomatic. In some cases, however, mitral valve prolapse is associated with symptoms, including palpitations, syncope, and chest pain. In some cases, chest pain indicates true myocardial ischemia despite normal epicardial coronary arteries, perhaps because excessive tension on the papillary muscles increases oxygen consumption. Palpitations, syncope, and presyncope, when present, are linked to autonomic dysfunction (Chapters 39, 49, and 386), which appears to be more prevalent in patients with mitral valve prolapse.

Physical Examination

On physical examination, the mitral valve prolapse syndrome produces the characteristic findings of a midsystolic click and a late systolic murmur. The click occurs when the chordae tendineae are stretched taut by the prolapsing mitral valve in mid-systole. As prolapse occurs, the mitral leaflets move past their coaptation point, permit mitral regurgitation, and cause the late systolic murmur (see Table 39-7 in Chapter 39). Maneuvers that make the left ventricle smaller, such as the Valsalva maneuver, cause the click to appear earlier and the murmur to be more holosystolic and often louder (see Table 39-8 in Chapter 39). In some cases of echocardiographically proven mitral valve prolapse, neither the click nor the murmur is present; in other cases, only one of these findings is present.

Noninvasive Evaluation

Echocardiography is useful to prove that prolapse is present, to image the amount of regurgitation and its physiologic effects, and to discern the pathoanatomy of the mitral valve. Although an echocardiogram is not necessary to diagnose prolapse in patients with the classic physical findings, the echocardiogram adds significant prognostic information because it can detect patients who have specifically abnormal valve morphology and in whom most of the complications of the disease occur.

TREATMENT

Because most cases of mitral valve prolapse are asymptomatic, therapy is usually unnecessary and prophylaxis against infective endocarditis is not recommended (Chapter 61). In patients with palpitations and autonomic dysfunction, β-blockers are often effective in relieving symptoms. If severe mitral regurgitation or a flail mitral leaflet develops, the therapy is the same as for other causes of mitral regurgitation. If surgical valve repair is chosen, leaflet preservation and leaflet resection provide equivalent results.[A11]

PROGNOSIS

Most patients with mitral valve prolapse, even patients with redundant and misshapen mitral leaflets, have a benign clinical course. Approximately 10% of patients with thickened leaflets experience infective endocarditis, stroke, progression to severe mitral regurgitation, or sudden death. The progression to severe mitral regurgitation varies with gender and age, and men are approximately twice as likely to progress as women. By 50 years of age, only approximately 1 in 200 men requires surgery to correct mitral regurgitation. By the age of 70 years, the risk increases to approximately 3%.

SECONDARY (FUNCTIONAL) MITRAL REGURGITATION

DEFINITION

Secondary or functional mitral regurgitation is a very different disease than primary mitral regurgitation. In primary mitral regurgitation, treating the mitral regurgitation cures the patient. Conversely, secondary mitral regurgitation is typically a consequence of left ventricular myocardial dysfunction, usually caused by myocardial infarction or dilated cardiomyopathy,[16] but sometimes occurs when atrial fibrillation results in annular dilatation and leaflet malcoaptation.[17] Because treating secondary mitral regurgitation cannot reverse those entities, the role of valve therapy is often unclear.

EPIDEMIOLOGY

An estimated 6 million Americans have heart failure (Chapters 45 and 46), and about half of them have heart failure with a reduced ejection fraction. About 75% of these latter patients also have some degree of secondary mitral regurgitation, which is severe in about 20% of them.

PATHOBIOLOGY

In secondary mitral regurgitation, the valve itself is normal. Regurgitation occurs because of leaflet malcoaptation that results from either displacement of the papillary muscles in patients with left ventricular dysfunction or annular dilatation in patients with atrial fibrillation. Mitral closing is further impaired by mitral annular dilation and reduced closing force from the weakened myocardium.

CLINICAL MANIFESTATIONS

Because virtually all patients with secondary mitral regurgitation have heart failure, almost all complain of the symptoms of heart failure. Some may note a worsening of symptoms when more than mild secondary mitral regurgitation develops. Probably because the mitral valve itself is normal, as well as because of the weakened force of contraction, the murmur of functional mitral regurgitation may be unimpressive or even inaudible.

DIAGNOSIS

Echocardiography is the mainstay of the diagnosis. In addition to evaluating the severity of the mitral regurgitation itself, the echocardiogram is helpful in establishing the extent of the dilated cardiomyopathy or of the prior myocardial infarction that is responsible for causing the secondary mitral regurgitation.

TREATMENT AND PROGNOSIS

The presence of mitral regurgitation in patients with systolic dysfunction is associated with worsened prognosis, which in turn probably reflects both poorer left ventricular function and the imposition of an extra volume overload on an already weakened left ventricle.

Because almost all patients with secondary mitral regurgitation have heart failure, the primary treatment is standard treatment for heart failure (Chapter 46). For secondary functional mitral regurgitation owing to heart failure with left ventricular dilation, the combination of sacubitril/valsartan (49/51 mg twice daily, titrated as tolerated at 4-week intervals to a maximum dose of 97/103 mg twice daily) is better than valsartan alone for reducing regurgitation.[A12] Many patients with secondary mitral regurgitation also have conducting system abnormalities, and patients with left bundle branch block may benefit from cardiac resynchronization therapy (Chapters 46 and 54), which improves systolic function while often reducing secondary mitral regurgitation, sometimes even eliminating it. When these therapies fail to relieve symptoms, surgical treatment can be considered.[18]

For severe *ischemic mitral regurgitation*, mitral valve repair and chordal-sparing mitral valve replacement provide equivalent clinical outcomes at 1 and 2 years, although replacement results in less residual mitral regurgitation and is associated with less severe heart failure, fewer heart failure–related adverse events, and fewer cardiovascular admissions.[A13] For moderate ischemic mitral regurgitation, mitral valve repair does not clearly add benefit above and beyond the benefits of coronary artery bypass surgery.[A14]

For *mitral regurgitation secondary to heart failure*, several studies have shown percutaneous mitral repair to be no better than optimal medical therapy[A15] or open surgery,[A16] but one trial demonstrated better survival than medical therapy.[A17] However, the average survival rate at 5 years is about 50%, and this figure has not changed much over the past several decades.

AORTIC REGURGITATION

DEFINITION

Aortic regurgitation is caused either by abnormalities of the aortic leaflets or by abnormalities of the proximal aortic root. Leaflet abnormalities causing aortic regurgitation include a bicuspid aortic valve, infective endocarditis, and rheumatic heart disease. Dopamine receptor agonists and serotonin receptor agonists have also been implicated. Common aortic root abnormalities that cause aortic regurgitation include Marfan syndrome (Chapter 239), hypertension-induced annuloaortic ectasia, aortic dissection (Chapter 63), syphilis (Chapter 295), ankylosing spondylitis (Chapter 244), and psoriatic arthritis (Chapter 244). Acute aortic regurgitation is usually caused by infective endocarditis (Chapter 61) or aortic dissection.

PATHOBIOLOGY

As with mitral regurgitation, aortic regurgitation imparts a volume overload on the left ventricle because it must pump the forward flow entering from the left atrium and the regurgitant volume returning through the incompetent aortic valve. Also as with mitral regurgitation, the volume overload is compensated for by the development of eccentric cardiac hypertrophy, which increases chamber size and allows the ventricle to pump a greater total stroke volume and a greater forward stroke volume. Ventricular enlargement also accommodates the volume overload at a lower filling pressure. Because pulse pressure is proportional to stroke volume and elastance of the aorta, the increased stroke volume increases systolic pressure. Systolic hypertension leads to afterload excess, which does not generally occur in mitral regurgitation. Accordingly, ventricular geometry also differs between mitral and aortic regurgitation because the afterload excess in aortic regurgitation causes a modest element of concentric hypertrophy, as well as severe eccentric hypertrophy.

In acute aortic insufficiency, such as might occur in infective endocarditis, severe volume overload of the previously unprepared left ventricle results in a sudden fall in forward output while precipitously increasing left ventricular filling pressure. It is probably this combination of pathophysiologic factors that leads to rapid decompensation, presumably because the severely diminished gradient for coronary blood flow causes ischemia and progressive deterioration in left ventricular function. In acute aortic insufficiency, reflex vasoconstriction increases peripheral vascular resistance. In compensated chronic aortic insufficiency, vasoconstriction is absent, and vascular resistance may be reduced and contribute to the hyperdynamic circulation observed in these patients.

CLINICAL MANIFESTATIONS

The most common symptoms from chronic aortic regurgitation are those of left-sided heart failure (Chapter 45); that is, dyspnea on exertion, orthopnea, and fatigue. In acute aortic regurgitation, cardiac output and shock may develop rapidly. The onset of symptoms in patients with chronic aortic regurgitation usually heralds the onset of left ventricular systolic dysfunction. Some patients with symptoms have apparently normal systolic function, however, and the symptoms may be attributed to diastolic dysfunction. Other patients may have ventricular dysfunction yet remain asymptomatic.

Angina may also occur in patients with aortic insufficiency but less commonly than in patients with aortic stenosis. Coronary blood flow reserve is reduced in some patients because diastolic runoff into the left ventricle lowers aortic diastolic pressure while increasing left ventricular diastolic pressure; these two influences lower the driving pressure gradient for flow across the coronary

bed. When angina occurs in aortic regurgitation, it may be accompanied by flushing. Other symptoms include carotid artery pain and an unpleasant awareness of the heartbeat.

DIAGNOSIS

Physical Examination

Chronic aortic regurgitation produces a myriad of signs because a hyperdynamic, enlarged left ventricle ejects a large stroke volume at high pressure into the systemic circulation. Palpation of the precordium finds a hyperactive apical impulse displaced downward and to the left. S_1 and S_2 are usually normal. S_2 is followed by a diastolic blowing murmur heard best along the left sternal border with the patient sitting upright. In mild disease, the murmur may be short and heard only in the beginning of diastole when the gradient between the aorta and the left ventricle is highest. As the disease worsens, the murmur may persist throughout diastole. A second murmur, a mitral valve rumble, is heard at the left ventricular apex in patients with severe aortic insufficiency. Although the cause is still debated, this Austin Flint murmur is probably produced as the regurgitant jet impinges on the mitral valve and causes it to vibrate.

In chronic aortic regurgitation, the high stroke volume and reduced systemic arterial resistance result in a wide pulse pressure, which may generate a number of signs, including Corrigan pulse (sharp upstroke and rapid decline of the carotid pulse), de Musset sign (head bobbing), Duroziez sign (combined systolic and diastolic bruits created by compression of the femoral artery with the stethoscope), and Quincke pulse (systolic plethora and diastolic blanching in the nail bed when gentle traction is placed on the nail). Perhaps the most reliable of physical signs indicating severe aortic regurgitation is Hill sign, an increase in femoral systolic pressure of 40 mm Hg or more compared with systolic pressure in the brachial artery.

In contrast to chronic aortic insufficiency with its myriad clinical signs, acute aortic insufficiency may have a subtle manifestation. The eccentric hypertrophy, which compensates for chronic aortic insufficiency, has not yet had time to develop, and the large total stroke volume responsible for most of the signs of chronic aortic insufficiency is absent. The only clues to the presence of acute aortic insufficiency may be a short diastolic blowing murmur and reduced intensity of S_1. This latter sign occurs because high diastolic left ventricular pressure closes the mitral valve early in diastole (mitral valve preclosure) so that when ventricular systole occurs, only the tricuspid component of S_1 is heard.

Noninvasive Evaluation

The ECG in patients with aortic insufficiency is nonspecific but almost always demonstrates left ventricular hypertrophy. The chest radiograph shows an enlarged heart, often with uncoiling and enlargement of the aortic root.

Echocardiography (Chapter 43) is the most important noninvasive tool for assessing the severity of aortic insufficiency and its impact on left ventricular geometry and function (Fig. 60-8). During echocardiography, the left ventricular end-diastolic dimension, end-systolic dimension, and fractional shortening are determined. Aortic valve anatomy and aortic root anatomy can be assessed, and the cause of the aortic regurgitation often can be determined. Color-flow Doppler examination of the aortic valve helps quantify the severity of aortic regurgitation by assessing the depth and width to which the diastolic jet penetrates the left ventricle. Another way to assess the severity of aortic regurgitation is the pressure half-time method: continuous-wave Doppler interrogation of the aortic valve displays the decay of the velocity of retrograde flow across the valve. In mild aortic insufficiency, the gradient across the valve is high throughout diastole, and its rate of decay is slow, with production of a long Doppler half-time (the time that it takes the velocity to decay from its peak to that value divided by the square root of 2). In severe aortic regurgitation, pressure in the aorta and pressure in the left ventricle equilibrate rapidly, and the Doppler half-time is short. In cases in which the severity of aortic insufficiency is in doubt, MRI can quantify regurgitant flow or catheterization with aortography can visualize regurgitant flow to resolve the issue.

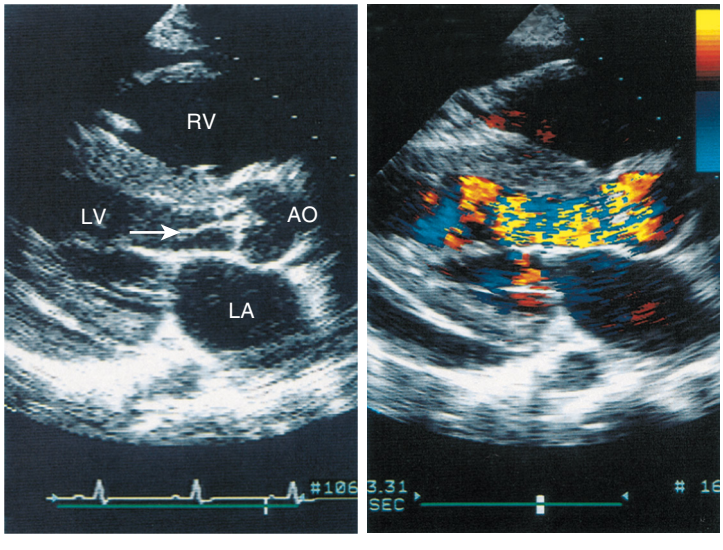

FIGURE 60-8. Echocardiogram of a patient with aortic regurgitation caused by infective endocarditis. The *left panel* shows a linear vegetation *(arrow)* prolapsing into the left ventricular (LV) outflow tract from the aortic valve leaflet in diastole. The *right panel* is a color-flow Doppler image exhibiting turbulent blood flow filling the LV tract during diastole. AO = aorta; LA = left atrium; RV = right ventricle. (Courtesy of Dr. Anthony DeMaria.)

TREATMENT AND PROGNOSIS

Acute Aortic Regurgitation

When any of the symptoms or signs of heart failure develop, even if mild, the medical mortality rate is high and approaches 75%. Echocardiographic evidence of preclosure of the mitral valve from high diastolic intracavitary left ventricular pressure is an especially ominous sign and an indication for urgent surgery. Therapy with vasodilators, such as nitroprusside, may temporarily improve the patient's condition before surgery but is never a substitute for surgery. In patients with acute aortic regurgitation caused by bacterial endocarditis (Chapter 61), surgery may be delayed to permit a full or partial course of antibiotics, but persistent, severe aortic regurgitation requires emergency valve replacement. Even when blood cultures have been positive recently and antibiotic therapy has been of brief duration, the valve reinfection rate is low, 0 to 10%, with valve replacement or valve repair. Emergency surgery should not be withheld simply because the duration of antibiotic therapy has been brief.

Chronic Aortic Regurgitation

Asymptomatic Patients

Because aortic regurgitation increases left ventricular afterload, which decreases cardiac efficiency, afterload reduction with nifedipine and other vasodilators, including ACE inhibitors, improves hemodynamics in the short term but does not reliably delay or reduce the need for aortic valve surgery. When hypertension accompanies aortic regurgitation, it should be treated according to standard guidelines (Chapter 64).

Asymptomatic patients who manifest evidence of left ventricular dysfunction benefit from surgery. When the left ventricular ejection fraction is less than 50% or the end-systolic dimension is greater than 50 mm, postoperative outcome is impaired, presumably because these markers indicate that left ventricular dysfunction has developed. Data suggest that surgery should be timed even before an end-systolic dimension of 45 mm has been reached.[19] A calculated regurgitant orifice above 30 mm^2 portends a poorer prognosis and may warrant surgery.

Symptomatic Patients or Patients with Left Ventricular Dysfunction

Patients who have symptoms or manifest left ventricular dysfunction should not be treated medically, except for short-term stabilization, but should undergo aortic valve surgery as soon as feasible before symptoms compromise their lifestyle. Although some patients may be able to undergo successful aortic valve repair to restore aortic valve competence, most patients require insertion of an aortic valve prosthesis.

TRICUSPID REGURGITATION

DEFINITION

As the population ages, the prevalence of tricuspid regurgitation has increased. Tricuspid regurgitation is usually caused by the hemodynamic load on the right ventricle, owing to pulmonary hypertension, an intracardiac shunt, left ventricular dysfunction, or mitral or aortic valve disease, rather than by a structural valve deformity. Because most of the force that is needed to fill the left ventricle is provided by the right ventricle, left ventricular dysfunction leading to elevated left ventricular filling pressure also places the right ventricle under a hemodynamic load and can eventually lead to right ventricular failure and tricuspid regurgitation. Another frequent cause of tricuspid regurgitation is atrial fibrillation, which can lead to annular dilatation and regurgitation on the right side similar to what happens on the left side with the mitral valve.[20] Less commonly, tricuspid regurgitation may be caused by pathology of the

valve itself, usually from infective endocarditis, typically stemming from intravenous drug abuse and unsterile injections (Chapter 61). Other causes include trauma (especially from hitting the steering wheel or dashboard in motor vehicle accidents), carcinoid syndrome (Chapter 213), rheumatic involvement of the tricuspid valve, myxomatous degeneration, and right ventricular infarction. Pacemaker leads placed across the tricuspid valve can also lead to significant tricuspid regurgitation by tethering the leaflets and preventing leaflet coaptation.[21]

DIAGNOSIS

The traditional symptoms of tricuspid regurgitation are those of right-sided heart failure (Chapter 45), including ascites, edema, and occasionally right upper quadrant pain. However, some patients may present with atypical symptoms of low cardiac output such as fatigue and dyspnea. In elderly patients, these symptoms often can be difficult to attribute solely to the tricuspid valve because they often have other comorbid conditions that could be responsible.

On physical examination, tricuspid regurgitation produces jugular venous distention accentuated by a large v wave as blood is regurgitated into the right atrium during systole. Regurgitation into the hepatic veins causes hepatic enlargement and liver pulsation. Right ventricular enlargement is detected as a parasternal lift. Ascites and edema are common. The murmur of tricuspid regurgitation is a holosystolic murmur heard along the left sternal border, often increasing with inspiration. The murmur may be faint, and it usually can be heard only under the best auscultatory conditions.

The definitive diagnosis of tricuspid regurgitation is made by echocardiography. Doppler interrogation of the tricuspid valve shows systolic disturbance of the right atrial blood pool. Echocardiography (Chapter 43) also can be used to determine the severity of pulmonary hypertension, measure right ventricular dilation and function, and assess whether the valve itself is intrinsically normal or abnormal.

TREATMENT AND PROGNOSIS

Therapy for secondary tricuspid regurgitation is generally aimed at the cause of the lesion. If left ventricular failure has been responsible for right ventricular failure and tricuspid regurgitation, the standard therapy for improving left ventricular failure (Chapter 46) lowers left ventricular filling pressure, reduces secondary pulmonary hypertension, relieves some of the hemodynamic burden of the right ventricle, and partially restores tricuspid valve competence. If pulmonary disease is the primary cause, therapy is directed toward improving lung function. Medical therapy directed at tricuspid regurgitation is usually limited to diuretics because the vasodilators that are so useful in the treatment of left-sided heart failure are often ineffective in treating pulmonary hypertension. However, a number of options can improve late-stage symptoms that are primarily caused by the pulmonary hypertension itself (Chapter 69).

Transcatheter repair[22] of severe tricuspid regurgitation can improve quality of life.[A18] Open surgical intervention for the tricuspid valve is rarely entertained in isolation. However, if other cardiac surgery is planned in a patient with severe tricuspid regurgitation, concomitant ring annuloplasty or tricuspid valve repair is frequently attempted to ensure postoperative tricuspid competence. Because a second operation to address residual tricuspid regurgitation after successful left-sided valve surgery carries an unacceptably high mortality rate, concomitant tricuspid annuloplasty is now entertained for even mild to moderate tricuspid regurgitation during left-sided valve surgery if annular dilatation is present. For example, concurrent tricuspid valve repair at the time of mitral valve surgery for mitral regurgitation reduces the likelihood of progressive tricuspid regurgitation but has not been shown to reduce subsequent all-cause mortality.[A19,A20] Tricuspid valve replacement is often not well tolerated and is rarely performed except when severe deformity, as is often seen in endocarditis or carcinoid disease, precludes valve repair.

PULMONIC STENOSIS

DEFINITION

Pulmonic stenosis is a congenital disease resulting from fusion of the pulmonic valve cusps (Chapter 55). It is usually detected and corrected during childhood, but occasionally cases are diagnosed for the first time in adulthood. Symptoms of pulmonic stenosis include angina and syncope. Occasionally, symptoms of right-sided heart failure develop. During physical examination, the uncalcified valve in pulmonic stenosis produces an early systolic ejection click on opening. During inspiration, the click diminishes or disappears because increased flow into the right side of the heart during inspiration partially opens the pulmonic valve in diastole so that systole causes less of an opening sound. The click is followed by a systolic ejection murmur that radiates to the base of the heart. If the transvalvular gradient is severe, right ventricular hypertrophy develops and produces a parasternal lift.

The diagnosis of pulmonic stenosis is confirmed by echocardiography, which quantifies the transvalvular gradient and the degree of right ventricular hypertrophy and dysfunction.

TREATMENT AND PROGNOSIS

In asymptomatic patients with a gradient less than 25 mm Hg, no therapy is required. If symptoms develop or the gradient exceeds 50 mm Hg, balloon commissurotomy is effective in reducing the gradient, improving right ventricular function, and relieving symptoms.[23] Although long-term prognosis is not yet established, 90% of patients do not require reintervention 10 years after balloon therapy. If pulmonary valve replacement is required, the transcatheter approach generally provides excellent outcomes.[24]

CHOICES AMONG PROSTHETIC VALVES

Different types of prosthetic valves (Fig. 60-9) have different advantages and disadvantages (Table 60-2). At long-term follow-up, primary valve failure with resulting need for reoperation is much more common with bioprosthetic valves, and bleeding is generally more common with mechanical valves. For mitral valves, long-term survival is similar with bioprosthetic and mechanical valves. Survival after aortic valve replacement is probably better with mechanical valves, except for young patients with congenital bicuspid aortic stenosis, in whom the Ross procedure is preferred.[25]

In general, a tissue valve is recommended in patients who have a life expectancy of less than 15 years or who are unable or unwilling to maintain warfarin anticoagulation. The choice of tissue valve is left to the implanting surgeon because no randomized trials have compared tissue valves to each other. A mechanical valve is preferred in patients who already have another indication for anticoagulation or who have a longer life expectancy and want to minimize the risk of reoperation. Because many patients prefer the risk of reoperation to that of anticoagulation, the age at which bioprostheses are implanted has steadily declined, and many 60-year-old patients now request and receive a bioprosthetic valve.

Reoperations to replace prosthetic valves are required when the valve becomes stenotic or regurgitant. Prosthetic valve failure is much more common in bioprosthetic valves compared with mechanical valves. For unclear reasons, bioprosthetic failure occurs more rapidly in younger patients, especially patients younger than age 50 years. Transcatheter aortic valve replacement is an alternative to open surgery in patients with an uninfected, nonthrombosed prior aortic bioprosthesis that now needs replacement.[26] Emerging data also support the use of transcatheter mitral valve insertion in patients who have a dysfunctional but noninfected or thrombosed mitral bioprosthesis and are at high risk for repeat open surgery.[27]

POSTOPERATIVE CARE OF PATIENTS WITH SUBSTITUTE HEART VALVES

After a prosthetic valve has been inserted, a baseline echocardiogram should be obtained to provide a reference point in the event that valve dysfunction is suspected at a later date. Echocardiography does not need to be repeated unless the patient's clinical status or physical findings change. The major causes of mechanical valve dysfunction are infective endocarditis and thrombus formation. For bioprostheses, endocarditis is also a risk, but valve degeneration, which can cause either stenosis or regurgitation, is a major concern.

Whenever a patient with a prosthetic heart valve has a temperature higher than 100° F, endocarditis must be excluded by blood culture; for fever with signs of sepsis, broad-spectrum antibiotics must be begun while awaiting culture results. For patients with bioprosthetic valves, mechanical prostheses, and homografts, endocarditis prophylaxis should be instituted at the time of procedures that are associated with a high risk for bacteremia (Chapter 61). Whether prophylaxis is necessary for a pulmonary autograft after the Ross procedure is currently unclear, but physicians usually prescribe prophylaxis for these patients.

All patients with a mechanical heart valve require warfarin anticoagulation. Recommended INR values range from 2.0 (1.5 for the On-X aortic valve) for a young normotensive patient in sinus rhythm with an aortic valve prosthesis to 3.5 for a patient with atrial fibrillation and a mitral valve prosthesis. Aspirin 75 to 100 mg/day added to warfarin may be beneficial in patients who have a separate indication for antiplatelet therapy. Direct-acting anticoagulants such as dabigatran are associated with more thrombosis and bleeding in patients with mechanical prosthetic valves[A21] and should not be used. Direct-acting oral anticoagulants are, however, appropriate for patients who have atrial fibrillation in the setting of a bioprosthetic valve.[A22] When thrombosis occurs on a prosthetic

FIGURE 60-9. Prosthetic aortic valves. TABLE 60-2 ADVANTAGES AND DISADVANTAGES OF SUBSTITUTE CARDIAC VALVES

TYPE OF VALVE	ADVANTAGES	DISADVANTAGES
Bioprosthesis (Carpentier-Edwards, Hancock)	Avoids anticoagulation in patients with sinus rhythm	Durability limited to 10-15 yr Relatively stenotic
Mechanical valves (St. Jude)	Good flow characteristics in small sizes	Require anticoagulation
Homografts and autografts	Anticoagulation not required Durability increased over that of bioprostheses	Surgical implantation technically demanding

valve, about 60% of patients can have restored valve function after intravenous infusion of a thrombolytic agent. In patients with periprosthetic paravalvular leaks, a percutaneous procedure can successfully close about 85% of the leaks.

61 INFECTIVE ENDOCARDITIS

VANCE G. FOWLER, JR., ARNOLD S. BAYER, AND LARRY M. BADDOUR

DEFINITION

Infective endocarditis is defined as an infection, usually bacterial, of the endocardial surface of the heart. Infective endocarditis affects primarily the cardiac valves, although in some cases the septa between the chambers, the mural endocardium, or cardiovascular implantable electronic devices (e.g., pacemakers) may be involved. In the past, infective endocarditis was categorized as "acute" or "subacute," based on the duration of symptoms before presentation. However, these strict categories have proven to be unreliable, so clinical classification considers the causative organism, the involved valve, and the "pace" of clinical disease.

EPIDEMIOLOGY

The true incidence of infective endocarditis is difficult to determine because of the different criteria for diagnosis and methods of reporting. An analysis based on strict case definitions reveals that only a relatively small proportion (≈20%) of clinically diagnosed cases are categorized as "definite." In 10 large surveys, infective endocarditis accounted for approximately one case per 1000 U.S. hospital admissions, with a range of 0.16 to 5.4 cases per 1000 admissions. Estimates from the American Heart Association (AHA) place the incidence of infective endocarditis in the United States at 10,000 to 20,000 new cases per year. Recent data also suggest that rates of *Staphylococcus aureus* infective endocarditis have increased significantly, in part due to an increase in injection drug use (Chapter 365) as part of the current opioid epidemic, as well as the increasing use of implantable cardiac devices.[1]

Men are more commonly affected than women (mean male : female ratio, 1.7 : 1 in 18 large series). However, in patients younger than 35 years, more cases occur in women. More than 50% of patients with infective endocarditis in the United States are now older than 50 years of age, due in part to the low incidence of acute rheumatic heart disease (Chapter 269) and a simultaneous rise in the prevalence of degenerative valvular heart disease in the aging population.

Although some patients have no clearly definable risk factors for endocarditis, cardiac conditions that cause turbulent flow at the endocardial surface or across a valve (Chapter 60) predispose patients to infective endocarditis (Table 61-1). The most commonly affected valves in descending order of prevalence are the mitral valve only, the aortic valve only, the mitral and aortic valves together, the tricuspid valve, mixed right- and left-sided infection, and the pulmonic valve.

Historically, rheumatic heart disease with valvular dysfunction was the most common underlying condition, although its contribution has diminished in the antibiotic era, especially in developed countries. Degenerative valvular disease is also associated with infective endocarditis, particularly in elderly patients; the increasing relevance of senile calcification as a risk factor is reflected in the increasing proportion of aortic valve involvement in infective endocarditis (e.g., calcific aortic stenosis). Most significant congenital heart defects (Chapter 55) confer an increased risk of infective endocarditis, particularly complex cyanotic disease such as single-ventricle states, transposition of the great vessels, and tetralogy of Fallot. Similarly, surgically constructed pulmonary–systemic shunts and ventricular septal defects are risk factors associated with infective endocarditis.

Mitral valve prolapse is currently the most common underlying cardiac condition in patients with infective endocarditis, a statistic that reflects its prevalence in the general population (4%). Notably, mitral valve prolapse is a risk only in patients with thickened mitral leaflets or significant regurgitation, in which case the risk of endocarditis increases by about 10-fold over that of the general population. In addition, patients with hypertrophic cardiomyopathy are at increased risk of infective endocarditis, particularly in the presence of outflow obstruction. Finally, previous endocarditis is among the highest risk factors for subsequent infective endocarditis cases.

Prosthetic cardiac valves represent an important risk factor for infective endocarditis. More than 150,000 heart valves are implanted annually worldwide, and prosthetic valve infective endocarditis develops in 1 to 4% of prosthetic valve recipients in the first year after valve replacement and in approximately 0.8% of recipients annually thereafter. Mechanical prosthetic valves may initially be more susceptible to infective endocarditis, but bioprosthetic valves are more likely to develop infective endocarditis after 1 year; overall, the rate is similar with either type of valve. Bioprosthetic valve endocarditis can also involve transcatheter-placed aortic, mitral, or pulmonic valve prostheses.

The incidence of infective endocarditis in injection drug users (Chapter 365) may be 30 times higher than in the general population and four times higher than in adults with rheumatic heart disease.[2] In some areas of the United States, injection drug use is the most common predisposing cause of infective endocarditis in patients younger than 40 years. *S. aureus* is the predominant organism, and tricuspid valve involvement is noted in 78% of cases, mitral involvement in 24%, and aortic involvement in 8%. More than

61 INFECTIVE ENDOCARDITIS

VANCE G. FOWLER, JR., ARNOLD S. BAYER, AND LARRY M. BADDOUR

DEFINITION

Infective endocarditis is defined as an infection, usually bacterial, of the endocardial surface of the heart. Infective endocarditis affects primarily the cardiac valves, although in some cases the septa between the chambers, the mural endocardium, or cardiovascular implantable electronic devices (e.g., pacemakers) may be involved. In the past, infective endocarditis was categorized as "acute" or "subacute," based on the duration of symptoms before presentation. However, these strict categories have proven to be unreliable, so clinical classification considers the causative organism, the involved valve, and the "pace" of clinical disease.

EPIDEMIOLOGY

The true incidence of infective endocarditis is difficult to determine because of the different criteria for diagnosis and methods of reporting. An analysis based on strict case definitions reveals that only a relatively small proportion (≈20%) of clinically diagnosed cases are categorized as "definite." In 10 large surveys, infective endocarditis accounted for approximately one case per 1000 U.S. hospital admissions, with a range of 0.16 to 5.4 cases per 1000 admissions. Estimates from the American Heart Association (AHA) place the incidence of infective endocarditis in the United States at 10,000 to 20,000 new cases per year. Recent data also suggest that rates of *Staphylococcus aureus* infective endocarditis have increased significantly, in part due to an increase in injection drug use (Chapter 365) as part of the current opioid epidemic, as well as the increasing use of implantable cardiac devices.[1]

Men are more commonly affected than women (mean male : female ratio, 1.7 : 1 in 18 large series). However, in patients younger than 35 years, more cases occur in women. More than 50% of patients with infective endocarditis in the United States are now older than 50 years of age, due in part to the low incidence of acute rheumatic heart disease (Chapter 269) and a simultaneous rise in the prevalence of degenerative valvular heart disease in the aging population.

Although some patients have no clearly definable risk factors for endocarditis, cardiac conditions that cause turbulent flow at the endocardial surface or across a valve (Chapter 60) predispose patients to infective endocarditis (Table 61-1). The most commonly affected valves in descending order of prevalence are the mitral valve only, the aortic valve only, the mitral and aortic valves together, the tricuspid valve, mixed right- and left-sided infection, and the pulmonic valve.

Historically, rheumatic heart disease with valvular dysfunction was the most common underlying condition, although its contribution has diminished in the antibiotic era, especially in developed countries. Degenerative valvular disease is also associated with infective endocarditis, particularly in elderly patients; the increasing relevance of senile calcification as a risk factor is reflected in the increasing proportion of aortic valve involvement in infective endocarditis (e.g., calcific aortic stenosis). Most significant congenital heart defects (Chapter 55) confer an increased risk of infective endocarditis, particularly complex cyanotic disease such as single-ventricle states, transposition of the great vessels, and tetralogy of Fallot. Similarly, surgically constructed pulmonary–systemic shunts and ventricular septal defects are risk factors associated with infective endocarditis.

Mitral valve prolapse is currently the most common underlying cardiac condition in patients with infective endocarditis, a statistic that reflects its prevalence in the general population (4%). Notably, mitral valve prolapse is a risk only in patients with thickened mitral leaflets or significant regurgitation, in which case the risk of endocarditis increases by about 10-fold over that of the general population. In addition, patients with hypertrophic cardiomyopathy are at increased risk of infective endocarditis, particularly in the presence of outflow obstruction. Finally, previous endocarditis is among the highest risk factors for subsequent infective endocarditis cases.

Prosthetic cardiac valves represent an important risk factor for infective endocarditis. More than 150,000 heart valves are implanted annually worldwide, and prosthetic valve infective endocarditis develops in 1 to 4% of prosthetic valve recipients in the first year after valve replacement and in approximately 0.8% of recipients annually thereafter. Mechanical prosthetic valves may initially be more susceptible to infective endocarditis, but bioprosthetic valves are more likely to develop infective endocarditis after 1 year; overall, the rate is similar with either type of valve. Bioprosthetic valve endocarditis can also involve transcatheter-placed aortic, mitral, or pulmonic valve prostheses.

The incidence of infective endocarditis in injection drug users (Chapter 365) may be 30 times higher than in the general population and four times higher than in adults with rheumatic heart disease.[2] In some areas of the United States, injection drug use is the most common predisposing cause of infective endocarditis in patients younger than 40 years. *S. aureus* is the predominant organism, and tricuspid valve involvement is noted in 78% of cases, mitral involvement in 24%, and aortic involvement in 8%. More than

ABSTRACT

Infective endocarditis is an uncommon illness associated with increased morbidity and mortality. The patient's presentation can sometimes present diagnostic challenges. Management of patients with infective endocarditis includes antimicrobial therapy and, often, valve surgery. Timing of and indications for surgery can be challenging, so a multispecialty team with expertise in the care of patients with infective endocarditis is advisable.

KEYWORDS

endocarditis
infective endocarditis
bacterial endocarditis

one valve is infected in approximately 20% of cases, and some of these infections are polymicrobial.

Health care–associated infective endocarditis arises primarily as a consequence of invasive therapies, including intravenous (IV) catheters, hyperalimentation lines, pacemakers, other cardiovascular implantable electronic devices,[3] and hemodialysis devices.[4] In a recent prospective, multinational cohort study of more than 1600 non–drug-using patients with native valve endocarditis, more than one third of patients had health care–associated endocarditis, many cases of which originated in the community (e.g., in patients on outpatient hemodialysis). The emerging importance of health care–associated infective endocarditis in industrialized nations has also influenced the microbiology of the disease, with an increasing prevalence of *S. aureus* and a decreasing prevalence of viridans group streptococci in much of the industrialized world.

Implantable cardiovascular electronic devices can become infected at the time they are implanted, particularly if patients develop local pocket site complications, such as a hematoma, at the incision site or need the device to be revised or replaced. Other factors that increase the risk of device infection include older age, comorbid conditions (particularly dialysis-dependent renal failure), and a larger number of device leads.

Systemic medical conditions can predispose patients to the development of infective endocarditis. For example, HIV infection is an independent risk factor for the development of infective endocarditis in injection drug users, with the risk increasing as the CD4 count decreases. Vascular catheter–related bacteremia is an important risk factor for nosocomial infective endocarditis. Patients with end-stage renal disease, particularly those receiving long-term hemodialysis, and patients with diabetes mellitus are also at increased risk, presumably because of the recurrent vascular access–site infections associated with the former and the low-level immunosuppression associated with both conditions.

PATHOBIOLOGY

Experimental models of infective endocarditis have demonstrated that the disease follows a predictable sequence: endocardial damage; aggregation of platelets, fibrin, and other coagulation molecules to create a "sterile vegetation" *(nonbacterial thrombotic endocarditis);* transient bacteremia resulting in seeding of the vegetation; microbial proliferation on and invasion of the endocardial surface; and metastatic infection to organs receiving high blood flow (e.g., kidneys, spleen, and brain). Such sterile vegetations can occur either on previously damaged native valves or at the sewing ring following prosthetic valve placement. Nonbacterial thrombotic endocarditis may also occur spontaneously in patients with systemic illnesses (e.g., the marantic endocarditis of malignancy [Chapter 47] or other wasting diseases or the Libman-Sacks marantic endocarditis of systemic lupus erythematosus [Chapter 245]).

When transient bacteremia occurs—for example, as a result of distant infection or gingival manipulations—the previously sterile vegetation may be seeded. Some bacterial species, such as staphylococci and streptococci, are more avidly adherent to vegetations, better able to evade innate endovascular host defenses, and, as a result, more frequently cause endocarditis. The bacteria then proliferate within the vegetation and may ultimately achieve an organism load of 10^9 to 10^{11} colony-forming units per gram of tissue. Lastly, the surfaces of cardiac valves and vegetations are avascular, thereby making antibiotic therapy and healing difficult. Implantable cardiac devices disrupt the endothelial surface and predispose to infection and the formation of biofilms, particularly early after their placement and before endothelialization and fibrosis occur.

CLINICAL MANIFESTATIONS

History

The initial presentation of infective endocarditis varies enormously from patient to patient. Some cases develop acutely, with symptoms progressing rapidly over days. Other cases develop insidiously and present with progressive but nonspecific symptoms for weeks to months. In patients suspected of having infective endocarditis, the initial history should include a complete review of systems, a travel history, exposures to pets or other animals, illicit drug use, and sexual activity. Most patients complain of fever and nonspecific constitutional symptoms such as fatigue, malaise, or weight loss. Nearly 50% of patients complain of musculoskeletal symptoms ranging from frank arthritis to diffuse myalgias. In about 5 to 10% of patients, low back pain is the chief complaint, even in the absence of osteomyelitis or epidural abscess. In IV drug users with tricuspid valve infective endocarditis and patients with venous or right heart implantable devices, endocarditis can present as pleuritic chest pain and multilobar pneumonia. Health care–associated infective endocarditis is more likely to be clinically occult and requires a high index of suspicion.

Physical Examination

A thorough physical examination should include a search for the prototypic stigmata of endocarditis (Table 61-2), which are very helpful when present but are less frequent than in the past, now that patients are diagnosed and treated more expeditiously. Although fever is present in up to 90% of patients, it is less common in elderly patients and in patients with renal or heart failure. A widened pulse pressure should alert the clinician to the possibility of acute aortic insufficiency (Chapter 60). The skin and nails should be carefully examined for evidence suggestive of embolic phenomena, such as petechiae (Fig. 61-1), Osler nodes, Janeway lesions, and splinter hemorrhages. Petechiae are most often found on the conjunctiva, palate, and extremities. Osler nodes are small, painful nodules found most often on the palmar surfaces of the fingers and toes; they frequently wax and wane (Fig. 61-2). Classically considered to be an immunologic phenomenon, Osler nodes may have an immune complex–mediated component but are most likely initiated by microemboli. Janeway

TABLE 61-2 PHYSICAL EXAMINATION AND LABORATORY FINDINGS IN INFECTIVE ENDOCARDITIS

FINDING	% OF CASES
Fever	96
Worsening of previous murmur	20

FIGURE 61-1. Petechiae in infective endocarditis.

FIGURE 61-2. Osler node in infective endocarditis.

lesions (Fig. 39-10 in Chapter 39) are hemorrhagic, nonpainful macules also found primarily on the palms and soles; they are embolic in origin and are less frequently noted than the other cutaneous stigmata. Splinter hemorrhages (see Fig. 39-10 in Chapter 39) are nonblanching, linear, brownish red lesions in the nail beds parallel to the direction of nail growth; they are nonspecific and may also be found in a significant percentage of hospitalized patients without infective endocarditis.

Funduscopic examination should be performed to look for Roth spots (see Fig. 391-26 in Chapter 391), chorioretinitis, or endophthalmitis; the latter two are present in a substantial proportion of cases of fungal endocarditis (e.g., *Candida*). A careful cardiac examination (Chapter 39) should be performed to detect any murmurs, especially new-onset or worsening murmurs, as well as any evidence of heart failure, which is an ominous sign. Of note, patients with health care–associated infective endocarditis are less likely than others to have a pathologic murmur on initial presentation. The abdomen should be examined for evidence of splenomegaly (Chapter 154), which is more common in patients with subacute endocarditis. Finally, a thorough neurologic examination should be performed, both to assess for any focal neurologic deficits and to serve as a baseline during the patient's hospital stay. The neurologic examination may demonstrate evidence of major vessel embolism, cranial nerve palsies, visual field defects, or generalized toxic-metabolic encephalopathy with altered mental status. Up to 15 to 20% of patients with endocarditis initially have or develop a stroke or stroke-like symptoms (Chapter 375). Patients with device-related infective endocarditis often have local signs and symptoms of infection at the site of implantation.

DIAGNOSIS

The "gold standard" for the diagnosis of infective endocarditis is culture of a pathologic organism from a valve or other endocardial surface. However, unless the patient undergoes valve surgery or postmortem examination, the diagnosis is usually made clinically.[5] The most widely accepted clinical criteria are the modified Duke criteria (Table 61-3), which rely heavily on blood culture results and echocardiographic data and have an estimated 76 to 100% sensitivity and 88 to 100% specificity, with a negative predictive value of at least 92%.

Microbiology

When bacteremia is suspected,[6] at least three sets of blood cultures, each set consisting of one aerobic and one anaerobic bottle, should be obtained from separate sites, with careful attention to aseptic technique. Because some bacteria may not be eliminated by skin surface disinfection, the likelihood of a contaminant can be reduced by 50% if the blood culture is obtained after another tube of blood is collected with the same venipuncture.[A1] Starting antibiotics before blood cultures are drawn will reduce their sensitivity by about one third.[7] Ideally, blood cultures should be collected at least 1 hour apart to document continuous bacteremia, which is a characteristic of infective endocarditis and is not seen in many other infectious syndromes; however, when patients are critically ill, this approach, which requires that antimicrobial therapy be delayed, may not be feasible. In this latter circumstance, the three sets of blood cultures should be drawn without interim time delays.

Causative Organisms

About 90% of community-acquired, native valve infective endocarditis is caused by staphylococci, streptococci, or enterococci, which are normal inhabitants of the skin, oropharynx, urogenital, and gastrointestinal tracts, respectively. These organisms express specific receptors for attachment and adherence to damaged endothelial surfaces. Streptococcal species (Chapter 269) are the most common cause of community-acquired infective endocarditis in patients with no history of injection drug use or health care contact. In patients with either of these latter epidemiologic risk factors, *S. aureus* (Chapter 267) is the predominant cause of infective endocarditis. Because of the emergence of health care contact as the predominant risk factor for blood stream infections, *S. aureus* is now the most common cause of infective endocarditis in most industrialized regions of the world.

Viridans group streptococci (Chapter 269) are the most common streptococci implicated in native valve endocarditis. This group of organisms, which normally inhabit the oropharynx, includes species such as *Streptococcus sanguinis, Streptococcus mutans,* and *Streptococcus mitis/oralis*. Group B streptococci (β-hemolytic organisms that are normal oropharyngeal and urogenital flora, as well as skin flora in patients with diabetes) most frequently cause infective endocarditis in patients with cirrhosis or diabetes mellitus, as well as in injection drug users. In contrast, group A streptococci, although also β-hemolytic, rarely cause infective endocarditis. Among streptococcal species, the risk of developing endocarditis after blood stream infection is highest with *Streptococcus mutans, Streptococcus gordonii, Streptococcus sanguinis, Streptococcus gallolyticus* (previously known as *Streptococcus bovis*), and *Streptococcus mitis/oralis*, and it is lowest with *Streptococcus pneumoniae*.[8] *Streptococcus gallolyticus* is now a leading cause of infective endocarditis in some parts of the world; for example,

TABLE 61-3 MODIFIED DUKE CRITERIA FOR THE DIAGNOSIS OF INFECTIVE ENDOCARDITIS

MAJOR CRITERIA

1. Blood culture positive (a *OR* b)
   a. Typical organism (α-hemolytic streptococcus, *Streptococcus gallolyticus,* HACEK organisms, or *Staphylococcus aureus,* or community-acquired *Enterococcus* species, without a primary focus) from two separate blood cultures *OR*
   b. Persistent bacteremia with any organism (two positive cultures >12 hr apart or three positive cultures or a majority of ≥4 cultures positive >1 hr apart)
2. Evidence of endocardial involvement (a *OR* b)
   a. Echocardiographic findings: mobile mass attached to valve or valve apparatus, abscess, or new partial dehiscence of prosthetic valve *OR*
   b. New valvular regurgitation
3. Serology: single positive blood culture for *Coxiella burnetii* or anti–phase 1 *C. burnetii* IgG antibody titer ≥1 : 800

MINOR CRITERIA

1. Predisposing condition: IV drug use or predisposing cardiac condition
2. Fever ≥38° C
3. Vascular phenomena: arterial embolism, septic pulmonary emboli, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
4. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
5. Echocardiogram findings consistent with endocarditis but not meeting major criteria
6. Microbiologic evidence: positive blood cultures not meeting major criteria or serologic evidence of active infection consistent with endocarditis

DEFINITE INFECTIVE ENDOCARDITIS (1 *OR* 2)

1. Pathologically proven infective endocarditis *OR*
2. Clinical diagnosis defined by
   a. Two major criteria *OR*
   b. One major and three minor criteria *OR*
   c. Five minor criteria

POSSIBLE INFECTIVE ENDOCARDITIS (1 *OR* 2)

1. One major criterion and one minor criterion *OR*
2. Three minor criteria

REJECTED INFECTIVE ENDOCARDITIS

1. Firm alternative diagnosis *OR*
2. Resolution of infective endocarditis syndrome with antibiotic therapy for ≤4 days *OR*
3. No pathologic evidence of infective endocarditis at surgery or autopsy with antibiotic therapy for ≤4 days *OR*
4. Does not meet criteria for possible infective endocarditis, as above

HACEK = *Haemophilus* spp, *Aggregatibacter* spp (formerly *Actinobacillus actinomycetemcomitans*), *Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* spp; IgG = immunoglobulin G; IV = intravenous.

Adapted from Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis*. 2000;30:633-638.

its incidence in France has increased significantly in recent years. Its presence in blood cultures should prompt endoscopic evaluation for adenocarcinoma of the colon or other malignant lesions of the gastrointestinal tract.

S. aureus (Chapter 267) is the predominate pathogen among injection drug users and patients with health care contact. The clinical course of *S. aureus* endocarditis is typically acute, with a rapid progression over the course of days. Because about 10 to 15% of patients with *S. aureus* bacteremia have echocardiographic evidence of endocarditis even in the absence of classic stigmata, possible cardiac involvement should always be considered in any patient with *S. aureus* bacteremia but especially in patients with relapsing or persistent bacteremia or fever, community-acquired infection, or an implantable cardiac device. Coagulase-negative staphylococci are an uncommon cause of native valve endocarditis but are important pathogens in the setting of prosthetic valves or other intracardiac devices.

Enterococci are responsible for a significant number of cases of both community-acquired and nosocomial endocarditis, and the bulk (>90%) are due to *Enterococcus faecalis*. In most cases, the source of bacteremia is thought to be the genitourinary tract, and the presentation is usually subacute. Endocarditis, which develops in about 25% of patients with *E. faecalis* bacteremia, is suggested by community acquisition of infection, the absence of a clear source of infection, preexistent valvular heart disease, and the absence of polymicrobial bacteremia. As with *S. gallolyticus* endocarditis, gastrointestinal screening for colonic neoplasms is recommended.[9]

The HACEK group of gram-negative organisms (*Haemophilus* spp, *Aggregatibacter* spp [formerly *Actinobacillus actinomycetemcomitans*], *Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* spp) accounts for about 5% of endocarditis cases. Because these fastidious organisms usually grow in blood cultures within 7 days using current methods, prolonged incubation is no longer required to isolate HACEK strains. Many other gram-negative bacilli can cause infective endocarditis but are even more unusual. Traditionally, injection drug use has been the primary risk factor for enteric aerobic gram-negative bacillary bacterial endocarditis. However, recent experience from large multinational studies shows that nosocomial health care contact, not injection drug use, is currently the most common risk factor for enteric gram-negative endocarditis.

Fungal endocarditis is often difficult to diagnose and treat; it is most commonly found in patients with a history of injection drug use, recent cardiac valve surgery, or prolonged use of indwelling vascular catheters, especially those used for total parenteral nutrition. The most common fungi found in infective endocarditis are *Aspergillus* and *Candida* spp. *Aspergillus* (Chapter 311) rarely grows in blood cultures and usually must be cultured from a pathologic specimen (either an embolic site or vegetation). Serodiagnostic strategies for antigen detection are often useful to diagnose *Aspergillus* endocarditis. By contrast, *Candida* spp (Chapter 310) frequently grow in blood cultures. Mortality is very high, and valve replacement surgery is usually necessary for fungal endocarditis.

Prosthetic valve endocarditis can be classified into one of two groups based on the time between valve surgery and disease onset: *early* (<2 months after surgery) and *late* (>2 months) (Table 61-4). Staphylococci, particularly *S. aureus,* predominate during the early postsurgery period, when most episodes of infective endocarditis are thought to be related to perioperative infection. In the late postsurgery period, the spectrum of organisms becomes more akin to that of community-acquired native valve endocarditis, in which *S. aureus* and viridans group streptococci predominate. Of note, among the coagulase-negative staphylococci, oxacillin resistance is frequently seen in these late cases. A transcatheter prosthetic valve placement (aortic, mitral, or pulmonic) procedure also can be complicated by endocarditis, with enterococci, *S. aureus,* and coagulase-negative staphylococci as the most common pathogens in the aortic valve position and *S. aureus* predominating in the pulmonic valve position.

Staphylococcal species account for the large majority (≥70%) of implantable cardiac device infections. The prevalence of oxacillin resistance among *S. aureus* strains varies but is generally in the 30 to 50% range; such resistance is even higher among coagulase-negative staphylococci.

TABLE 61-4 CAUSES OF PROSTHETIC VALVE ENDOCARDITIS*

EARLY (<2 mo POSTOPERATIVELY)	LATE (>2 mo POSTOPERATIVELY)
Staphylococcus aureus	Coagulase-negative staphylococci
Coagulase-negative staphylococci	*Staphylococcus aureus*
Gram-negative bacilli	Viridans group streptococci
Enterococci	Enterococci
Fungi	*Mycobacterium chimaera*†
Diphtheroids	

*Listed in order of relative frequency.
†May occur up to 4-5 years after valve replacement.

Endocarditis with Negative Blood Cultures

In most patients who have infective endocarditis and who have not received previous antibiotic therapy, every blood culture is positive. Blood cultures are truly negative in less than 5% of cases of endocarditis; however, prior antibiotic administration may decrease the yield of blood cultures by up to 35%. Accordingly, the large majority of "culture-negative" cases of endocarditis occur in patients who have recently received antimicrobial agents. These cases are probably caused by the same organisms responsible for most native valve endocarditis; viridans group streptococci and the HACEK organisms are the most "likely suspects" because they are much more fastidious than staphylococci and enterococci and are therefore more likely to be affected by previous antibiotic administration. Ultimately, however, when blood cultures are negative and endocarditis is suspected, especially when a history of recent antimicrobial treatment is lacking, consideration should be given to fastidious bacterial organisms, fungi, and noncultivatable organisms (Table 61-5), particularly when the patient's history suggests exposure to farm animals or unpasteurized milk (*Coxiella burnetii, Brucella* spp), cats (*Bartonella henselae*), body lice (*Bartonella quintana*), or pet birds (*Chlamydophila psittaci*). It is important to notify the microbiology laboratory that endocarditis is suspected because special culture techniques, including prolonged (>5 days) incubation of blood cultures, can occasionally increase the yield for nutritionally variant streptococci (*Abiotrophia* and *Granulicatella* spp), *Brucella* spp, *Legionella* spp, *Cutibacterium acnes,* and some fungi. Specific serologic tests can diagnose endocarditis related to *C. burnetii* (the agent of Q fever; Chapter 302), *Brucella* spp (Chapter 286), *Bartonella* spp (Chapter 291), and *C. psittaci* (Chapter 294). *Tropheryma whippelii,* the etiologic agent in Whipple disease (Chapter 305), and multiple other organisms may be diagnosed by broad-range polymerase chain reaction testing in plasma or especially on resected cardiac tissue.[10] Histopathologic features of resected tissue also can provide clues in the etiologic diagnosis of culture-negative endocarditis. If the search for a causative organism is fruitless, noninfectious causes such as marantic or Libman-Sacks endocarditis and atrial myxoma (Chapter 47) should be considered.

Laboratory Findings

Initial laboratory tests should include a complete blood count with differential, serum electrolytes, measurement of renal function, and urinalysis. Most patients with subacute infective endocarditis have the serum iron profile of "anemia of chronic disease" (Chapter 145). The peripheral white blood cell count is frequently elevated in acute infective endocarditis, particularly if *S. aureus* is the causative organism, but may not be elevated in more subacute forms. Microscopic hematuria is common, as is proteinuria.

Rheumatoid factor, which is an ancillary test that has been included in the modified Duke criteria as a "minor criterion" in the category of "immunologic phenomenon," may be positive in subacute or chronic endocarditis. Other ancillary tests, such as the erythrocyte sedimentation rate, the C-reactive protein level, and the procalcitonin level, are generally not helpful in establishing the diagnosis of endocarditis.

Imaging, Including Echocardiography

The chest radiograph is abnormal—demonstrating consolidation, atelectasis, pleural effusion, or clear septic emboli—in the overwhelming majority of patients with right-sided endocarditis. In others, it may show evidence of heart failure. The electrocardiogram (ECG) should be carefully examined for evidence of atrioventricular conduction blocks, especially a prolonged PR interval (see Figs. 51-4 through 51-9 in Chapter 51), suggestive of an aortic ring abscess or frank myocardial infarction (see Figs. 58-1 and 58-2 in Chapter 58).

Both transthoracic echocardiography and transesophageal echocardiography (Chapter 43) are highly specific tests for defining valvular vegetations (≈98%) when used as part of the diagnostic evaluation of suspected endocarditis. By contrast, transesophageal echocardiography has a much

TABLE 61-5 ORGANISMS CAUSING "CULTURE-NEGATIVE" ENDOCARDITIS*

ORGANISM	EPIDEMIOLOGY	DIAGNOSTIC TESTS
HACEK spp	Mostly oral flora, so often history of periodontal disease	May require up to 7 days to grow
Nutritionally variant streptococci	Slow and indolent course	Supplemented culture media or growth as satellite colonies around *Staphylococcus aureus* streak
Coxiella burnetii (Q fever)	Worldwide; exposure to raw milk, farm environment, or rural areas	Serologic tests (high titers of antibody to both phase 1 and phase 2 antigens); also PCR on blood or valve tissue
Brucella spp	Ingestion of contaminated milk or milk products; close contact with infected livestock	Bulky vegetations usually seen on echocardiography; blood cultures positive in 80% of cases with incubation time of 4-6 wk; lysis-centrifugation technique may expedite growth; serologic tests are available
Bartonella spp	*Bartonella henselae:* transmitted by cat scratch or bite or by cat fleas; *Bartonella quintana:* transmitted by human body louse; predisposing factors include homelessness and alcohol abuse	Serologic testing (may cross-react with *Chlamydophila psittaci*); PCR of valve or emboli is best test; lysis-centrifugation technique may be useful
Chlamydophila psittaci	Exposure to birds	Serologic tests available, but must exclude *Bartonella* spp because of cross-reactivity; monoclonal antibody direct stains on tissue may be useful; PCR now available
Tropheryma whippelii (Whipple disease)	Systemic symptoms include arthralgias, diarrhea, abdominal pain, lymphadenopathy, weight loss, CNS involvement; however, endocarditis may be present without systemic symptoms	Histologic examination of valve with PAS stain; valve cultures may be done using fibroblast cell lines; PCR on vegetation material
Legionella spp	Contaminated water distribution systems; often nosocomial outbreaks; usually prosthetic valves	Lysis-centrifugation technique; also periodic subcultures onto buffered charcoal yeast extract medium; serologic tests and PCR available
Aspergillus and other noncandidal fungi	Prosthetic valve	Lysis-centrifugation technique; also culture and direct examination of any emboli; serodiagnostic test for *Aspergillus* antigen
Mycobacterium chimaera	Following cardiac surgery with contaminated heater/cooler units used for cardiopulmonary bypass; often delayed months-years	PCR and mycobacterial cultures of blood and other sterile body sites

*Listed in approximate order of relative frequency.
CNS = central nervous system; HACEK = *Haemophilus* spp, *Aggregatibacter* spp, *Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* spp; PAS = periodic acid–Schiff; PCR = polymerase chain reaction.

higher sensitivity (90 to 95%) in this setting than transthoracic echocardiography (48 to 63%). In most cases in which endocarditis is a serious diagnostic consideration, the evaluation should begin with initial transthoracic echocardiography followed by transesophageal echocardiography as soon as possible because both studies provide complementary information (Fig. 61-3). Because transesophageal echocardiography is a relatively noninvasive means of detecting perivalvular extension of infection, any patient with a new conduction system abnormality or persistent fever—clinical predictors of perivalvular extension—should be evaluated with it. Likewise, transesophageal echocardiography is strongly preferred in the evaluation of suspected prosthetic valve– or device–related endocarditis. Of note is that bland clots can occur on the leads of 5 to 10% of patients with intracardiac devices, and the finding of a "vegetation" on a lead is not specific for infection. The high sensitivity of transesophageal echocardiography in detecting valvular vegetations on native valves also may be used in combination with clinical parameters (e.g., prompt resolution of bacteremia and defervescence) to support the clinical decision to abbreviate therapy in patients with vascular catheter–associated *S. aureus* bacteremia. A vegetation greater than 10 mm is a significant predictor of an increased risk of peripheral embolization and mortality.[11]

A negative transesophageal echocardiography result has a negative predictive value of about 95%. Nevertheless, when clinical suspicion of endocarditis is high (e.g., persistent fever or embolic events) and the initial transesophageal echocardiography is negative, repeat transesophageal echocardiography in 3 to 5 days may reveal the diagnosis.

When echocardiographic results are negative or indeterminant, multislice computed tomography with or without angiography can be helpful in patients with possible prosthetic valve endocarditis or with a perivalvular extension of infection.[12] Positron emission tomography with computed tomography (PET/CT) scanning may be useful for identifying prosthetic valve endocarditis [13] and may sometimes identify a noncardiac primary source of infection, a metastatic site that requires a change in the therapeutic approach, or evidence of undiagnosed tumors. However, these tests should not be obtained routinely but rather should be reserved for difficult diagnostic situations.

The diagnosis of infective endocarditis complicating transcatheter aortic or pulmonic valve replacements can be difficult. Vegetations may not be detected with echocardiography, but leaflet thickening and an increased transvalvular gradient are often seen.

TREATMENT

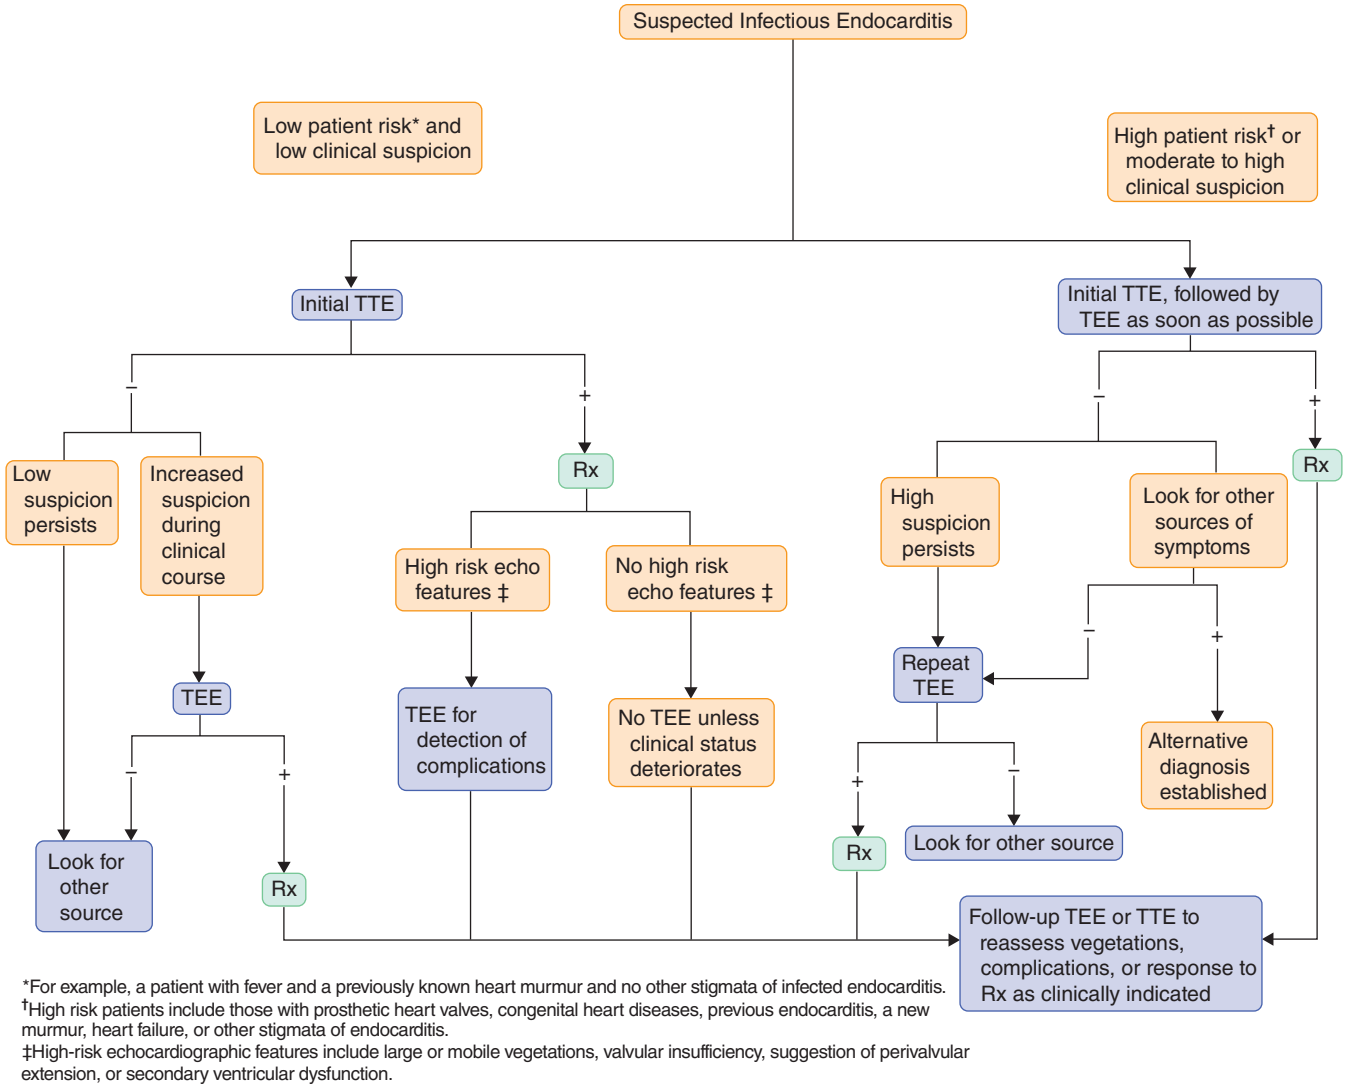
Definitive antibiotic treatment of infective endocarditis (Table 61-6) is guided by antimicrobial susceptibility testing of the responsible pathogen isolated from clinical cultures.[14–16] Although it is often advisable to begin empiric treatment before definitive culture results are available, not all patients who are admitted because of possible endocarditis necessarily need to be treated empirically.[17] Patients who are clinically stable, with a subacute presentation syndrome and without evidence of heart failure or other end-organ complications, can be closely observed without antibiotics so that serial blood cultures can be obtained. Likewise, such stable patients who were started on empiric antibiotics before hospitalization and before blood was drawn for cultures can discontinue antibiotics so that blood cultures can be obtained, preferably as long as possible after stopping the antibiotics. A normal procalcitonin level does not exclude endocarditis, but procalcitonin-guided treatment may help reduce the duration of antibiotic treatment in patients with positive blood cultures.[A2] By contrast, acutely ill patients, patients with evidence of complications of endocarditis, and patients who are at high risk for endocarditis (e.g., prosthetic valve recipients)[18] should be treated empirically with antibiotics pending culture results. An infectious diseases specialist, as part of an multidisciplinary endocarditis team, is critical in guiding the diagnostic evaluation and designing an appropriate initial empiric (and subsequent definitive) antibiotic regimen. This consultation may guide molecular diagnostic testing by the hospital's microbiology laboratory or a reference laboratory to secure a specific etiologic diagnosis.

Empiric Therapy

Either of two regimens provides appropriate empirical coverage for patients with suspected native valve endocarditis when cultures have not revealed a specific organism: nafcillin (or oxacillin)–penicillin–gentamicin or vancomycin–gentamicin (Table 61-7). Some experts recommend a regimen of nafcillin–ceftriaxone–penicillin–gentamicin to cover for HACEK isolates that produce β-lactamase. If methicillin-resistant *S. aureus* (MRSA) is an important consideration, as in injection drug users and patients with health care contact, empirical therapy should consist of vancomycin–ceftriaxone–gentamicin. Patients with prosthetic valves should be empirically treated with vancomycin–gentamicin–rifampin for adequate coverage of the most important pathogens in this setting (MRSA, methicillin-sensitive staphylococci, and coagulase-negative staphylococci).

Treatment of Specific Organisms

When the organism is definitively identified, the antibiotic treatment must be narrowed accordingly, and validated regimens should be followed (see Table 61-6). Infectious disease consultation should be obtained in all cases of infective endocarditis as part of an "Endocarditis Team" approach, which has been shown to improve outcomes.



*For example, a patient with fever and a previously known heart murmur and no other stigmata of infected endocarditis.
†High risk patients include those with prosthetic heart valves, congenital heart diseases, previous endocarditis, a new murmur, heart failure, or other stigmata of endocarditis.
‡High-risk echocardiographic features include large or mobile vegetations, valvular insufficiency, suggestion of perivalvular extension, or secondary ventricular dysfunction.

FIGURE 61-3. Approach to the diagnostic use of echocardiography (Echo). Rx = treatment, TEE = transesophageal echocardiography, TTE = transthoracic echocardiography. (Adapted from Baddour LM, Wilson WR, Bayer AS, et al. Infective endocarditis in adults: diagnosis, antimicrobial therapy, and management of complications: a scientific statement for healthcare professionals from the American Heart Association. *Circulation*. 2015;132:1435-1486.)

Many regimens recommend consideration of low-dose gentamicin to provide antibacterial synergy with a low risk of toxicity. However, aminoglycoside toxicity is a significant risk in elderly patients and in patients with preexisting renal disease or hearing impairment; even low-dose gentamicin increases the likelihood of a decrease in creatinine clearance by about three-fold. Among the organisms listed in Table 61-6, added gentamicin is critical for cure only in enterococcal endocarditis (when combined with penicillin). As a result of these risks and the minimal data supporting its benefit, initial low-dose gentamicin should not be routinely used.

In uncomplicated viridans group streptococcal endocarditis, outpatient therapy with once-daily ceftriaxone is as effective as more complex regimens, provided the patient has been observed in the hospital for the development of complications. The decision to administer antimicrobial therapy in the outpatient setting must, of course, take into account the patient's social situation, likelihood of compliance, and other risks involved with either an indwelling IV line or recurrent peripheral IV line placements.

Traditional therapy for infective endocarditis caused by fully susceptible enterococci includes penicillin or ampicillin plus gentamicin. Although gentamicin is preferred over streptomycin, the choice of a specific aminoglycoside should be based on in vitro susceptibility testing. Nonrandomized data suggest that the duration of aminoglycoside therapy can be limited to 2 to 3 weeks in combination with either penicillin, ampicillin, or vancomycin; an aminoglycoside can be avoided in favor of combination therapy with ampicillin plus high-dose (2 g IV every 12 hours) ceftriaxone in endocarditis that is due to *Enterococcus faecalis*. Optimal therapy for enterococci that are resistant to aminoglycosides or vancomycin is not well defined. Endocarditis caused by vancomycin-resistant enterococci may be treated with daptomycin, quinupristin–dalfopristin (7.5 mg/kg IV every 8 hours), or linezolid (600 mg orally or IV twice daily); however, clinical experience with these agents is limited. In this situation, relapse or failure rates are likely to be high, and many cases require surgical intervention (discussed later).

Semisynthetic penicillins, such as nafcillin, are advocated for endocarditis caused by methicillin-susceptible *S. aureus*. Cefazolin represents an alternative to semisynthetic penicillins in patients in whom the latter are not tolerated or feasible to administer. Although vancomycin is recommended in patients who are allergic to β-lactams, the microbiologic and clinical cure rates are less than those of β-lactam therapy. Because of this lower cure rate and the fact that over 90% of patients who report a history of penicillin allergy do not have it when skin tested, an allergy expert should be consulted. Daptomycin (6 mg/kg/day for 10 to 42 days, depending on the severity of infection) is as effective as either a semisynthetic antistaphylococcal penicillin or vancomycin for the treatment of *S. aureus* bacteremia and right-sided infective endocarditis caused by methicillin-susceptible *S. aureus* and MRSA; the combination of daptomycin plus fosfomycin may be slightly better than daptomycin alone.[A3] Non-randomized data suggest that higher-dose daptomycin regimens (8-10 mg/kg/d) are safe and may be superior for clearing bacteremia in *S. aureus* endocarditis. Ceftaroline, a fifth-generation cephalosporin, can be successful in patients with MRSA bacteremia and endocarditis, especially when combined with daptomycin.

Data suggest that after about 2 weeks of successful IV therapy, patients with stable left-sided endocarditis due to streptococcus, *Enterococcus faecalis*, *Staphylococcus aureus*, or coagulase-negative staphylococci have been safely switched from IV to oral antibiotics for the duration of their treatment,[A4] although experience with *S. aureus* endocarditis, especially MRSA, is relatively limited.

Rifampin or gentamicin can be added to either nafcillin or vancomycin for the treatment of prosthetic valve infection caused by methicillin-susceptible *S. aureus* or to MRSA, respectively. Gentamicin is administered for 2 weeks, and rifampin is given for the duration of either nafcillin or vancomycin therapy.

TABLE 61-6 DEFINITIVE THERAPY OF BACTERIAL ENDOCARDITIS

ORGANISM AND REGIMEN*	COMMENTS
PCN-SUSCEPTIBLE VIRIDANS STREPTOCOCCI (MIC ≤0.1 μg/mL) AND *STREPTOCOCCUS GALLOLYTICUS (formerly S. bovis)*	
1. Aqueous crystalline PCN G 2-3 million units IV q4h × 4 wk; 6 wk for prosthetic valve endocarditis	1. Also effective for other PCN-susceptible nonviridans streptococci
2. Ceftriaxone 2 g IV qd × 4 wk; 6 wk for prosthetic valve endocarditis	2. Useful in outpatient therapy and in patients with non-IgE-mediated PCN allergy
3. Aqueous crystalline PCN G 2-3 million units IV q4h × 2 wk plus gentamicin 3 mg/kg IV per 24 h in 1 dose × 2 wk	3. Uncomplicated infection with none of the following features: renal insufficiency, eighth cranial nerve deficit, prosthetic valve infection, CNS complications, severe heart failure, age >65 yr; also not acceptable for nutritionally variant streptococci; this option is not commonly used
4. Vancomycin 15-20 mg/kg IV q8-12h × 4 wk	4. For IgE-mediated PCN allergy; goal trough level of 15-20 mg/L
RELATIVELY PCN-RESISTANT VIRIDANS STREPTOCOCCI (MIC 0.12-<0.5 μg/mL)	
1. Aqueous crystalline PCN G 4 million units IV q4h × 4 wk plus gentamicin 3 mg/kg IV q24h × 2 wk	—
2. Vancomycin 15-20 mg/kg IV q8-12h × 4 wk	For IgE-mediated PCN allergy or to avoid gentamicin; goal trough level of 15-20 mg/L
ENTEROCOCCI† *ABIOTROPHIA*, AND *GRANULICATELLA* SPECIES, AND PCN-RESISTANT VIRIDANS STREPTOCOCCI (PCN MIC ≥0.5 μg/mL)	
1. Penicillin‡ 18-30 million units IV per day in divided doses × 4-6 wk or ampicillin 12 g/24 hr IV in 6 equally divided plus gentamicin 3 mg/kg IV q24h × 4-6 wk	1. Increase duration of both drugs to 6 wk for prosthetic valve endocarditis or symptoms >3 mo in enterococcal infection
2. Vancomycin 15-20 mg/kg IV q8-12h × 6 wk plus gentamicin 1 mg/kg q8h × 6 wk§	2. For IgE-mediated PCN allergy; high risk of nephrotoxicity with this regimen
3. Ampicillin 12 g/24 h IV in 6 equally divided doses plus ceftriaxone 2 g IV q12h × 6 wk	3. An alternative to aminoglycoside-containing regimens in infective endocarditis due to *Enterococcus faecalis*, especially in patients with pre existing renal disease
STAPHYLOCOCCUS AUREUS	
1. Nafcillin 2 g IV q4h × 6 wk	1. Methicillin-susceptible strain; gentamicin discouraged for native valve endocarditis
2. Vancomycin 15-20 mg/kg IV q8-12h × 6 wk	2. PCN allergy (immediate hypersensitivity or anaphylaxis) or MRSA
3. Nafcillin 2 g IV q4h × 2 wk	3. Methicillin-susceptible strain; 2-wk regimen for use only in people who inject drugs and have uncomplicated tricuspid valve endocarditis
4. Nafcillin 2 g IV q4h × ≥6 wk plus gentamicin 1 mg/kg IV q8h × 2 wk plus rifampin 300 mg PO/IV q8h × ≥6 wk	4. Prosthetic valve endocarditis with methicillin-susceptible strain; use vancomycin instead of nafcillin for MRSA
5. Cefazolin 2 g IV q8h × 4-6 wk	5. Non-IgE-mediated PCN allergy
6. Daptomycin 6 mg/kg IV qd × 14-42 days	6. Daptomycin is FDA-approved for treatment of right-sided *S. aureus* infective endocarditis; for adults; some experts recommend up to 10 mg/kg IV qd
COAGULASE-NEGATIVE STAPHYLOCOCCI, PROSTHETIC VALVE INFECTION	
Vancomycin 15-20 mg/kg IV q8-12h × ≥6 wk plus gentamicin 1 mg/kg IV q8h × 2 wk plus rifampin 300 mg PO/IV q8h × ≥6 wk	Can substitute nafcillin in above listed doses for vancomycin if isolate is sensitive to methicillin
HACEK STRAINS	
1. Ceftriaxone 2 g IV qd × 4 wk; 6 wk for prosthetic valve endocarditis	This regimen is used in most patients
2. Ampicillin–sulbactam 3 g IV q6h × 4 wk; 6 wk for prosthetic valves	HACEK strains increasingly may produce β-lactamase
NON-HACEK GRAM-NEGATIVE BACILLI	
Enterobacteriaceae	
Extended-spectrum PCN or cephalosporin plus aminoglycosides for susceptible strains	Treat for a minimum of 6-8 wk; some species exhibit inducible resistance to third-generation cephalosporins; valve surgery is required for most patients with left-sided endocarditis caused by gram-negative bacilli
Pseudomonas aeruginosa	
High-dose tobramycin (8 mg/kg/day IV or IM in once-daily doses) with maintenance of peak and trough concentrations of 15 to 20 μg/mL and ≤2 μg/mL, respectively, in combination with an extended-spectrum PCN (e.g., ticarcillin, piperacillin, azlocillin); ceftazidime, cefepime, or imipenem in full doses; or imipenem	Treat for a minimum of 6-8 wk; early valve surgery usually required for left-sided *Pseudomonas* endocarditis
Fungi	
Treatment with a parenteral antifungal agent (usually a lipid-containing amphotericin B product, 3-5 mg/kg/day IV for at least 6 weeks) with or without flucytosine (25 mg/kg PO four times daily in patients with normal renal function) in patients with *Candida* infections; fluconazole, 400 mg daily PO is an alternative for susceptible yeasts; other azoles, such as voriconazole, may be required for resistant yeasts or molds	Combined with valve replacement and subsequent lifelong suppressive therapy with oral antifungal agents; for patients who are not candidates for surgery, lifelong oral suppressive therapy should follow completion of initial IV therapy.

‡Ampicillin 12 g/day can be used instead of PCN.

§The need to add an aminoglycoside has not been demonstrated for PCN-resistant streptococci.

*Dosages are for patients with normal renal function; for those with renal insufficiency, adjustments must be made for all drugs except nafcillin, rifampin, and ceftriaxone. Gentamicin doses should be adjusted to achieve a peak serum concentration of approximately 3 μg/mL 30 min after dosing and a trough gentamicin level of <1 μg/mL.

†Enterococci must be tested for antimicrobial susceptibility. These recommendations are for enterococci sensitive to PCN, gentamicin, and vancomycin.

HACEK = *Haemophilus* spp, *Aggregatibacter* spp (formerly *Actinobacillus actinomycetemcomitans*), *Cardiobacterium hominis, Eikenella corrodens*, and *Kingella* spp; ID = infectious diseases; IM = intramuscular; IV = intravenous; MIC = minimum inhibitory concentration; MRSA = methicillin-resistant *Staphylococcus aureus;* PCN = penicillin; PO = oral; q = every; qd = every day.

Consultation with an infectious diseases specialist is recommended in all cases of infective endocarditis.

TABLE 61-7 EMPIRICAL TREATMENT OF ENDOCARDITIS

CHARACTERISTICS OF PATIENTS	TREATMENT REGIMEN*
Native valve, community-acquired infection, MRSA unlikely	Nafcillin 2 g IV q4h plus penicillin 4 million units IV q4h plus gentamicin 1 mg/kg IV q8h
Any of the following: health care–associated infection or other reason to suspect MRSA; severe penicillin allergy	Vancomycin 15-20 mg/kg IV q8-12h† plus gentamicin 1 mg/kg IV q8h
Prosthetic valve	Vancomycin 15-20 mg/kg IV q8-12h† plus gentamicin 1 mg/kg IV q8h plus rifampin 300 mg PO/IV q8h

*Dosages are for patients with normal renal function; for those with renal insufficiency, adjustments must be made for all drugs except nafcillin.
†Goal is trough level of 15-20 mg/L.
IV = intravenous; MRSA = methicillin-resistant *Staphylococcus aureus;* PO = oral; q = every.

Rifampin is never used as monotherapy because of the rapid development of resistance.

Fungal endocarditis is usually a consequence of extensive health care contact. Traditionally, fungal endocarditis was regarded as a primary indication for valvular surgery, and intravenous amphotericin B was considered the adjunctive treatment of choice (Chapter 307). However, selected patients with *Candida* endocarditis have been successfully treated medically (with azole-containing antimicrobial agents, with or without amphotericin B), particularly patients who have been deemed not to be surgical candidates. Importantly, the management of fungal endocarditis should always involve the collaboration of an experienced infectious diseases specialist.

Zoonotic endocarditis is usually culture-negative and most commonly caused by *Bartonella* spp (Chapter 291), *C. burnetii* (Chapter 302), or *Brucella* spp (Chapter 286). The treatments of choice for these fastidious pathogens are based on limited data, but documented *Bartonella* endocarditis is treated with doxycycline for 6 weeks plus gentamicin for the first 2 weeks.

In cases of presumed culture-negative endocarditis in which unusual organisms (see Table 61-5) and other infections have been reasonably excluded, an empirical course of treatment may be undertaken. The choice of antimicrobial therapy should be influenced by the specifics of the patient's presentation, and an infectious diseases consultation is recommended.

Continuing Care of the Patient with Endocarditis

In addition to antibiotics, appropriate inpatient care includes attention to other chronic medical issues. For endocarditis in people who inject drugs, early inpatient consultation with an addiction medicine specialist is strongly advised to optimize adherence to completion of antimicrobial therapy as well as to implement strategies to mitigate subsequent drug use and reduce harm in this high-risk population that is at risk of a variety of serious infectious diseases, including recurrent endocarditis (Chapter 365).[19,20]

Regular surveillance should assess the potential development of complications. A careful cardiac examination should be performed on a daily basis to assess for new regurgitant murmurs. Widening of the pulse pressure should alert the clinician to the possible development of acute aortic insufficiency (Chapter 60). New conduction delays on the ECG suggest a possible myocardial abscess.

Repeat echocardiography is recommended during therapy for patients with persistent fever, recurrent embolic events, a new murmur, widening of the pulse pressure, or signs or symptoms of heart failure. Repeat echocardiography is also recommended to look for periannular complications in prosthetic valve endocarditis. Although end-of-therapy echocardiography is not routinely recommended if patients respond adequately to antimicrobial therapy, serial echocardiography is usually suggested over the ensuing years to screen for long-term valvular dysfunction.

Routine serial ECGs are not recommended. ECG-documented conduction abnormalities are a late sign of perivalvular infections in patients with endocarditis; transesophageal echocardiography (TEE) is the screening method of choice if this complication is suspected.

Any new neurologic findings should prompt a search for evidence of central nervous system (CNS) complications such as embolic events, cerebral hemorrhage, mycotic aneurysm, or brain abscess. Renal function should be closely monitored so that antibiotic doses can be adjusted if necessary. If gentamicin is used for more than a few days, the patient should be alerted to watch for the signs and symptoms of vestibular or ototoxicity. Audiometric testing at baseline and periodically thereafter should be considered in patients at high risk for aminoglycoside-induced ototoxicity, including elderly patients, patients with preexisting renal dysfunction or hearing damage, patients receiving prolonged courses of gentamicin, and patients who also receive other potentially nephrotoxic agents. Serum gentamicin trough concentrations should also be assayed at regular intervals (e.g., twice weekly and more often if renal function is changing) and should be targeted for 1 to 3 μg/mL or less; higher concentrations should prompt either lower or less frequent dosing or both.

Serial blood cultures, especially early in the treatment course, are indicated in patients whose infective endocarditis is caused by virulent organisms that commonly fail first-line treatment, such as *S. aureus* or aerobic gram-negative bacilli. Positive follow-up blood cultures in this setting might suggest the need to change therapy, search for metastatic abscesses, or repeat echocardiography. Infectious disease consultation is highly recommended in this scenario.

Patients with infective endocarditis may continue to be febrile for some time after the institution of appropriate antibiotic treatment. About 50% of patients defervesce within 3 days of starting antibiotics, 75% by 1 week, and 90% by 2 weeks. Patients whose endocarditis is caused by *S. aureus*, aerobic gram-negative organisms, or fungi tend to defervesce more slowly than patients infected with other organisms. Prolonged fever (>1 week after the institution of appropriate antibiotics) should prompt repeat blood cultures. If such cultures are negative, several possibilities should be considered: myocardial abscess, extracardiac infection (e.g., mycotic aneurysm, psoas or splenic abscess, vertebral osteomyelitis, septic arthritis), immune complex–mediated tissue damage, or a complication of hospitalization and therapy (e.g., drug fever, nosocomial superinfection, pulmonary embolism). Appropriate studies might include TEE, CT scan of the abdomen, bone scan, and urinalysis with microscopy (to elicit evidence of interstitial nephritis). IV line sites should be carefully examined for evidence of infection, and indwelling central lines should be changed according to published guidelines.

Anticoagulation in individuals with infective endocarditis is controversial. Although new anticoagulation in the setting of native valve endocarditis does not appear to provide a benefit, continuing ongoing anticoagulation may be advisable. Some authorities recommend continuing anticoagulation in patients with mechanical prosthetic valve endocarditis. However, discontinuation of all anticoagulation for at least the first 2 weeks of antibiotic therapy is generally advised in patients who have *S. aureus* prosthetic valve endocarditis and who have experienced a recent CNS embolic event. This approach allows any CNS thrombus to organize and potentially prevents the acute hemorrhagic transformation of such embolic lesions. Reintroduction of anticoagulation in these patients must be cautious, and the international normalized ratio must be monitored carefully. The best option for patients with other indications for anticoagulation, such as deep vein thrombosis, major vessel embolization, or atrial fibrillation, is less clear and should be decided in a multidisciplinary fashion that balances the risks and benefits for each individual patient.

Initiation of high-dose (325 mg/day) aspirin in patients with infective endocarditis does not prevent subsequent embolic events and tends to increase the incidence of bleeding. Whether patients should remain on chronic, low-dose (81 mg) prophylactic aspirin if they develop subsequent infective endocarditis is uncertain, although nonrandomized data suggest such an approach is safe and may even reduce the risk of embolization from the infected valve.

Complications

The complications of infective endocarditis can be divided into four groups for ease of classification: direct valvular damage and consequences of local microbial invasion, embolic complications, metastatic infections from bacteremia, and immunologic phenomena. Local damage to the endocardium or myocardium may directly erode through the involved cardiac valve or adjacent myocardial wall, resulting in hemodynamically significant valvular perforations or intracardiac or extracardiac fistulae. Such local complications typically present clinically with the acute onset of heart failure and carry a poor prognosis, even with prompt cardiac surgery. Valve ring abscesses also require surgical intervention and are more frequent in patients with prosthetic valves. Although a conduction defect on ECG may suggest the diagnosis, TEE is the diagnostic technique of choice for detecting paravalvular abscess, valve perforation, or intracardiac fistulae. Frank myocardial abscesses are found in up to 20% of cases on autopsy, and *Aspergillus* endocarditis invades the myocardium in more than 50% of cases. Purulent pericarditis is rare and is usually associated with a concomitant myocardial abscess. Myocardial infarction (MI), thought to be caused by embolism of vegetative material into the coronary arteries, is seen in 40 to 60% of cases on autopsy, although most cases are clinically silent and lack characteristic ECG changes. However, up to 15% of elderly patients may present with clinical evidence of acute MI, with potentially disastrous complications if the MI is thought to be the primary event and the patient is given thrombolytic therapy. Heart failure is the leading cause of death in infective endocarditis, usually related to direct valvular damage.

About 35% of patients have at least one clinically evident embolic event. In fungal endocarditis, the majority of patients have at least one embolic event, frequently with a large embolus. The presence of large (>10 mm), mobile vegetations on the echocardiogram, particularly when the anterior mitral valve leaflet is involved, predicts a high risk of embolic complications. Systemic emboli most commonly lodge in the kidneys, spleen, large peripheral blood vessels, or especially in the CNS. Vegetations in right-sided endocarditis usually embolize to the lungs and cause abnormalities on the chest radiograph, although occasionally such emboli reach the left-sided circulation via a patent foramen ovale.

Renal abscesses are rare in infective endocarditis; however, bland renal infarction is a frequent, asymptomatic finding on abdominal CT scanning (about 50%

of cases at autopsy). Similarly, splenic infarction occurs in up to 44% of autopsy-confirmed cases. Such emboli may be asymptomatic but also can cause left upper quadrant pain radiating to the left shoulder, sometimes as the presenting symptom of infective endocarditis. A splenic infarction that progresses to form an abscess can cause persistent fever or bacteremia, so such patients should undergo abdominal CT to search for this complication.

Mycotic vascular aneurysms, which frequently occur at bifurcation points, are found in about 10 to 15% of cases at autopsy but may be clinically silent until they rupture (which may be months to years after apparently successful antibiotic treatment of infective endocarditis). Whereas peripheral mycotic aneurysms require surgical resection, intracerebral aneurysms can be resected or managed with intravascular techniques (e.g., coils) if they bleed, increase in size, and/or cause a mass effect (Chapter 377). For mycotic aneurysms of the abdominal aorta, endovascular repair may be preferable, but long-term antibiotics are generally recommended.

Many patients may have evidence of cerebrovascular emboli, which have a predilection for the middle cerebral artery distribution. Most emboli to the CNS occur early in the course of the disease, and are evident at the time of presentation or shortly thereafter. Embolic strokes may undergo hemorrhagic transformation, with a sudden worsening of the patient's neurologic status. Many patients with fungal endocarditis present with an embolic stroke or large emboli that occlude major vessels.

Some complications of infective endocarditis result when bacteremic seeding causes metastatic infection at a distant site. Patients may present with or develop osteomyelitis, septic arthritis, or epidural abscess. Purulent meningitis (Chapter 381) is a rare complication except in pneumococcal endocarditis, although many patients with *S. aureus* infective endocarditis who undergo lumbar puncture have a pleocytosis, without frank meningitis. Importantly, the finding of one metastatic complication of infective endocarditis does not exclude the possibility of additional sites of hematogenous infection, particularly in *S. aureus* endocarditis. Thus, the need for additional diagnostic evaluations should be guided by the patient's clinical course.

Immunologic phenomena complicating infective endocarditis are often directly related to high levels of circulating immune complexes. Renal biopsy results are usually abnormal in the setting of active infective endocarditis, especially in patients with renal impairment and abnormal urinalyses. Endocarditis classically causes a hypocomplementemia-related glomerulonephritis (Chapter 107). Histopathologically, the glomerular changes may be focal, diffuse, or membranoproliferative, or they may be akin to the immune complex disease found in systemic lupus erythematosus. In addition, many of the musculoskeletal conditions associated with infective endocarditis, including monoarticular and oligoarticular arthritides, are probably mediated by immune complexes. These immunologic phenomena usually abate with successful antimicrobial therapy.

Surgery

Some patients with infective endocarditis require surgical treatment, either to cure the infection or to address its complications (Table 61-8).[21] Most patients with evidence of direct extension of infection to myocardial structures, prosthetic valve dysfunction, or heart failure from endocarditis-induced valvular damage should undergo surgery. In addition, many cases of endocarditis caused by fungi, aerobic gram-negative bacilli, or multidrug-resistant organisms (e.g., vancomycin- or gentamicin-resistant enterococci) require surgical management. Progression of disease or persistence of fever and bacteremia for more than 7 to 10 days in the presence of appropriate antibiotic therapy also may indicate the need for valve surgery, although a thorough search must first be conducted to exclude other primary or metastatic foci of infection. In a randomized trial of patients with left-sided infective endocarditis, severe valve disease, and large vegetations (>10 mm), early valve surgery did not significantly reduce all-cause mortality at 6 months, but it markedly decreased the risk of systemic embolism, including stroke and MI. Surgical management also should be considered for patients who have recurrent (two or more) embolic events on appropriate antibiotic therapy and sometimes in patients who have large vegetations (>10 mm) on echocardiography plus one embolic event. The presence of *S. aureus* endocarditis involving the anterior mitral valve leaflet and large vegetations (>10 mm) may be a special circumstance calling for early surgical intervention to reduce the high risk of CNS emboli, especially when mitral valve repair, rather than valve replacement, can be accomplished. Unfortunately, only about 15 to 20% of these latter patients are judged to be candidates for valve repair at the time of valve surgery.

After 7 days of preoperative antibiotics, the risk of infection on a newly implanted valve is low.[22] Delaying surgery in patients with deteriorating cardiac function in an attempt to sterilize the affected valve is ill advised because the risk of progressive heart failure or further complications usually outweighs the relatively small risk of recurrent infective endocarditis after prosthetic valve implantation. Relative contraindications to valve replacement include recent large CNS emboli (>2 cm) or bleed (because of the risk of CNS bleeding in the perioperative period, when systemic anticoagulation is required), multiple prior valve replacements (because of the difficulty of sewing a new valve into tissue already weakened from previous surgeries), and ongoing injection drug use. On occasion, patients have both a compelling indication for valve replacement (e.g., acute heart failure) and a recent CNS embolic event. The risk of hemorrhagic transformation of such lesions during cardiac bypass–associated anticoagulation is controversial, but the greatest risk of such transformation is with larger (>2 cm) emboli, especially those that have exhibited a hemorrhagic component. In these latter scenarios, it is prudent to try to delay surgery for at least 2 to 4 weeks to allow organization and resolution of such emboli. However, there appears to be no survival benefit in delaying indicated valve replacement surgery (>7 days) after an ischemic stroke, especially in patients who have smaller CNS lesions.

After definitive surgical treatment, most patients should receive further antibiotic therapy unless a full course of antibiotics was administered before surgery and there is no evidence of ongoing infection. If the patient received antibiotics for less than 1 week before surgery or the culture from the operative site is positive, the patient should receive the equivalent of a full initial course of antibiotics appropriate for the organism. If the patient received antibiotics for 2 weeks or more and the culture result from the operative site is negative (regardless of whether valve histopathology shows inflammation or a positive Gram stain result), the patient should receive whatever remains of the originally planned course of appropriate antibiotic therapy.

In patients with infective endocarditis related to implanted cardiovascular devices, complete device removal is usually mandatory, regardless of the pathogen, if the goal is to cure the infection.[23] In patients who truly cannot tolerate device removal, chronic antibiotic therapy, sometimes delivered regionally in situ,[24] is the best alternative. If a replacement device needs to be implanted, the optimal timing for such a procedure is unclear. However, blood culture results should be negative, and any concomitant local or pocket site infection should be completely resolved.

The duration of antimicrobial therapy after device extraction depends on the device and the infection. For lead-related infective endocarditis, which is usually

TABLE 61-8 INDICATIONS FOR VALVE SURGERY IN ENDOCARDITIS

INDICATION	CLASS*
NATIVE VALVE ENDOCARDITIS	
Acute aortic insufficiency or mitral regurgitation with heart failure	I
Acute aortic insufficiency with tachycardia and pre-closure of the mitral valve on echocardiogram	I
Fungal endocarditis	I
Evidence of annular or aortic abscess, sinus or aortic true or false aneurysm, valvular dehiscence, rupture, perforation, or fistula	I
Evidence of valve dysfunction and persistent infection after a prolonged period (7-10 days) of appropriate therapy, provided there are no noncardiac causes of infection	I
Recurrent emboli after appropriate antibiotic therapy	I
Infection with enteric gram-negative organisms or organisms with a poor response to antibiotics in patients with evidence of valve dysfunction	I
Anterior mitral leaflet vegetation (especially with size >10 mm) or persistent vegetation after systemic embolization	IIa
Increase in vegetation size despite appropriate antimicrobial therapy	IIb
Early infections of the mitral valve that probably can be repaired, especially in the presence of large vegetations and/or recurrent emboli	III
Persistent fever and leukocytosis with negative blood cultures	III
PROSTHETIC VALVE ENDOCARDITIS	
Early prosthetic valve endocarditis (<2 mo after surgery)	I
Heart failure with prosthetic valve dysfunction	I
Nonstreptococcal/non-HACEK endocarditis	I
Evidence of perivalvular leak, annular or aortic abscess, sinus or aortic true or false aneurysm, fistula formation, or new-onset conduction disturbances	I
Persistent bacteremia after 7-10 days of appropriate antibiotic therapy, with noncardiac causes for bacteremia excluded	IIa
Recurrent peripheral embolus despite therapy	IIa

*Class I = conditions for which there is evidence or general agreement that a given procedure or treatment is useful and effective; class II = conditions for which there is conflicting evidence or a divergence of opinion about the usefulness or efficacy of a procedure or treatment; class IIa = weight of evidence or opinion is in favor of usefulness or efficacy; class IIb = usefulness or efficacy is less well established by evidence or opinion; class III = conditions for which there is evidence or general agreement that the procedure or treatment is not useful and in some cases may be harmful.
HACEK = *Haemophilus, Aggregatibacter, Cardiobacterium, Eikenella,* and *Kingella* spp.
Adapted from Otto CM, Nishimura RA, Bonow RO, et al. 2020 ACC/AHA guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines. *Circulation.* 2021;143:e72-e227.

associated with blood stream infection, 2 weeks of therapy is recommended if there are no infection complications. For infection caused by *S. aureus*, therapy should be extended for up to 4 weeks.

Nearly 40% of patients with infective endocarditis related to implantable cardiovascular electronic devices have concomitant valve involvement, predominantly tricuspid valve infection, with in-hospital and 1-year mortality rates of 15% and 23%, respectively. Removal of the device appears to reduce the mortality rate by about 50% (from about 40% to about 20%). In such patients, 4 to 6 weeks of concomitant antibiotic therapy is recommended after complete removal of the device.

PREVENTION

No randomized clinical trials have addressed whether dental procedures predispose to infective endocarditis and whether antibiotic prophylaxis prevents it. However, data support a temporal association between invasive dental procedures and the subsequent development of infective endocarditis in high-risk patients,[25] and antibiotic prophylaxis is associated with reduced incidence of endocarditis following these procedures.[26] Based on these observational data, antibiotic prophylaxis is recommended by the American Heart Association (Table 61-9) when patients with the highest risk of endocarditis-related adverse outcomes undergo dental procedures that involve manipulation of the gingival tissue, the periapical region of teeth, or perforation of the oral mucosa.[27] Antibiotic prophylaxis is also recommended when high-risk patients undergo an invasive procedure of the respiratory tract, with incision or biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy; or invasive procedures involving infected skin, skin structures, or musculoskeletal tissue (Table 61-10). Other consensus guidelines have also narrowed the indications for antibiotic prophylaxis with dental procedures. For example, guidelines from the European Society of Cardiology are largely consistent with American Heart Association guidelines. In contrast, guidelines in the United Kingdom state that no prophylaxis is routinely advised for any dental patient, regardless of underlying cardiac valvular conditions, while still giving dentists the latitude to prescribe antibiotic prophylaxis for selected patients. Since the recent publications of these more limited recommendations, follow-up surveys in these countries have generated mixed results without definitive evidence of cause-and-effect between reduction in the use of dental prophylaxis and any increased incidence of endocarditis due to viridans group streptococci.[28]

Amoxicillin is the usual first choice for prophylaxis of infective endocarditis in patients undergoing invasive dental procedures, but other options are likely equally given (Table 61-11). More than 90% of patients labeled as being "penicillin allergic" are not truly allergic by skin testing. If such patients require ongoing antibiotic prophylaxis, allergy evaluation (Chapter 234) is warranted so that appropriate patients can be "de-labeled" and receive amoxicillin in the future.

Patients with implanted electronic cardiovascular devices do not require antibiotic prophylaxis for dental or other invasive procedures, but such patients do require surgical site prophylaxis at the time of device placement. The recommended regimens for this latter scenario generally include a β-lactam (commonly cefazolin, 2 g IV 1 hour before device placement), regardless of whether a new device is being placed or a device is being revised. More aggressive prophylaxis with vancomycin, intraprocedural bacitracin pocket wash, and 2 days of postprocedural oral cephalexin does not significantly reduce infection rates.[A5] However, one randomized trial showed that use of an absorbable antibiotic-eluting envelope at the time

TABLE 61-9 UNDERLYING CONDITIONS FOR WHICH ANTIBIOTIC PROPHYLAXIS IS AND IS NOT SUGGESTED FOR DENTAL PROCEDURES

ANTIBIOTIC PROPHYLAXIS GENERALLY RECOMMENDED
Prosthetic cardiac valve or material
Presence of cardiac prosthetic valve
Transcatheter prosthetic valves
Cardiac valve repair with devices, including annuloplasty, rings, or clips
Left ventricular assist devices or implantable heart
Previous, relapsed, or recurrent infectious endocarditis
Congenital heart disease
Unrepaired cyanotic congenital congenital heart disease, including palliative shunts and conduits
Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by transcatheter during the first 6 mo after the procedure
Repaired congenital heart disease with residual defects at the site of or adjacent to the site of a prosthetic patch or prosthetic device
Surgical or transcatheter pulmonary artery valve or conduit placement
Cardiac transplant recipients who develop cardiac valvulopathy
ANTIBIOTIC PROPHYLAXIS NOT RECOMMENDED
Implantable electronic devices such as a pacemaker or similar devices
Septal defect closure devices when complete closure is achieved
Peripheral vascular grafts and patches, including those used for hemodialysis
Coronary artery stents or other vascular stents
Central nervous system ventriculoatrial shunts
Vena cava filters

TABLE 61-10 PROCEDURES FOR WHICH ENDOCARDITIS PROPHYLAXIS IS AND IS NOT RECOMMENDED

PROPHYLAXIS IS RECOMMENDED*
Dental: all dental procedures involving manipulation of gingival tissue, the periapical region of teeth, or perforation of the oral mucosa
Respiratory: procedures involving incision or biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy
Other: procedures involving infected skin, skin structures, or musculoskeletal tissue prior to incision and drainage
PROPHYLAXIS IS NOT RECOMMENDED
Dental: routine anesthetic injections through noninfected tissue, dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, bleeding from trauma to the lips or oral mucosa
Respiratory: procedures not involving incision or biopsy of the respiratory mucosa, including bronchoscopy (unless the procedure involves incision of the respiratory tract mucosa)
Genitourinary: antibiotic prophylaxis solely to prevent infective endocarditis is not recommended
Gastrointestinal: antibiotic prophylaxis solely to prevent infective endocarditis is not recommended

*Only in patients with underlying cardiac conditions associated with the highest risk for adverse outcome from endocarditis (listed in Table 61-9).

Reprinted with permission *Circulation*. 2021;143:e963-e978 ©2021 American Heart Association, Inc.

TABLE 61-11 ANTIBIOTIC REGIMENS FOR AN ADULT UNDERGOING A DENTAL PROCEDURE: SINGLE DOSE 30 TO 60 MINUTES BEFORE PROCEDURE*†

PATIENT CHARACTERISTICS	REGIMEN‡
Able to take oral medications	Amoxicillin 2 g PO
Unable to take oral medications	Ampicillin 2 g IV or IM; or cefazolin or ceftriaxone 1 g IM or IV
Allergic to penicillin or ampicillin and able to take oral medications	Cephalexin 2 g PO (or other first- or second-generation oral cephalosporin in equivalent adult doses); azithromycin 500 mg PO; or clarithromycin 500 mg PO; or doxycycline 100 mg PO
Allergic to penicillin or ampicillin and unable to take oral medications	Cefazolin or ceftriaxone 1 g IM or IV

*For the applicable procedures, see Table 61-10.

†For the applicable conditions, see Table 61-9.

‡Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillin or ampicillin.

Clindamycin is no longer recommended for antibiotic prophylaxis for a dental procedure.

IM = intramuscular; IV = intravenous; PO = oral.

Reprinted with permission *Circulation*. 2021;143:e963-e978 ©2021 American Heart Association, Inc.

of device placement, replacement, or pocket revision could significantly reduce infections without adverse effects.[A6]

PROGNOSIS

Untreated infective endocarditis is uniformly fatal. Aggressive medical and surgical management dramatically improves the outcome. The overall mortality rate from both native and prosthetic valve endocarditis remains fairly high, ranging from 17 to 36%. Whereas certain subgroups, such as patients with viridans group streptococcal endocarditis, have a lower risk of death, patients with *S. aureus,* fungal, aerobic gram-negative bacillary, and zoonotic endocarditis have higher mortality rates. Heart failure and CNS events are the most frequent causes of death.

Endocarditis recurs in about 12 to 16% of patients and is more common in injection drug users, elderly people, and patients with prosthetic valves. The rate of relapse also varies depending on the causative organism. Easily treated infections, such as those with viridans group streptococci, have a low rate of relapse (5%), but more difficult-to-eradicate organisms may have significantly higher rates.

62 PERICARDIAL DISEASES

BRIAN D. HOIT AND JAE K. OH

The pericardium is a two-layered sac composed of visceral and parietal components. The visceral pericardium is a serosal cell monolayer that adheres firmly to the epicardium, reflects over the origin of the great vessels, and, together with a tough, fibrous parietal layer encases the heart. The pericardial space enclosed between the two serosal layers normally contains up to 50 mL of plasma ultrafiltrate. The pericardium is well innervated, so pericardial inflammation may produce severe pain and trigger vagally mediated reflexes.

As a result of its relatively inelastic physical properties, the pericardium limits acute cardiac dilation and enhances mechanical interactions of the cardiac chambers.[1] In response to chronic stretch, the pericardium dilates to allow a slowly accumulating pericardial effusion to become quite large without compressing the cardiac chambers and to allow left ventricular remodeling to occur without excessive pericardial restraint. Conversely, a scarred or thickened pericardium can limit the filling of the heart, resulting in pericardial constriction. Despite the important functions of the normal pericardium, congenital absence or surgical resection of the pericardium does not appear to have any major untoward effects.

ACUTE PERICARDITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute inflammation of the pericardium, with or without an associated pericardial effusion, can occur as an isolated clinical problem or as a manifestation of systemic disease. Although about 85% of isolated cases of acute pericarditis are idiopathic or viral, the list of other potential causes is quite extensive (Table 62-1). Viral causes include echoviruses, group B coxsackieviruses, and, recently, severe acute respiratory syndrome coronavirus 2 (Chapter 336),[2] but obtaining specific viral titers does not alter patient management. About 6% of cases are neoplastic in origin, about 4% are caused by tuberculosis, about 3% are caused by other bacterial or fungal infections, and about 2% are caused by collagen vascular disease. Patients with fever greater than 38° C or a subacute course or who fail to respond promptly to therapy are most likely to have pericarditis caused by a systemic autoimmune disease, malignancy, drugs (including checkpoint inhibitors [Chapter 164]),[3] or bacterial infection.

CLINICAL MANIFESTATIONS

Most patients with acute pericarditis experience sharp retrosternal chest pain (see Table 39-2 in Chapter 39), which can be quite severe and debilitating. In some cases, however, pericarditis is asymptomatic, such as when it accompanies rheumatoid arthritis. Pericardial pain is usually worse with inspiration and when supine, and it is generally relieved by sitting and leaning forward. Typically, pericardial pain is referred to the scapular ridge, presumably owing to irritation of the phrenic nerves, which provide sensory innervation to the pericardium. The chest pain of acute pericarditis must be differentiated from pulmonary embolism and myocardial ischemia or infarction (Table 62-2).

The pericardial friction rub is the classic finding in patients with acute pericarditis. A friction rub is a high-pitched, scratchy sound that can have one, two, or three components corresponding to ventricular ejection, rapid ventricular filling in early diastole, and atrial systole. A pericardial rub, which is differentiated from a murmur by its scratchy quality, is sometimes localized to a small area on the chest wall and may come and go spontaneously or with changes in position. To hear a rub, it may be necessary to auscultate the heart with the patient in multiple positions, especially using the diaphragm with the patient learning forward and not breathing after full expiration. The pericardial friction rub must be differentiated from a pleural rub, which is absent during suspended respiration, but the pericardial rub is unaffected.

DIAGNOSIS

A targeted evaluation (Table 62-3) can help distinguish pericarditis from other conditions as well as help establish the cause of true pericarditis (Table 62-4).[4] The diagnosis of acute pericarditis can be made with two of the following criteria: typical chest pain, pericardial friction rub, characteristic electrocardiogram (ECG) changes, and pericardial effusion. Early in the course of acute pericarditis, the ECG typically displays diffuse ST elevation in association with PR depression (Fig. 62-1). The ST elevation is usually present in all leads except for aVR, but the changes may be atypical in post–myocardial infarction (MI) pericarditis. Classically, the ECG changes of acute pericarditis evolve over several days; resolution of the ST elevation is followed by widespread T wave inversion that subsequently normalizes, although the temporal evolution of ECG changes is highly variable. Uremic pericarditis usually occurs without the typical ECG abnormalities.

Patients with acute pericarditis usually have evidence of systemic inflammation, including leukocytosis, an elevated erythrocyte sedimentation rate (ESR), and increased C-reactive protein (CRP) level. A low-grade fever is common, but a temperature greater than 38° C is unusual and suggests the possibility of bacterial pericarditis.

Troponin levels typically are minimally elevated in acute pericarditis owing to some involvement of the epicardium by the inflammatory process. An elevated troponin level in acute pericarditis usually returns to normal within 1 to 2 weeks and is not associated with a worse prognosis. Although the elevated troponin level may lead to the misdiagnosis of an ST elevation MI (Chapter 58), most patients with elevated troponin levels and acute pericarditis have normal coronary angiograms. An echocardiogram (Chapter 43) can help avoid a misdiagnosis of MI.

Echocardiography may demonstrate a small pericardial effusion in the presence of acute pericarditis, but a normal echocardiogram does not exclude the diagnosis of acute pericarditis. An echocardiogram is critical, however, in excluding the diagnosis of cardiac tamponade (see later). When the diagnosis of acute pericarditis is unclear, cardiac magnetic resonance imaging (MRI) can demonstrate pericardial inflammation as delayed enhancement of the pericardium (Fig. 62-2). Diagnostic pericardiocentesis is indicated in suspected purulent tuberculosis or malignant pericarditis or if the patient has cardiac tamponade.

of device placement, replacement, or pocket revision could significantly reduce infections without adverse effects.[A6]

PROGNOSIS

Untreated infective endocarditis is uniformly fatal. Aggressive medical and surgical management dramatically improves the outcome. The overall mortality rate from both native and prosthetic valve endocarditis remains fairly high, ranging from 17 to 36%. Whereas certain subgroups, such as patients with viridans group streptococcal endocarditis, have a lower risk of death, patients with *S. aureus,* fungal, aerobic gram-negative bacillary, and zoonotic endocarditis have higher mortality rates. Heart failure and CNS events are the most frequent causes of death.

Endocarditis recurs in about 12 to 16% of patients and is more common in injection drug users, elderly people, and patients with prosthetic valves. The rate of relapse also varies depending on the causative organism. Easily treated infections, such as those with viridans group streptococci, have a low rate of relapse (5%), but more difficult-to-eradicate organisms may have significantly higher rates.

62 PERICARDIAL DISEASES

BRIAN D. HOIT AND JAE K. OH

The pericardium is a two-layered sac composed of visceral and parietal components. The visceral pericardium is a serosal cell monolayer that adheres firmly to the epicardium, reflects over the origin of the great vessels, and, together with a tough, fibrous parietal layer encases the heart. The pericardial space enclosed between the two serosal layers normally contains up to 50 mL of plasma ultrafiltrate. The pericardium is well innervated, so pericardial inflammation may produce severe pain and trigger vagally mediated reflexes.

As a result of its relatively inelastic physical properties, the pericardium limits acute cardiac dilation and enhances mechanical interactions of the cardiac chambers.[1] In response to chronic stretch, the pericardium dilates to allow a slowly accumulating pericardial effusion to become quite large without compressing the cardiac chambers and to allow left ventricular remodeling to occur without excessive pericardial restraint. Conversely, a scarred or thickened pericardium can limit the filling of the heart, resulting in pericardial constriction. Despite the important functions of the normal pericardium, congenital absence or surgical resection of the pericardium does not appear to have any major untoward effects.

ACUTE PERICARDITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute inflammation of the pericardium, with or without an associated pericardial effusion, can occur as an isolated clinical problem or as a manifestation of systemic disease. Although about 85% of isolated cases of acute pericarditis are idiopathic or viral, the list of other potential causes is quite extensive (Table 62-1). Viral causes include echoviruses, group B coxsackieviruses, and, recently, severe acute respiratory syndrome coronavirus 2 (Chapter 336),[2] but obtaining specific viral titers does not alter patient management. About 6% of cases are neoplastic in origin, about 4% are caused by tuberculosis, about 3% are caused by other bacterial or fungal infections, and about 2% are caused by collagen vascular disease. Patients with fever greater than 38° C or a subacute course or who fail to respond promptly to therapy are most likely to have pericarditis caused by a systemic autoimmune disease, malignancy, drugs (including checkpoint inhibitors [Chapter 164]),[3] or bacterial infection.

CLINICAL MANIFESTATIONS

Most patients with acute pericarditis experience sharp retrosternal chest pain (see Table 39-2 in Chapter 39), which can be quite severe and debilitating. In some cases, however, pericarditis is asymptomatic, such as when it accompanies rheumatoid arthritis. Pericardial pain is usually worse with inspiration and when supine, and it is generally relieved by sitting and leaning forward. Typically, pericardial pain is referred to the scapular ridge, presumably owing to irritation of the phrenic nerves, which provide sensory innervation to the pericardium. The chest pain of acute pericarditis must be differentiated from pulmonary embolism and myocardial ischemia or infarction (Table 62-2).

The pericardial friction rub is the classic finding in patients with acute pericarditis. A friction rub is a high-pitched, scratchy sound that can have one, two, or three components corresponding to ventricular ejection, rapid ventricular filling in early diastole, and atrial systole. A pericardial rub, which is differentiated from a murmur by its scratchy quality, is sometimes localized to a small area on the chest wall and may come and go spontaneously or with changes in position. To hear a rub, it may be necessary to auscultate the heart with the patient in multiple positions, especially using the diaphragm with the patient learning forward and not breathing after full expiration. The pericardial friction rub must be differentiated from a pleural rub, which is absent during suspended respiration, but the pericardial rub is unaffected.

DIAGNOSIS

A targeted evaluation (Table 62-3) can help distinguish pericarditis from other conditions as well as help establish the cause of true pericarditis (Table 62-4).[4] The diagnosis of acute pericarditis can be made with two of the following criteria: typical chest pain, pericardial friction rub, characteristic electrocardiogram (ECG) changes, and pericardial effusion. Early in the course of acute pericarditis, the ECG typically displays diffuse ST elevation in association with PR depression (Fig. 62-1). The ST elevation is usually present in all leads except for aVR, but the changes may be atypical in post–myocardial infarction (MI) pericarditis. Classically, the ECG changes of acute pericarditis evolve over several days; resolution of the ST elevation is followed by widespread T wave inversion that subsequently normalizes, although the temporal evolution of ECG changes is highly variable. Uremic pericarditis usually occurs without the typical ECG abnormalities.

Patients with acute pericarditis usually have evidence of systemic inflammation, including leukocytosis, an elevated erythrocyte sedimentation rate (ESR), and increased C-reactive protein (CRP) level. A low-grade fever is common, but a temperature greater than 38° C is unusual and suggests the possibility of bacterial pericarditis.

Troponin levels typically are minimally elevated in acute pericarditis owing to some involvement of the epicardium by the inflammatory process. An elevated troponin level in acute pericarditis usually returns to normal within 1 to 2 weeks and is not associated with a worse prognosis. Although the elevated troponin level may lead to the misdiagnosis of an ST elevation MI (Chapter 58), most patients with elevated troponin levels and acute pericarditis have normal coronary angiograms. An echocardiogram (Chapter 43) can help avoid a misdiagnosis of MI.

Echocardiography may demonstrate a small pericardial effusion in the presence of acute pericarditis, but a normal echocardiogram does not exclude the diagnosis of acute pericarditis. An echocardiogram is critical, however, in excluding the diagnosis of cardiac tamponade (see later). When the diagnosis of acute pericarditis is unclear, cardiac magnetic resonance imaging (MRI) can demonstrate pericardial inflammation as delayed enhancement of the pericardium (Fig. 62-2). Diagnostic pericardiocentesis is indicated in suspected purulent tuberculosis or malignant pericarditis or if the patient has cardiac tamponade.

ABSTRACT

The pericardium is a two-layered sac that encases the heart and constrains its filling. The pericardium can be affected by virtually every category of disease, including infectious, neoplastic, immune-inflammatory, metabolic, iatrogenic, traumatic, and congenital causes. Pericardial heart disease includes pericarditis, cardiac tamponade, constrictive pericarditis, and cysts. Pericarditis is an acute inflammatory condition, typically as a result of viral infection. Such cases usually resolve, occasionally recur, and infrequently progress to pericardial tamponade. Pericarditis caused by acute bacterial infection requires urgent drainage. Tuberculous pericarditis can progress to chronic constriction. The primary abnormality of cardiac tamponade is pan-cyclic compression of the cardiac chambers by increased pericardial fluid, so that all four cardiac chambers compete for a fixed intrapericardial volume. Features responsible for the pathophysiology include transmission of thoracic pressure through the pericardium and heightened ventricular interdependence. In constrictive pericarditis, the pericardium limits diastolic filling, causes dissociation of intracardiac and intrathoracic pressures, and heightens ventricular interdependence. Both conditions result in diastolic dysfunction, elevated and equal venous and ventricular diastolic pressure, respiratory variation in ventricular filling, and, ultimately, reduced cardiac output.

TABLE 62-1 CAUSES OF PERICARDITIS: INFECTIOUS AND NONINFECTIOUS

INFECTIOUS PERICARDITIS (⅔ OF CASES)

Viral (most common): echovirus and coxsackievirus (usual), influenza, EBV, CMV, adenovirus, varicella, rubella, mumps, SARS-CoV-2, HBV, HCV, HIV, parvovirus B19, human herpesvirus 6
Bacterial: tuberculosis (4-5%)* and *Coxiella burnetii* (most common); other bacterial causes (rare) include pneumococcosis, meningococcosis, gonococcosis, *Haemophilus,* staphylococci, *Chlamydia, Mycoplasma, Legionella, Leptospira, Listeria*
Fungal (rare): histoplasmosis more likely in immunocompetent patients; aspergillosis, blastomycosis, candidiasis more likely in immunosuppressed patients
Parasitic (very rare): *Echinococcus, Toxoplasma*

NONINFECTIOUS PERICARDITIS (⅓ OF CASES)

Autoimmune Pericarditis (<10%)*
Pericardial injury syndromes: post–myocardial infarction syndrome; postpericardiotomy syndrome; posttraumatic pericarditis, including iatrogenic pericarditis (e.g., after percutaneous coronary interventions, pacemaker insertion, ablation)
Pericarditis in systemic autoimmune and autoinflammatory diseases: more common in systemic lupus erythematosus, Sjögren syndrome, rheumatoid arthritis, systemic sclerosis, systemic vasculitides, Behçet syndrome, sarcoidosis, familial Mediterranean fever
Autoreactive pericarditis†
Neoplastic Pericarditis (5-7%)*
Primary tumors (rare): pericardial mesothelioma
Secondary metastatic tumors (common): lung and breast cancer, lymphoma
Metabolic Pericarditis: Uremia, Myxedema (common); others rare
Traumatic Pericarditis (rare)
Direct injury: penetrating thoracic injury, esophageal perforation, iatrogenic
Indirect injury: nonpenetrating thoracic injury, radiation injury
Drug-related pericarditis (rare): procainamide, hydralazine, isoniazid, and phenytoin (lupus-like syndrome), penicillins (hypersensitivity pericarditis with eosinophilia), doxorubicin, and daunorubicin (often associated with cardiomyopathy; may cause pericardiopathy), immune checkpoint inhibitors (e.g., ipilimumab, pembrolizumab)

*Percentages refer to unselected cases.
†The diagnosis of autoreactive pericarditis is established using the following criteria: (1) increased number of lymphocytes and mononuclear cells >5000/μL (autoreactive lymphocytic) or the presence of antibodies against heart muscle tissue (antisarcolemmal) in the pericardial fluid (autoreactive antibody mediated), (2) signs of myocarditis on epicardial or endomyocardial biopsies by ≥14 cells/mm^2, and (3) exclusion of infections, neoplasia, and systemic and metabolic disorders.
CMV = cytomegalovirus; EBV = Epstein-Barr virus; HBV = hepatitis B virus; HCV = hepatitis C virus; HIV = human immunodeficiency virus; SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2.

TABLE 62-2 DIFFERENTIATION OF PERICARDITIS FROM MYOCARDIAL ISCHEMIA OR INFARCTION AND PULMONARY EMBOLISM

FINDINGS	MYOCARDIAL ISCHEMIA OR INFARCTION	PERICARDITIS	PULMONARY EMBOLISM
CHEST PAIN			
Character	Pressure-like heavy, squeezing	Sharp, stabbing, occasionally dull	Sharp, stabbing
Change with respiration	No	Worsened with inspiration	In phase with respiration (absent when the patient is apneic)
Change with position	No	Worse when supine; improved when sitting up or leaning forward	No
Duration	Minutes (ischemia); hours (infarction)	Hours to days	Hours to days
Response to nitroglycerin	Improved	No change	No change
PHYSICAL EXAMINATION			
Friction rub	Absent (unless pericarditis is present)	Present in most patients	Pleural friction rub may occur
ELECTROCARDIOGRAM			
ST segment elevation	Localized convex	Widespread concave	Limited to leads III, aVF, and V_1
PR segment depression	Rare	Frequent	None

Modified from Little WC, Freeman GL. Pericardial disease. *Circulation*. 2006;113:1622-1632.

TREATMENT

Patients who have manifestations of an underlying systemic process, such as an inflammatory disease, have high-risk features (i.e., fever >38° C, subacute course, failure to respond to treatment, an elevated troponin level with evidence of concomitant left ventricular dysfunction, a large pericardial effusion, incipient or established pericardial tamponade), or have suspected acute MI (Chapter 58) warrant hospitalization and further evaluation. Patients without these features can usually be followed as outpatients (Fig. 62-3).

If acute pericarditis is a manifestation of an underlying disease, such as a systemic rheumatologic condition, it often responds to treatment of the primary condition. Most cases of acute idiopathic or viral pericarditis are self-limited and respond to treatment with aspirin (650 mg every 6 hours) or another nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen (300 to 800 mg every 6 to 8 hours).[5] The dose of NSAID should be tapered after symptoms and any pericardial effusion have resolved, but the medication should be taken for at least 3 to 4 weeks to minimize the risk of recurrent pericarditis.

In addition, colchicine (0.6 to 1.2 mg/day for 3 months) should be started in all patients with acute pericarditis[6] to reduce the rate of persistent symptoms at 72 hours, reduce the likelihood of recurrent pericarditis from 55 to 24% at 18 months, and reduce the rate of subsequent hospitalization.[A1] The major side effect of colchicine is diarrhea. The lower dose of colchicine should be used in patients who weigh less than 70 kg or who have side effects with the higher dose. Colchicine should be avoided in patients with abnormal renal or hepatic function and in patients being treated with macrolide antibiotics, which alter its metabolism.

A proton pump inhibitor, such as omeprazole (20 mg/day), should be considered to improve the gastric tolerability of NSAIDs. Warfarin and heparin should be avoided to minimize the risk of hemopericardium, but anticoagulation may be required if the patient is in atrial fibrillation or has a prosthetic heart valve. It is prudent to avoid exercise until after the chest pain completely resolves. If pericarditis recurs, the patient can be reloaded with colchicine and intramuscular ketorolac (15 to 30 mg, once) and then continued on an oral NSAID and colchicine for at least 3 months.

TABLE 62-3 SELECTED DIAGNOSTIC TESTS IN ACUTE PERICARDITIS

IN ALL PATIENTS
Tuberculin skin test (plus control skin test to exclude anergy)
BUN and creatinine to exclude uremia
Erythrocyte sedimentation rate
Electrocardiogram
Chest radiograph
Echocardiogram
IN SELECTED PATIENTS
Cardiac magnetic resonance imaging
ANA and rheumatoid factor to exclude SLE or rheumatoid arthritis in patients with acute arthritis or pleural effusion
TSH and T_4 to exclude hypothyroidism in patients with clinical findings suggestive of hypothyroidism and in asymptomatic patients with unexplained pericardial effusion
HIV test to exclude AIDS in patients with risk factors for HIV disease or a compatible clinical syndrome
Blood cultures in febrile patients to exclude infective endocarditis and bacteremia
Fungal serologic tests in patients from endemic areas or in immunocompromised patients
ASO titer in children or teenagers with suspected rheumatic fever
Heterophil antibody test to exclude mononucleosis in young or middle-aged patients with a compatible clinical syndrome or acute fever, weakness, and lymphadenopathy

AIDS = acquired immunodeficiency virus; ANA = antinuclear antibody; ASO = antistreptolysin O; BUN = blood urea nitrogen; HIV = human immunodeficiency virus; SLE = systemic lupus erythematosus; T_4 = thyroxine; TSH = thyroid-stimulating hormone.

Modified from Nishimura RA, Kidd KR. Recognition and management of patients with pericardial disease. In: Braunwald E, Goldman L, eds. *Primary Cardiology*. 2nd ed. Philadelphia: WB Saunders; 2003:625.

Although acute pericarditis usually responds dramatically to systemic corticosteroids, observational studies strongly suggest that the use of steroids increases the probability of relapse in patients treated with colchicine. Except when needed to treat an underlying inflammatory disease, every effort should be made to avoid the use of steroids, reserving low-dose steroids for patients who cannot tolerate aspirin and other NSAIDs or whose recurrence is not responsive to colchicine and intravenous NSAIDs. If steroids are used, low-dose prednisone (0.2 to 0.5 mg/kg) appears to be as effective as higher doses and is less likely to be associated with recurrence. Steroids should be continued for at least 1 month before slow tapering, which can be guided by return of the CRP level to the normal range. Pericardiocentesis is not recommended unless purulent or tuberculous pericarditis is clinically suspected or the patient fails to respond to 2 to 3 weeks of NSAID therapy.

PROGNOSIS

The course of viral and idiopathic pericarditis is usually self-limited. Although most patients recover completely, the 5-year mortality after hospitalization for pericarditis is about 30% higher than in age-matched controls.

About 25% of patients, however, have recurrent pericarditis weeks to months later, probably caused by an immune response, and some patients may have multiple debilitating episodes.[7] Interestingly, in patients whose acute pericarditis is accompanied by myocarditis, as evidenced by elevation of serum troponin levels, the recurrence rate is closer to 10%. Recurrent pericarditis is more common in patients treated with steroids for the acute episode, especially during a rapid steroid taper. Prolonged high-dose NSAID treatment (e.g., ibuprofen 300 to 600 mg three times a day) plus colchicine (0.5 to 0.6 mg twice daily, reducing to once daily after 3 to 6 months) is effective for recurrent pericarditis.[A2] In patients who cannot tolerate colchicine or who have recurrent episodes despite colchicine and high-dose NSAID treatment (e.g., indomethacin 50 mg three times a day or ibuprofen 800 mg four times a day), oral steroids (e.g., prednisone 0.2 to 0.5 mg/kg/day for 2 to 4 weeks and then slowly tapered over several months) are generally recommended. The addition of an anti–interleukin 1 drug, such as rilonacept[A3] (after a 320-mg load, 160 mg subcutaneously once weekly) or anakinra[A4] (100 mg subcutaneously once daily), lowers the risk of recurrent pericarditis by over 90%.[A5] In patients with refractory, recurrent pericarditis, surgical pericardiectomy can be considered. Patients who have tuberculous or purulent pericarditis have the highest risk for progression to constrictive pericarditis (see later).

PERICARDIAL EFFUSION AND TAMPONADE

EPIDEMIOLOGY

A pericardial effusion can be caused by any disease that causes acute pericarditis (see Table 62-1), but a majority of cases are caused by conditions other than viral or idiopathic pericarditis (Table 62-5). For example, tamponade occurs in about 10 to 15% of patients with idiopathic pericarditis, but it develops in more than 50% of patients with malignant, tuberculous, or purulent pericarditis. Tuberculosis and neoplastic disease are typically associated with serosanguineous effusions, but such effusions also can be seen with typical viral or idiopathic pericarditis, with uremia, and after mediastinal irradiation. Hemopericardium is seen most commonly with trauma, myocardial rupture after MI, catheter-induced myocardial or epicardial coronary artery rupture, aortic dissection with rupture into the pericardial space, or primary hemorrhage in patients receiving anticoagulant therapy, often after cardiac valve surgery. Chylopericardium is rare and usually results from traumatic or surgical injury to, or neoplastic obstruction of, the thoracic duct.

PATHOBIOLOGY

Under normal conditions, the space between the parietal and visceral pericardium can accommodate only a small amount of fluid before the development of tamponade physiology. The clinical consequences of a pericardial effusion depend on the rate of increase. A rapidly accumulating effusion, as in hemopericardium caused by trauma or aortic dissection, may result in tamponade physiology with just 100 to 200 mL of fluid. It is not surprising, therefore, that cardiac perforation quickly results in tamponade. By comparison, a more slowly developing effusion gradually stretches the pericardium and shifts the normally steep pericardial pressure-volume relation to the right; this explains why large but slowly developing effusions may not produce tamponade.

Tamponade physiology occurs when fluid accumulation in the intrapericardial space is sufficient to compress the heart, resulting in impaired cardiac filling. The increased pericardial pressure in cardiac tamponade accentuates the interdependence among the cardiac chambers as the total cardiac volume is limited by the pericardial effusion. With normal inspiration, right ventricular filling is enhanced, the intraventricular septum is displaced toward the left ventricle, and left ventricular filling and the resulting stroke volume are reduced; these changes are reversed during expiration. In tamponade, these physiologic variations are enhanced and are responsible for the clinical finding of "paradoxical pulse." A small (<10 mm Hg) pulsus paradoxus, which is a decline in systemic blood pressure during inspiration, is normal and is related to the ventricles being confined within the pericardium and sharing a common septum. In cardiac tamponade, this phenomenon is exaggerated, and systemic blood pressure falls by more than 10 mm Hg during inspiration. A pulsus paradoxus also may be present with hypovolemic shock, chronic obstructive pulmonary disease, and bronchospasm.

CLINICAL MANIFESTATIONS

A slowly accumulating, isolated pericardial effusion is often completely asymptomatic. The physical examination results may be normal, but the heart sounds may be muffled. The diagnosis is usually suggested by a chest radiograph that shows cardiomegaly with a globular heart (Fig. 62-4; see also Fig. 44-5) or by an echocardiogram, computed tomography (CT) scan, or MRI performed for another indication. Patients with hypothyroidism, uremia, or collagen vascular disease may have asymptomatic effusions discovered during comprehensive evaluations.

Patients with tamponade are usually anxious and tachycardic, and they may complain of dyspnea, orthopnea, and chest pain. The increased venous pressure is usually apparent as jugular venous distention.[8] The x descent (during ventricular systole) is typically the dominant jugular venous wave, with little or no y descent (during early diastole) (Chapter 39). The heart sounds are classically soft or muffled, especially if there is a large pericardial effusion. In rapidly developing cardiac tamponade, especially hemorrhagic cardiac tamponade, the jugular veins may not be distended because the time course has been insufficient for a compensatory increase in venous pressure. Such "low-pressure" tamponade may also occur in volume-depleted patients. The patient may have signs of right heart failure, with peripheral edema, right upper quadrant pain caused by hepatic congestion, or abnormal liver enzymes and serum bilirubin level.

TABLE 62-4 PRESENTATION AND TREATMENT OF THE MOST COMMON CAUSES OF PERICARDITIS

TYPE	PATHOGENESIS OR ETIOLOGY	DIAGNOSIS	TREATMENT	COMPLICATIONS	COMMENTS
Viral	Coxsackievirus B Echovirus type 8 Epstein-Barr virus	Leukocytosis Elevated ESR Mild cardiac biomarker elevation	Symptomatic relief, NSAIDs, colchicine	Tamponade Relapsing pericarditis	Peaks in spring and fall
Tuberculous	*Mycobacterium tuberculosis*	Isolation of organism from biopsy fluid Granulomas not specific	Triple-drug antituberculosis regimen Pericardial drainage followed by early (4-6 wk) pericardiectomy if signs of tamponade or constriction develop	Tamponade Constrictive pericarditis	1-8% of patients with tuberculosis pneumonia; rule out HIV infection
Bacterial	Group A streptococcus *Staphylococcus aureus* *Streptococcus pneumoniae*	Leukocytosis with marked left shift Purulent pericardial fluid	Pericardial drainage by catheter or surgery Systemic antibiotics Pericardiectomy if constrictive physiology develops	Tamponade in one third of patients	Very high mortality rate if not recognized early
Post–myocardial infarction	12 hr–10 days after infarction	Fever Pericardial friction rub Echo: effusion	Aspirin Prednisone	Tamponade rare	More frequent in large Q wave infarctions Anterior > inferior
Uremic	Untreated renal failure: 50% Chronic dialysis: 20%	Pericardial rub: 90%	Intensive dialysis Indomethacin: probably ineffective Catheter drainage Surgical drainage	Tamponade Hemodynamic instability on dialysis	Avoid NSAIDs ≈50% respond to intensive dialysis
Neoplastic	In order of frequency: lung cancer, breast cancer, leukemia and lymphoma, others	Chest pain, dyspnea Echo: effusion CT, MRI: tumor metastases to pericardium Cytologic examination of fluid positive in 85%	Catheter drainage Subxiphoid pericardiectomy Chemotherapy directed at underlying malignant neoplasm	Tamponade Constriction	

CT = computed tomography; Echo = echocardiogram; ESR = erythrocyte sedimentation rate; HIV = human immunodeficiency virus; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs.

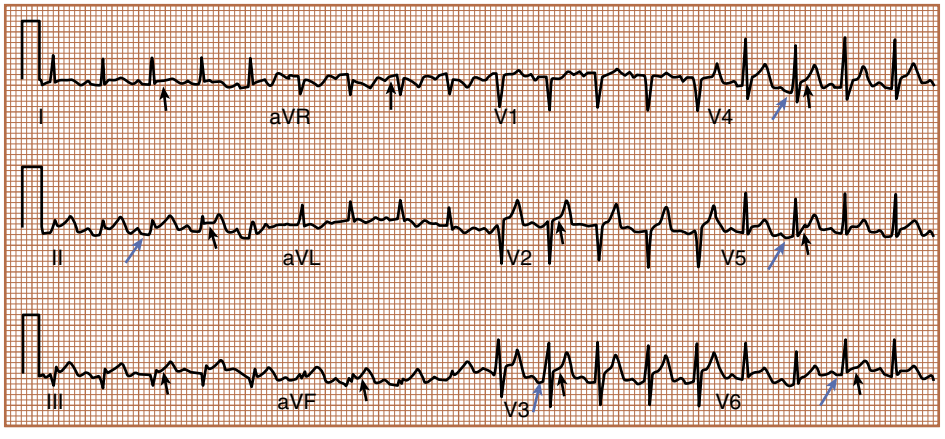

FIGURE 62-1. Electrocardiogram demonstrating typical features of acute pericarditis on presentation. There is diffuse ST elevation and PR depression, except in aVR, in which there is ST depression and PR elevation.

The hallmark of cardiac tamponade is a paradoxical pulse, which is defined as a drop of more than 10 mm Hg in inspiratory systolic arterial pressure (usually measured with a sphygmomanometer during slow inspiration). When severe, the paradoxical pulse may be apparent as the absence of a palpable brachial or radial pulse during inspiration. A paradoxical pulse can also occur when there are wide swings in intrathoracic pressure, pulmonary embolism (Chapter 68), or hypovolemic shock (Chapter 92). A paradoxical pulse may be difficult to recognize in the presence of severe shock.

DIAGNOSIS

Cardiac tamponade, which is a treatable cause of shock (Chapter 93), can be rapidly fatal if unrecognized. As such, cardiac tamponade should be considered in the differential diagnosis of any patient with shock or pulseless electrical activity.

Cardiac tamponade is usually suspected based on jugular venous distention, sinus tachycardia with hypotension, narrow pulse pressure, elevated (>10 mm Hg) pulsus paradoxus, and distant heart sounds.

The ECG often shows low voltage and sometimes electrical alternans (Fig. 62-5) when the heart swings within a large pericardial effusion. The chest radiograph shows a globular, enlarged cardiac shadow (see Fig. 44-5 and Fig. 62-6) without pulmonary venous congestion.

Echocardiography, which is the key diagnostic test for cardiac tamponade, must be performed without delay in any patient suspected of having this condition. Echocardiography detects pericardial effusions as an echo-free space around the heart (Fig. 62-4), demonstrates the size and distribution of the pericardial effusion, and reflects its hemodynamic consequences. The inferior vena cava is almost always enlarged, right atrial and right ventricular collapse indicates cardiac compression, and enhanced respiratory variation of ventricular filling is a manifestation of increased ventricular interdependence.

FIGURE 62-2. Cardiac magnetic resonance image of a patient with acute pericarditis shows late gadolinium hyperenhancement of the pericardium and epicardium.

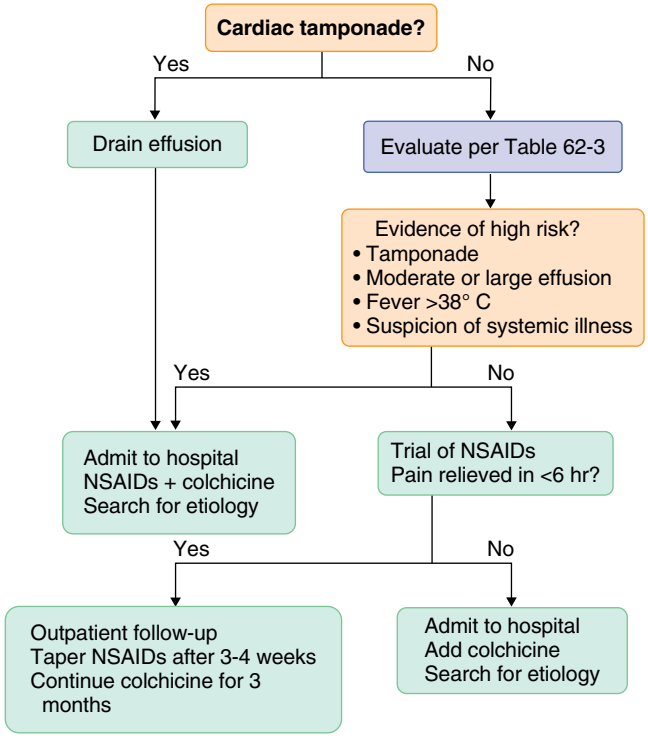

FIGURE 62-3. Initial management of patients with pericarditis. NSAID = nonsteroidal anti-inflammatory drug.

Right ventricular collapse is more specific for tamponade than is right atrial collapse, but the right-sided chambers may not collapse when tamponade occurs in patients with pulmonary hypertension. Cardiac tamponade can result from a loculated pericardial effusion after cardiac surgery or trauma and may present atypically. A loculated effusion may not be apparent on transthoracic echocardiography, but transesophageal echocardiography and thoracic CT or MRI can delineate loculated pericardial effusions.

On Doppler study, mitral inflow velocity (especially early diastolic velocity, designated as E velocity) normally increases with expiration and decreases with inspiration; the opposite respiratory variation is seen in tricuspid inflow velocity. Doppler findings for tamponade, which are more sensitive than two-dimensional echocardiography, include augmented respiratory variation of mitral and tricuspid inflow E velocities as a function of ventricular interdependence. These changes may be seen even before frank hemodynamic compromise caused by pericardial effusion. Although Doppler echocardiography provides important information, it must be emphasized that cardiac tamponade is ultimately a clinical diagnosis.

TABLE 62-5 CAUSES OF MODERATE TO LARGE ASYMPTOMATIC PERICARDIAL EFFUSIONS

CAUSE	CASES (%)
Idiopathic or viral	37
Neoplastic	19
Iatrogenic or trauma	13
Tuberculous or purulent	6
Acute myocardial infarction	6
Collagen vascular disease	4
Heart failure	4
Uremia	4
Radiation induced	2
Aortic dissection	2
Hypothyroidism	1
Other	2

Modified from Nishimura RA, Kidd KR. Recognition and management of patients with pericardial disease. In: Braunwald E, Goldman L, eds. *Primary Cardiology*. 2nd ed. Philadelphia: WB Saunders; 2003:625.

The routine evaluation should include an assessment of renal function, a thyroid-stimulating hormone level, a complete blood count with differential, a platelet count, coagulation parameters, and a tuberculin skin test. Common medications that can cause a pericardial effusion include cromolyn, isoniazid, phenytoin, hydralazine, and procainamide. Blood cultures are indicated if an infectious cause is suspected. Complement levels, antinuclear antibodies, and the ESR can suggest systemic lupus erythematosus (Chapter 245), which may initially present as an isolated pericardial effusion.

TREATMENT

Pericardial Effusion without Tamponade

Acute pericarditis is often accompanied by a small pericardial effusion that does not produce tamponade. If there is no hemodynamic compromise and the diagnosis can be established by other means, pericardiocentesis is not necessary (Fig. 62-7). Even small pericardial effusions may be related to underlying systemic illnesses such as systemic lupus erythematosus (Chapter 245), cardiac amyloid (Chapter 174), scleroderma (Chapter 246), hypothyroidism (Chapter 207), or AIDS, so it is important to consider and treat associated illnesses. Chylous pericardial effusion, which is usually related to obstruction of the thoracic duct, may require a surgical procedure for relief.

For suspected pericardial effusion, transthoracic echocardiography is the initial test of choice, although loculated effusions may be identified better by CT or MRI. If a small (0.5 to 1 cm) echolucent or "organized" pericardial effusion is observed, a follow-up echocardiogram in 1 to 2 weeks, or sooner if the patient deteriorates, is recommended. If the effusion is getting smaller, subsequent echocardiograms are not necessary unless the patient's clinical condition changes.

For moderate (1 to 2 cm) or large (>2 cm) effusions in patients who are hemodynamically stable and in whom tamponade is not suspected, a follow-up echocardiogram should be performed in 7 days and then every month until the effusion is minimal. If bacterial or malignant pericarditis is suspected, diagnostic pericardiocentesis should be performed immediately even in the absence of clinical instability or suggestion of tamponade; tuberculous pericarditis is diagnosed best by pericardial biopsy. Anticoagulation with heparin or warfarin should be discontinued unless the patient has a mechanical heart valve or atrial fibrillation.

In hypothyroidism (Chapter 207), the effusion and the coexistent cardiomyopathy respond to hormone replacement, sometimes over several months. Uremic pericardial effusions often respond to initiation of dialysis or more intensive dialysis (Chapter 117).

Cardiac Tamponade

The treatment of cardiac tamponade is urgent drainage of the pericardial effusion, especially when there is hemodynamic compromise. Fluid resuscitation may be of transient benefit if the patient is volume depleted (hypovolemic cardiac tamponade), but inotropic agents are usually ineffective because there is already intense endogenous adrenergic stimulation. The initiation of mechanical ventilation in a patient with tamponade may produce a sudden drop in blood pressure because the positive intrathoracic pressure further impairs cardiac filling.

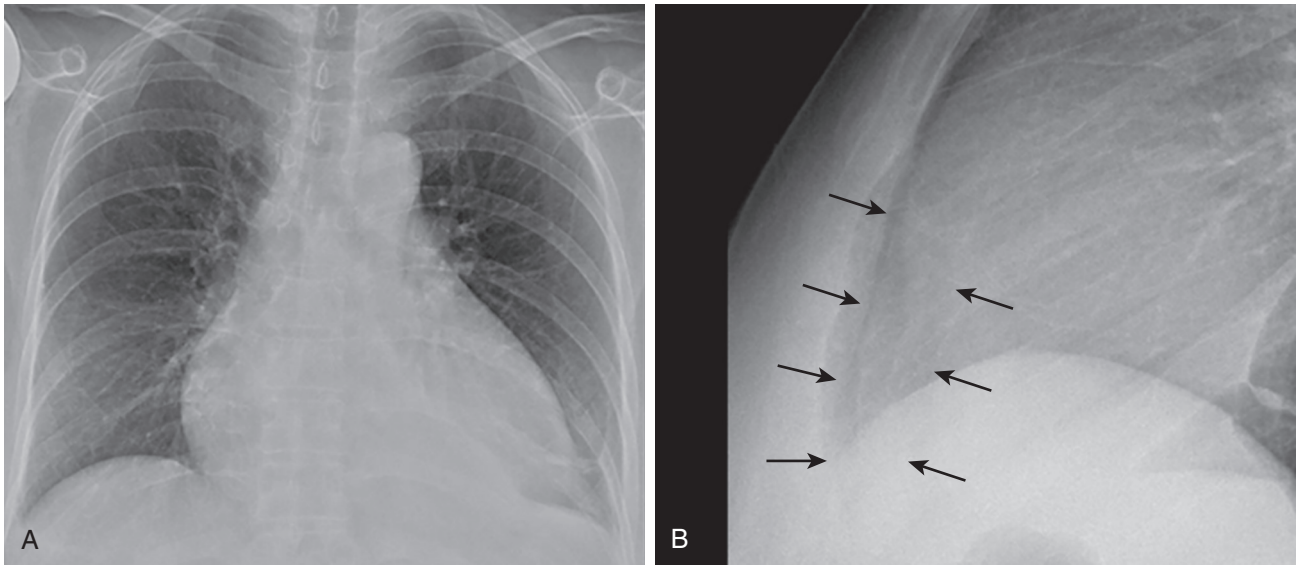

FIGURE 62-4. Chest radiographs in a patient with a large pericardial effusion. The cardiac silhouette on the posteroanterior view (**A**) is enlarged with a "water bag" configuration. The lateral view (**B**) shows a separation between the pericardial and epicardial fat stripes *(arrows)*.

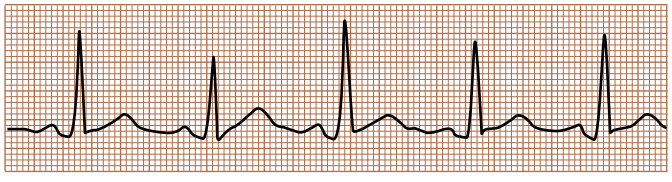

FIGURE 62-5. Electrical alternans. Lead V_5 rhythm strip from a patient with a large pericardial effusion and tamponade physiology. Note the relatively low voltage and electrical alternans.

Echocardiographic-guided percutaneous pericardiocentesis, which can be performed at the bedside by experienced operators (Fig. 62-8), is indicated if a patient is in dire circumstances and at least 1 cm of fluid is seen anterior to the mid-right ventricular free wall throughout diastole. The ideal entry site (usually near the apex) is defined using echocardiography as the minimal distance from the skin to pericardial fluid without intervening structures. The pericardial space is entered with a needle and then drained through a catheter. Although clinical and epidemiologic clues should tailor the extent of the diagnostic evaluation, pericardial fluid should be analyzed for lactate dehydrogenase, protein, cell count, cytology, polymerase chain reaction for tuberculosis, and culture for bacteria and tuberculosis. Continued drainage of the pericardial fluid through an indwelling catheter minimizes the risk of recurrent effusion. For hemodynamically significant effusions of less than 1 cm, organized or multiloculated effusions, and focal effusions, a limited thoracotomy-mediastinoscopy and creation of a pericardial window are advised.

Surgical drainage may be the preferred treatment if pericardial tissue is required for diagnosis or in the case of recurrent effusions or bacterial pericarditis. Malignant pericardial effusions frequently recur and, similar to other recurrent pericardial effusions, may necessitate the surgical creation of a pericardial window that allows the effusion to drain into the pleural space, preventing recurrence of cardiac tamponade. An attractive alternative in these patients, especially if their overall prognosis is poor from the malignancy, is the percutaneous creation of a pericardial window by balloon dilation. Hemorrhagic effusions related to cardiac trauma or aortic dissection are best managed by emergency surgery.

PROGNOSIS

A pericardial effusion may recur or persist. Symptoms are usually weight loss, fatigue, dyspnea on exertion, and whatever symptoms are associated with the specific cause. Treatment of chronic or recurrent idiopathic effusions is similar to the treatment of recurrent pericarditis. If medical therapy is unsuccessful, creation of a pericardial window is indicated.

A large idiopathic, asymptomatic effusion that persists for 6 months or longer can unpredictably result in tamponade in as many as 30% of patients over long-term follow-up; diagnostic pericardiocentesis occasionally detects a neoplastic or tuberculous cause. Pericardiocentesis with prolonged drainage resolves many chronic large pericardial effusions, but pericardiectomy is often required. The long-term prognosis depends on the cause of the effusion. With pericardial tamponade, the in-hospital mortality rate is less than 10%, but the subsequent mortality rate is about 75% with a malignant effusion compared with only a 3 to 5% subsequent annual mortality rate for other causes.

PERICARDIAL CONSTRICTION

EPIDEMIOLOGY AND PATHOBIOLOGY

Pericardial constriction, which is usually the result of pericardial inflammation and subsequent scarring, occurs when a scarred and usually thickened pericardium impairs cardiac filling, thereby limiting the total cardiac volume and causing venous congestion. As the pericardium thickens from its normal 2 mm or less, it may also calcify and adhere to the adjacent epicardium.

The most frequent causes in the developed world are previous cardiac surgery, chronic idiopathic or viral pericarditis, and mediastinal radiation. Constriction may follow cardiac surgery by several weeks to months and may occur decades after chest wall irradiation. In developing countries, tuberculous pericarditis remains a more common cause of constrictive pericarditis. Other less common causes include malignant disease, especially lung cancer, breast cancer, or lymphoma; histoplasmosis; rheumatoid arthritis; and uremia. However, a specific cause may not be identified in many patients.

Fibrous scarring and adhesions of both pericardial layers obliterate the pericardial cavity. The ventricles are unable to fill beyond the rapid filling period because of physical constraints imposed by a thickened, rigid, and sometimes calcified pericardium. In a subset of patients with constriction, especially patients with superimposed myocardial diseases after previous cardiac surgery or radiation therapy, the pericardium may be only minimally thickened and less calcified. The pathophysiologic hallmarks of pericardial constriction are exaggerated interventricular dependence and the dissociation of intracardiac and intrathoracic pressures.

CLINICAL MANIFESTATIONS

Patients with pericardial constriction typically present with manifestations of elevated systemic venous pressures and low cardiac output. Because there is equalization of all cardiac pressures (including right and left atrial pressures), systemic congestion is much more marked than pulmonary congestion. Typically, patients develop marked jugular venous distention, hepatic congestion, ascites, and peripheral edema, but their lungs usually remain clear, and patients with pericardial constriction are much more likely to have left-sided or bilateral pleural effusions than the right-sided effusions that are typically seen in heart failure (Chapter 45). The limited cardiac output typically presents as exercise intolerance and may progress to cardiac cachexia with muscle wasting. In long-standing pericardial constriction, lower extremity edema, ascites, and hepatic dysfunction may be prominent clinical features. Because of the prominent clinical symptoms of ascites and liver enzyme abnormalities, patients may be evaluated for hepatic disease before constrictive pericarditis

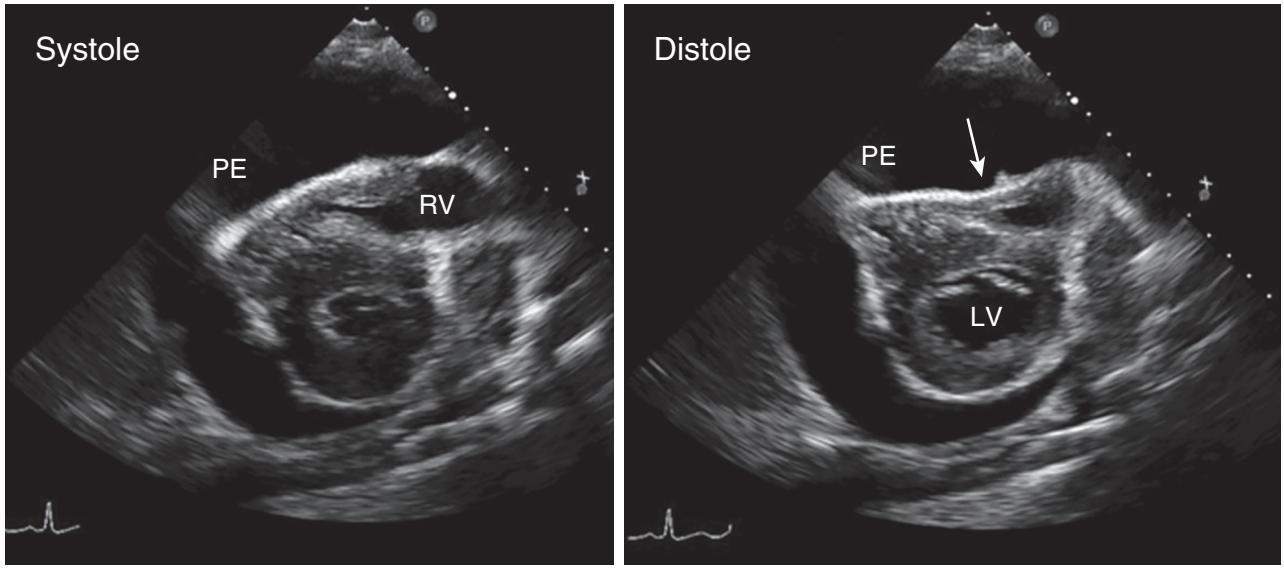

FIGURE 62-6. Two-dimensional echocardiogram from a patient with cardiac tamponade. A large pericardial effusion (PE) is apparent as an echo-free space surrounding the left ventricle (LV) and right ventricle (RV). In diastole, there is collapse of the right ventricle *(arrow)*.

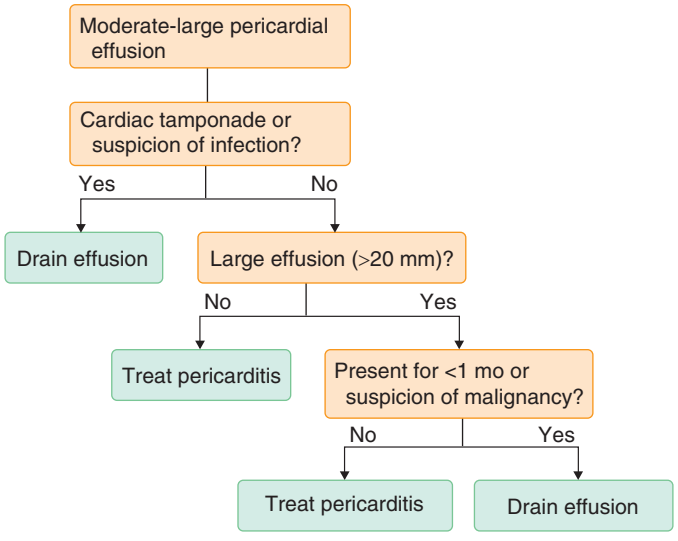

FIGURE 62-7. Algorithm for managing patients with moderate to large pericardial effusions. (Modified from Little WC, Freeman GL. Pericardial disease. *Circulation*. 2006;113:1622-1632.)

is recognized. If a patient has patent foramen ovale, hypoxemia from right to left shunting with increased right atrial pressure may be a presenting symptom of constrictive pericarditis.

The jugular veins are distended with prominent y descent. The normal inspiratory drop in jugular venous distention may be replaced by a rise in venous pressure (Kussmaul sign). The y descent, which is when rapid diastolic ventricular filling suddenly ceases, coincides with the timing of the classic auscultatory finding of pericardial constriction, which is an audible pericardial knock (Fig. 39-5)—a high-pitched sound early in diastole.

DIAGNOSIS

Pericardial constriction should be considered in any patient with unexplained systemic venous congestion or a low cardiac output syndrome. Pericardial calcification, seen best on the lateral plain chest radiograph, is a classic finding but is present in only 25% of patients with constrictive pericarditis, mostly in those with long-standing constriction.

Transthoracic echocardiography, which is usually the initial diagnostic tool, classically shows paradoxical interventricular dependence, with ventricular septal motion during inspiration; restrictive mitral inflow velocity, often with respiratory variation; normal or increased (≥8 cm/sec) medial mitral annulus e′ velocity; and reversal of diastolic flow in the hepatic vein during expiration (E-Fig. 62-1). In addition, the hepatic veins are plethoric, and cardiac morphology may be pear shaped, with the narrowest dimension at the atrioventricular grooves. Echocardiography also differentiates pericardial constriction from right heart failure caused by tricuspid valve disease or associated pulmonary hypertension (see later).

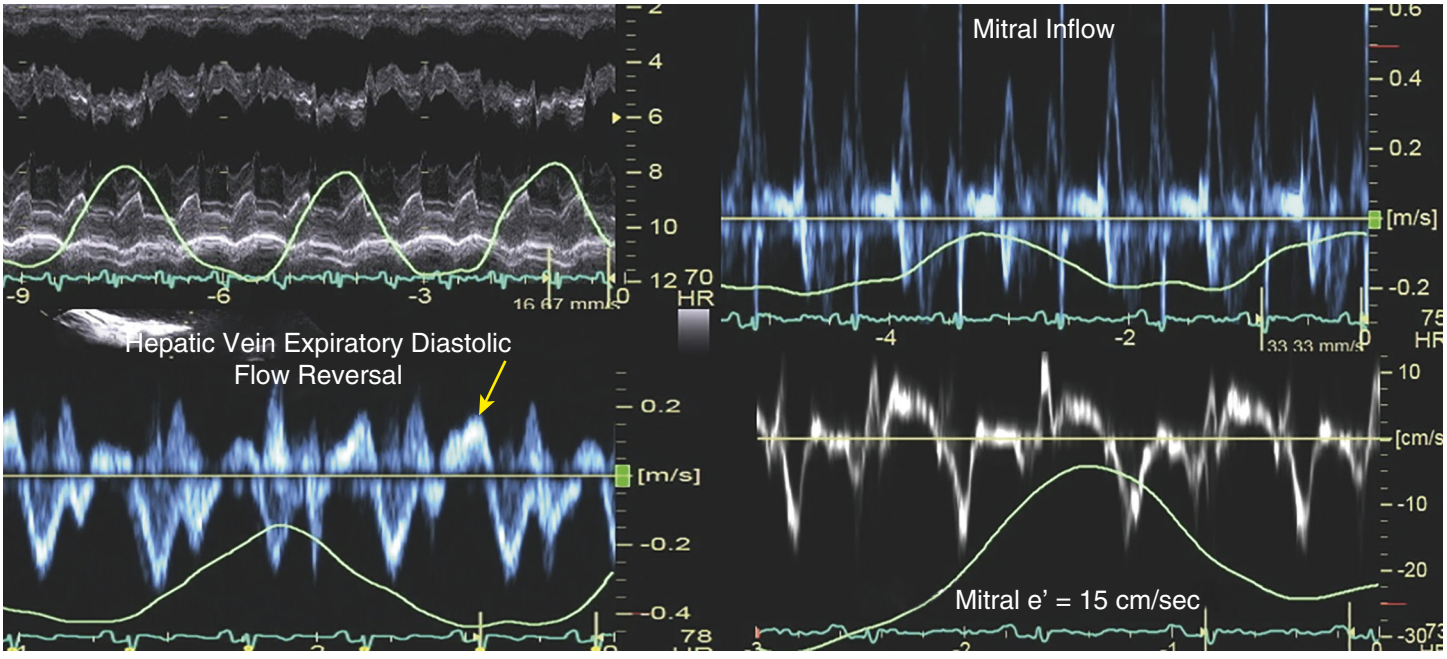
Most patients with pericardial constriction have a thickened pericardium (>2 mm) that can be imaged by echocardiography (better by transesophageal than transthoracic echocardiography), CT, and MRI (Fig. 62-9). It is important to recognize, however, that most patients with pericardial constriction present without pericardial calcification and, in about 20% of patients, without any obvious pericardial thickening.[9]

At cardiac catheterization, both cardiac tamponade and pericardial constriction impair diastolic ventricular filling and elevate venous pressure. However, the impairment in ventricular filling with constriction is minimal in early diastole until cardiac volume reaches the anatomic limit set by the noncompliant pericardium, at which time diastolic pressure rises abruptly and remains elevated until the onset of systole. The result is a prominent "y" descent with an elevated plateau of ventricular pressure, which has been termed the "square root" sign (E-Fig. 62-2) and which differentiates constriction from tamponade, in which the y descent is absent.

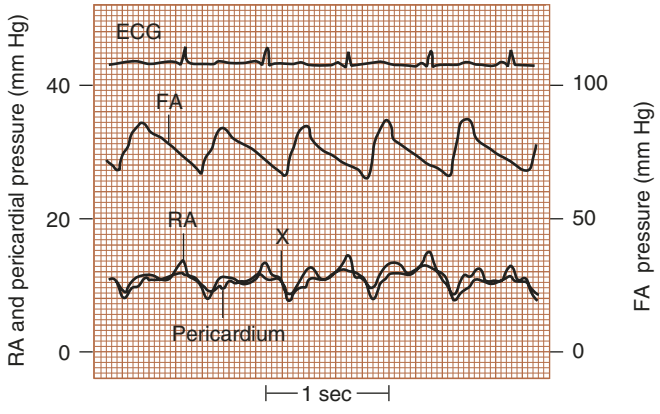
The pulmonary artery systolic pressure is typically less than 50 mm Hg, and the end-diastolic pressures of both ventricles are equalized. However, the best way to distinguish constrictive pericarditis from a restrictive cardiomyopathy (Chapter 47) is a discordant change in the systolic pressure of the left and right ventricles with respiration compared with a concordant change seen in restrictive cardiomyopathy. In restrictive pericarditis, the left ventricular systolic pressure decreases with inspiration, whereas the right ventricular systolic pressure increases; the opposite change occurs with expiration (E-Fig. 62-3). Stroke volume and cardiac output are reduced because of impaired filling, but the intrinsic systolic function of the ventricles is usually normal.

Differential Diagnosis

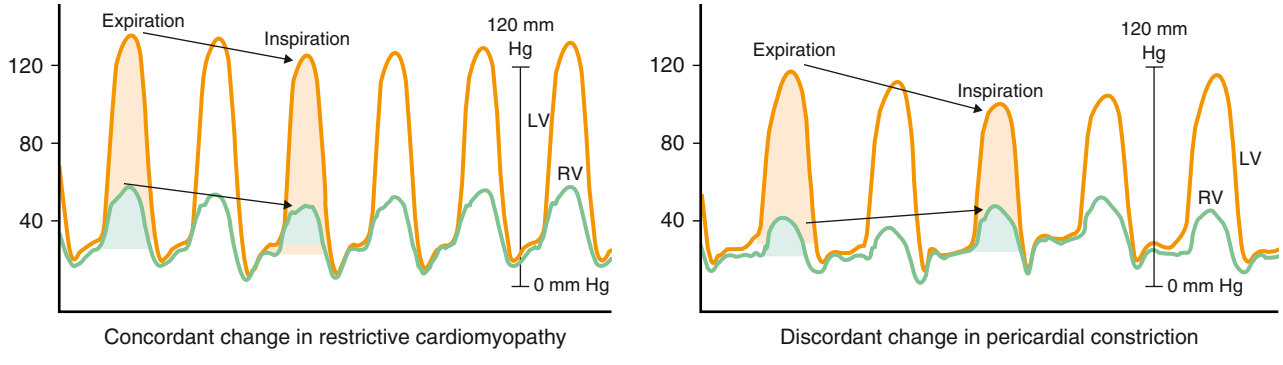
The most difficult differentiation is between pericardial constriction and restrictive cardiomyopathy (Chapter 47) (Fig. 62-10), the clinical manifestations of which may be very similar to those of pericardial constriction (Table 62-6).[10] Doppler echocardiography is the most useful method to distinguish constriction from restriction. Whereas patients with pericardial constriction usually have pronounced respiratory variation (>25%) of mitral inflow E velocity, patients with restrictive cardiomyopathies do not. In some patients with pericardial constriction and markedly elevated venous pressures, the respiratory variation may not be present unless preload can be decreased; for example, with head-up tilt. The tissue Doppler measurement of early diastolic septal mitral annular velocity (e′) is almost always reduced in patients with myocardial restriction due to abnormal myocardial relaxation, but it remains normal or increased in patients with



E-FIGURE 62-1. **A composite of echocardiographic features diagnostic for constrictive pericarditis.** *Upper left,* M-mode echocardiogram of left ventricle showing respiratory variation of ventricular septum due to interventricular dependence. *Upper right,* Variation in mitral inflow velocity with respiration. Mitral E velocity decreases with inspiration and increases with expiration. It is also restrictive because of increased filling pressure. *Lower* left, Hepatic vein Doppler velocity showing diastolic flow reversal with expiration. *Lower right,* Medial mitral annulus early diastolic velocity (e') is increased to 15 cm/sec.



E-FIGURE 62-2. **Right atrial (RA) pressure recording from a patient with constrictive pericarditis.** Note the elevation in pressure and the prominent y descent, corresponding to rapid, early diastolic right atrial emptying. ECG = electrocardiogram; FA = femoral artery. (From Lorell BH. Profiles in constriction, restriction and tamponade. In: Baim DS, Grossman W, eds. *Cardiac Catheterization, Angiography, and Intervention*. 6th ed. Philadelphia: Williams Wilkins; 2000:832.)



E-FIGURE 62-3. **Simultaneous left ventricular (LV) and right ventricular (RV) pressure tracing in patients with a restrictive cardiomyopathy *(left)* and constrictive pericarditis (right). In restrictive cardiomyopathy, LV and RV systolic pressures appropriately decrease with inspiration and increase with expiration, concordantly.** In contrast, LV and RV pressures move discordantly in constrictive pericarditis.

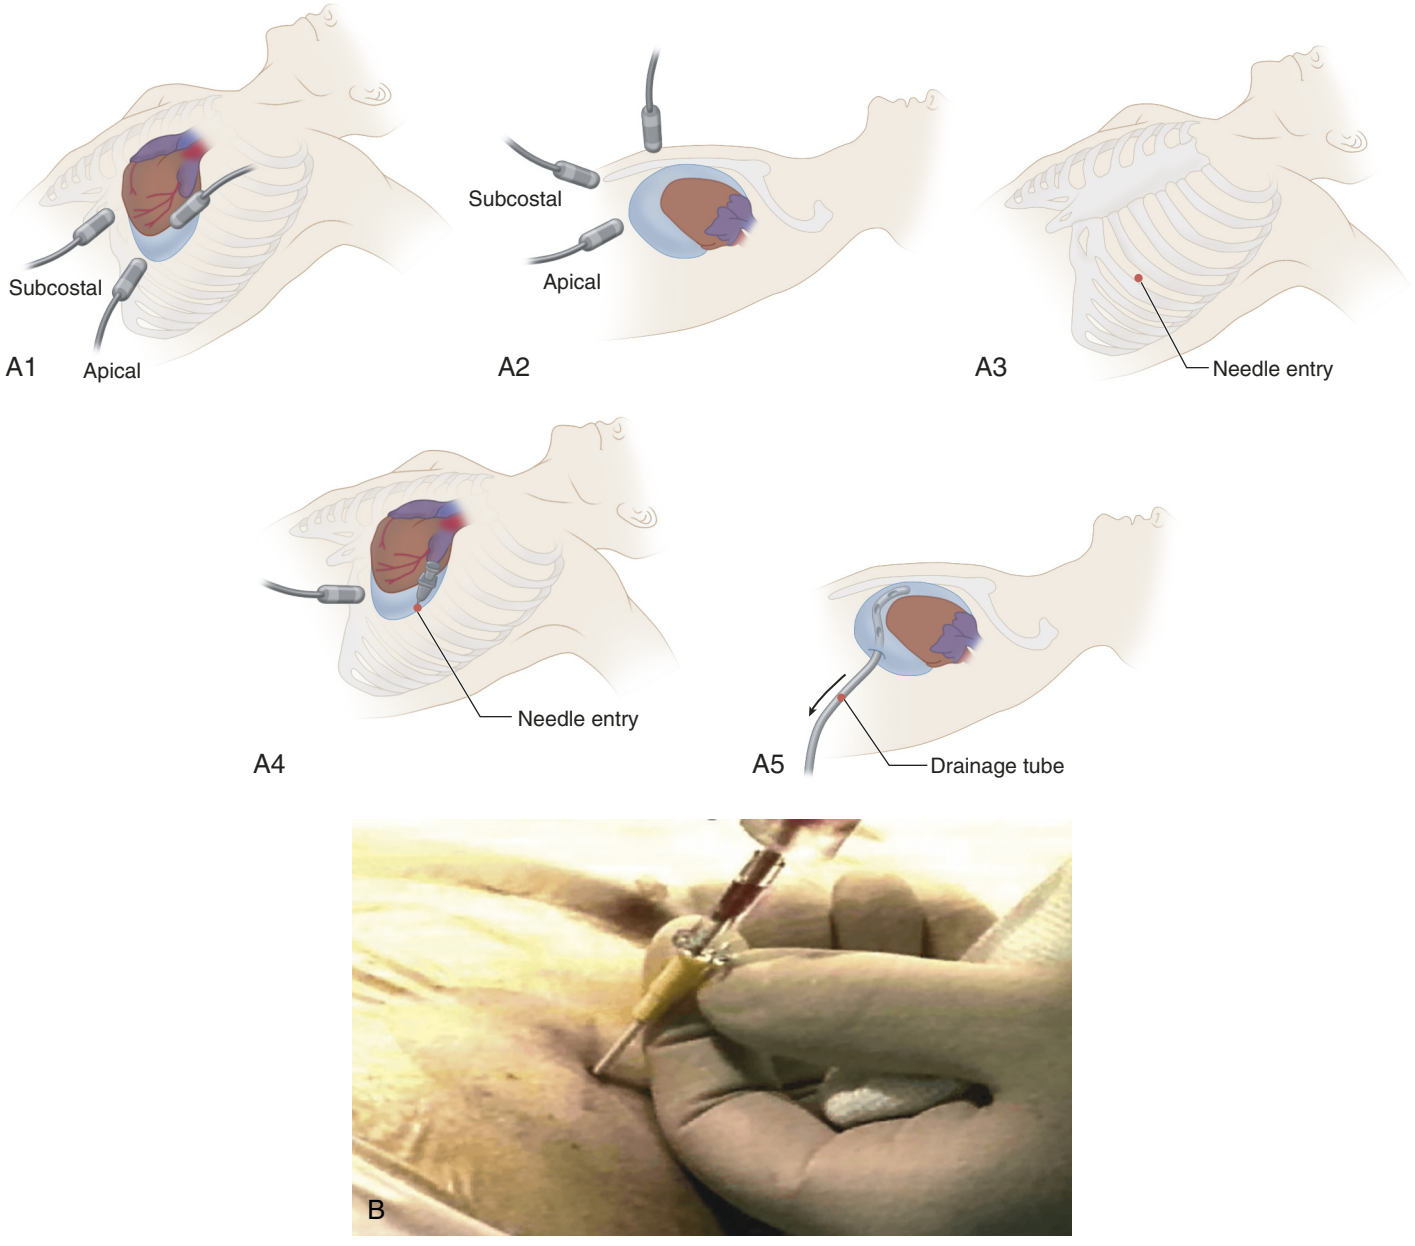


FIGURE 62-8. **Pericardiocentesis. A,** Schematic diagrams demonstrate steps of echocardiography-guided pericardiocentesis.
Step 1. Locate an area on the chest or subcostal region from which the largest amount of pericardial effusion can be visualized and mark it (A1-A3).
Step 2. Determine the depth of effusion and the optimal angulation from the marked position.
Step 3. After sterile preparation and local anesthesia, perform pericardiocentesis (A4).
Step 4. When in doubt about the location of the needle, inject saline solution through the needle and image it from a remote site to locate the bubbles.
Step 5. Monitor the completeness of the pericardiocentesis with repeat echocardiography.
Step 6. Place a 6 F or 7 F pigtail catheter in the pericardial space to minimize the reaccumulation of fluid (A5).
Step 7. Drain any residual fluid or fluid that has reaccumulated via the pigtail catheter every 4 to 6 hours. If after 2 to 3 days pericardial fluid has not reaccumulated by echocardiography, the pigtail catheter may be removed. Always have the pericardial fluid analyzed for cell counts, glucose and protein measurements, culture, and cytology. (Modified from Callahan JA, Seward JB, Tajik AJ, et al. Pericardiocentesis assisted by two-dimensional echocardiography. *J Thorac Cardiovasc Surg*. 1983:85:877-879. Used with permission.)
B, A photo of actual pericardiocentesis. Echocardiography determined the site and the angulation of needle insertion as well as anticipated depth of needle insertion. In this case, bloody fluid is being drained.

pericardial constriction. In addition, lateral e′, which is higher than septal or medial e′ velocity in normal and restrictive cardiomyopathy, is lower than septal e′ in most patients with constrictive pericarditis ("Annulus Reversus"). Whereas a prominent diastolic reversal of hepatic vein flow velocity during expiration is characteristic of constriction, the reversal flow velocity occurs during inspiration in patients with right heart failure from other causes. Patients with pericardial constriction usually have only minimally elevated (<200 pg/mL) brain natriuretic peptide (BNP), but BNP levels are typically markedly increased (<600 pg/mL) in patients with restrictive cardiomyopathy.

Confirmation of the diagnosis of constriction may require cardiac catheterization in patients whose noninvasive evaluation is not clear-cut. Traditional invasive hemodynamic findings of equalized end-diastolic pressures in the right and left ventricles and the "dip and plateau" pattern of left ventricular diastolic pressure do not reliably differentiate constriction from restrictive cardiomyopathy. More specific invasive hemodynamic features of constriction and restriction are based on the respiratory variation in ventricular filling; the simultaneous measurement of left and right ventricular pressures demonstrates discordant changes in their systolic pressures with respiration in constrictive pericarditis. By comparison, the direction of these pressures is concordant (both left and right sides increase with expiration and decrease with inspiration) in restrictive cardiomyopathy.

All patients with documented but otherwise unexplained pericardial constriction should be evaluated for potential tuberculosis.

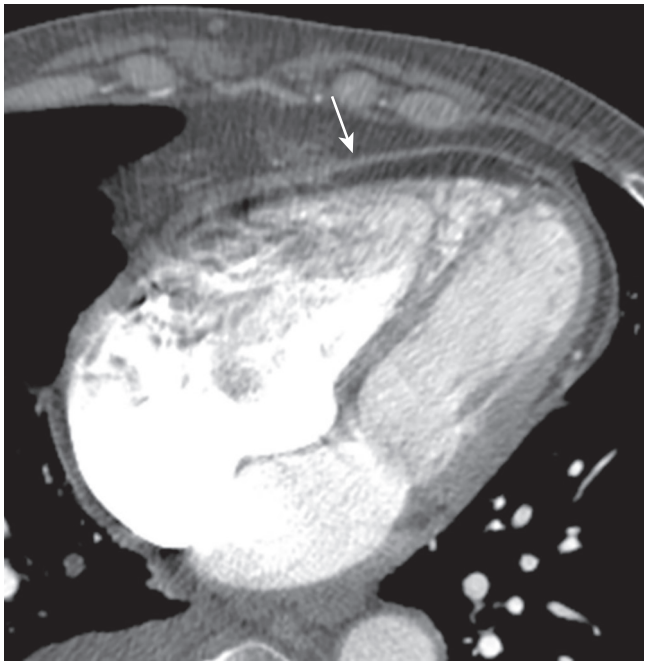

FIGURE 62-9. **Computed tomography in a patient with constrictive pericarditis shows a thickened pericardium *(arrow)*.**

TREATMENT AND PROGNOSIS

In some patients with pericardial constriction of less than 3 months' duration, the symptoms and constriction may resolve over several weeks with medical therapy consisting of NSAIDs (e.g., ibuprofen 300-800 mg every 6-8 hours), colchicine (0.6 mg once or twice daily), and the cautious use of diuretics. If the patient is severely compromised hemodynamically, steroid therapy (e.g., 0.5 to 1.0 mg/kg up to a maximum dose of 60 mg tapered slowly over 3 months as guided by the clinical response and normalization of the CRP) can be very effective. Patients with constriction who respond to medical therapy usually have high inflammatory biomarkers (ESR and CRP) and intense inflammation of the pericardium on cardiac MRI. For more chronic pericardial constriction or cases that do not respond to medical therapy, the definitive treatment is surgical pericardial decortication, with a wide resection of both the visceral and parietal pericardium. This operation is a major undertaking, but it can be undertaken with acceptable risk (about a 5% mortality rate in the most experienced centers).[11] In many patients, surgery does not immediately restore normal cardiac function; it may take weeks after removal of the constricting pericardium to return to normal. Empirical treatment of tuberculosis (Chapter 299) may be required in patients with constriction and a high suspicion of tuberculosis, even without a definitive diagnosis.

EFFUSIVE-CONSTRICTIVE PERICARDITIS

In about 10 to 20% of patients who present with cardiac tamponade, the elevated right atrial pressure and jugular venous distention do not resolve after removal of the pericardial fluid. In these patients, pericardiocentesis converts the hemodynamics from those typical of tamponade to those of constriction.[12] Thus, the restriction of cardiac filling is not only attributable to pericardial effusion but also to pericardial constriction, predominantly involving the visceral pericardium. Effusive-constrictive pericarditis[13] most likely represents an intermediate transition from acute pericarditis with pericardial effusion to pericardial constriction. Restrictive mitral inflow and plethora of the hepatic veins on echocardiography may be early predictors of which patients will progress to constriction.[14] Frequently, the symptoms resolve after several weeks of treatment with an NSAID (e.g., ibuprofen 300 to 800 mg every 6 to 8 hours). Pericardiectomy may be necessary if constrictive pericarditis persists.

SPECIFIC FORMS OF PERICARDIAL DISEASE

POSTPERICARDIOTOMY SYNDROME

The postcardiac injury syndromes comprise the postpericardiotomy syndrome, post–myocardial infarction pericarditis (Dressler syndrome), and post-traumatic pericarditis. The postpericardiotomy syndrome, like all of the post–cardiac injury syndromes, is initiated by the combination of damage to mesothelial pericardial cells and blood in the pericardial space, which releases cardiac antigens and stimulates an immune response. An inflammatory response is later generated by immune complexes that deposit in the pericardium, pleura, and lungs. This syndrome occurs several days to weeks after cardiothoracic surgery. It most commonly occurs after surgery involving the pericardium, but it can also occur after pacemaker lead implantation, coronary stenting, and other therapeutic misadventures. Patients have typical symptoms of acute pericarditis, which is associated with antimyocardial antibodies. Leukocytosis and elevated inflammatory markers are common laboratory findings. Pericardial effusions are commonly seen, but tamponade physiology is rare. Pleural effusions or pulmonary infiltrates may also be seen.

Treatment of postcardiotomy syndrome is similar to the treatment of acute pericarditis. One month of colchicine therapy (0.5 mg twice daily for patients weighing 70 kg or more; half that dose for smaller patients or patients with side effects) started 48 to 72 hours prior to cardiac surgery appears to reduce the rate of the postcardiotomy syndrome from about 30% to less than 20% but does not reduce the occurrence of atrial fibrillation.

Some patients who have undergone cardiac surgery develop late pericardial constriction without preceding acute pericarditis owing to bleeding in and around the open pericardium followed by inflammation, scarring, and fibrosis. If active inflammation is present, a trial of anti-inflammatory agents may be instituted; however, surgical removal of the blood clot, usually accompanied by more extensive pericardiectomy, is typically required.

UREMIC PERICARDITIS

Pericardial effusions develop in patients with severe renal failure, especially those on dialysis (Chapter 117). Aggressive dialysis may decrease the pericardial effusion, but sometimes the effusion persists and requires drainage or even pericardiectomy.

INFECTIOUS PERICARDITIS

BACTERIAL PERICARDITIS

Purulent bacterial pericarditis may result from direct extension of bacterial pneumonia, direct extension of pleural empyema, or, rarely, peritonitis or a subphrenic abscess. Most patients are acutely ill with systemic sepsis and develop acute tamponade. The most common organisms are streptococci, pneumococci, and staphylococci. Urgent pericardiocentesis, which is required for both diagnosis and therapy, shows leukocytosis and frank pus, and the fluid glucose level is markedly depressed. Persistent or recurrent drainage with an indwelling catheter or repeated taps combined with antimicrobial therapy leads to a high survival rate, but late constrictive pericarditis requiring pericardiectomy develops in 30 to 40% of patients.

TUBERCULOUS PERICARDITIS

Tuberculous pericarditis is common in developing countries but accounts for less than 5% of cases of acute pericarditis in developed countries, usually in patients who are immunosuppressed, including patients infected with the human immunodeficiency virus. Symptoms are often nonspecific, and acute painful pericarditis is rare. Most patients have an effusive-constrictive physiology or pericardial constriction. The chest radiograph suggests active pulmonary tuberculosis in about 30% of cases, and a pleural effusion is present in 40 to 60% of cases. The echocardiogram typically shows fibrinous strands in the pericardial effusion, with multiple echo densities adherent to the pericardial surface. Pericardiocentesis is mandatory if tuberculous pericarditis is suspected. About 75% of patients have a positive culture, and a pericardial fluid adenosine deaminase level of 40 U/L or greater is seen in 75% of patients. Polymerase chain reaction testing and pericardial biopsy are recommended when tuberculous pericarditis is strongly suspected but not otherwise confirmed.

Aggressive antituberculosis therapy (Chapter 299) yields a cure rate of about 85 to 90%. Neither corticosteroids nor adjunctive immunotherapy improves outcome.[A6] Empirical treatment may be required in patients with a consistent clinical picture but without a confirmed diagnosis.

Even with prompt treatment, 30 to 60% of patients develop constrictive pericarditis, for which surgical pericardiectomy is the treatment of choice. In cases of suspected tuberculous constriction, antituberculosis therapy (Chapter 299) should be administered before and after pericardial surgery.

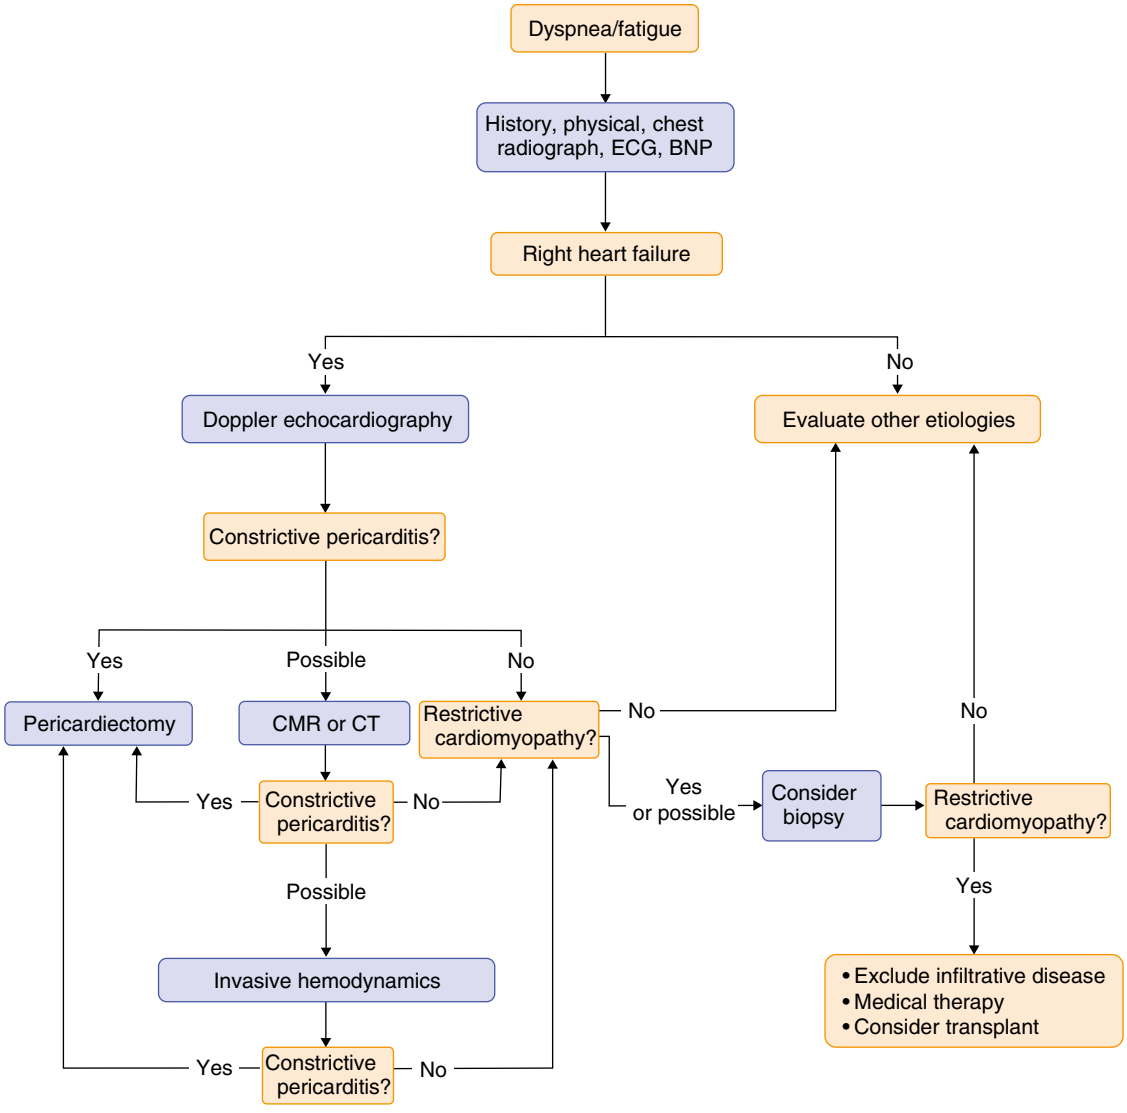

FIGURE 62-10. Approach to the differentiation of constrictive pericarditis vs. restrictive cardiomyopathy. BNP = brain natriuretic peptide; CMR = cardiovascular magnetic resonance; CT = computed tomography; ECG = electrocardiogram.

FUNGAL PERICARDITIS

The most common fungal pericarditis is histoplasmosis, which usually resolves in several weeks and can be treated successfully with NSAIDs. Specific antifungal therapy (Chapter 307) is recommended only in patients with disseminated histoplasmosis (Chapter 308).

MALIGNANT PERICARDITIS

About 6% of cases of acute pericarditis that initially have no obvious cause, and about 20% of cases of moderate to large pericardial effusions are related to malignant diseases; in patients with cardiac tamponade, the percentage is even higher. About 80% of malignant pericarditis is linked to breast cancer (Chapter 183), lymphoma (Chapters 171 and 172), and leukemia (Chapters 168, 169, and 170). Melanoma (Chapter 188) is an uncommon cause of malignant pericarditis, but a large proportion of patients with melanoma have pericardial involvement.

Most patients have direct tumor extension from an adjacent malignant lesion or a tumor from hematogenous or lymphatic spread.[15] Pericardial effusions also may be caused by pericardial irritation or compromised lymphatic drainage in patients with mediastinal lymphoma.

Pericardiocentesis is key to diagnosis and management. Fluid cytology results are positive in about 85% of patients. Complete drainage with an indwelling catheter for 2 or 3 days is the treatment of choice. Colchicine (0.6 mg twice daily for 6 months) may be useful,[16] and cancer chemotherapy may sometimes be helpful.[17] If the effusion does not resolve, pericardiectomy is generally recommended, but extended catheter drainage is also an option.[18]

The prognosis depends on the treatment of the underlying malignancy. The 1-year mortality rate is 80% or higher, but patients with breast cancer may have 1-year survival rates as high as 40%.

POSTRADIATION PERICARDITIS

Postradiation pericarditis develops in about 2% of patients after mantle radiation for Hodgkin disease (Chapter 172) and in 0.4 to 5% of patients after irradiation for breast cancer. Pericardial injury occasionally manifests during treatment, but it more commonly appears months or even a decade later. The initial pericarditis and effusion may resolve spontaneously, but constrictive pericarditis, adjacent myocarditis, and even coronary artery damage can develop. Pericardiocentesis is critical to distinguish postradiation pericarditis from malignant pericardial disease. Pericardiectomy is recommended for recurrent pericarditis and for large recurrent pericardial effusions.

AUTOIMMUNE PERICARDITIS

Pericarditis, often with an effusion, can complicate systemic rheumatologic conditions.[19] Up to 50% of patients with systemic lupus erythematosus (Chapter 245) have pericarditis, usually during an acute flare.[20] Patients usually present with acute pericarditis or an asymptomatic effusion; cardiac tamponade is uncommon, and constrictive pericarditis is rare. If purulent pericarditis is not suspected, pericardiocentesis is not usually required. The underlying disease should be treated aggressively.

Acute pericarditis or asymptomatic pericardial effusions also can develop in patients with advanced rheumatoid arthritis (Chapter 243), scleroderma

TABLE 62-6 DIFFERENTIATION OF PERICARDIAL CONSTRICTION FROM RESTRICTIVE CARDIOMYOPATHY

FINDINGS	PERICARDIAL CONSTRICTION	RESTRICTIVE CARDIOMYOPATHY
PHYSICAL EXAMINATION		
Pulmonary congestion	Usually absent	Usually present
Early diastolic sound	Pericardial knock	S_3 (low pitched)
ECHO/DOPPLER		
Respiratory variation in E wave (%)	>25	<20
Mitral septal annular early diastolic velocity (cm/sec)	>7	<7
CT/MRI		
Pericardial thickness	>2 mm (but <2 mm in 20%)	<2 mm
BIOMARKER		
B-type natriuretic peptide (pg/mL)	<200	>600
HEMODYNAMICS		
PA systolic pressure (mm Hg)	<60	>60
PCW-LV diastolic pressure	Respiratory variation with reduction in inspiration	No variation
Respiratory variation in RV/LV peak systolic pressure	Discordant	Concordant

CT = computed tomography; LV = left ventricular; MRI = magnetic resonance imaging; PA = pulmonary artery; PCW = pulmonary capillary wedge; RV = right ventricular.

(Chapter 246), or mixed connective tissue disease (Chapter 246). The process is usually self-limited or responds to aggressive treatment of the underlying disease, although cardiac tamponade can develop.

A wide variety of drugs and toxins may cause pericardial heart disease (see Table 62-1) by producing either drug-induced lupus, a hypersensitivity or idiosyncratic reaction, pericardial irritation, or hemorrhage. Immune checkpoint inhibitors are monoclonal antibodies that target a critical mechanism of immune evasion and thereby activate immune responses against tumor cells; cases of pericarditis, pericardial effusion, and cardiac tamponade can complicate cancer treatment with these drugs.

MYOPERICARDITIS
